Ions in high-salt conditions could be imagined to have any of three roles in effecting helix transformations: (1) specific binding to DNA, (2) charge-cloud screening of phosphate–phosphate backbone repulsions, or (3) a general lowering of activity of water molecules because of hydration of ions. Phosphate screening has been invoked to explain both the B to Z and the B to C transitions[1,3,17], but this seems unlikely for two reasons. Although phosphate groups on different helix strands are closer together in the Z or C helices than in the B, they are fully as close in A and Z. If the screening argument were valid, the A helix should be stabilized by high-salt conditions. In fact, it seems to be the form of choice only in minimal salt conditions, whether in fibres or in solution. Moreover, the B to Z conversion is favoured both by alcohol and by salt, and these have opposite effects on phosphate repulsions: salt diminishes the repulsion by charge-cloud screening, but alcohol increases the strength of negative charge repulsion by lowering the dielectric constant of the surrounding medium. Manning[24] has also pointed out that, because of the phenomenon of charge condensation along a polyelectrolyte, the local ion concentration around a polyelectrolyte charge and its degree of neutralization do not follow a simple law of mass action; the phosphate charges in DNA may be largely neutralized by even a small excess of cations, as recent ^{23}Na NMR experiments have shown[25].

The one effect that is shared by the drying of fibres, increasing salt concentration and increasing the amounts of such solvents a ethanol, isopropanol or dioxane, is a general lowering of the activity or effective concentration of water molecules. Each treatment, in a sense, is a kind of local dehydration of the polymer. If one regards the B form as most stabilized by interactions with water molecules, whether specific or nonspecific, and the A and Z forms as less involved with water, then all of the inter-family transitions in Fig. 6 become consistent. Although achieved by different means, they have a common result. This interpretation would also explain why both the 'low-salt' hexamer and the high-salt tetramer of CG adopt a Z conformation in the crystal, because the water activity is lowered by both the high DNA concentration and the high cation concentration required for charge neutrality. The act of crystallization is a process of concentration for both DNA and ions.

As Fig. 6 suggests, the left-handed Z helix family actually seems to be the conformation of choice when water activity is lowered, but only if the base sequence permits its adoption. At present, this seems to require an alternating purine/pyrimidine sequence, or even poly(dG-dC). Is this preference for the Z helix sufficiently strong to produce it even if adjacent regions of DNA are of sequences that cannot adopt the Z conformation? More information is needed from crystal structure analyses of related double helices. Data have been collected in this laboratory by Drew and Wing[26] on a self-complementary DNA dodecamer with the sequence CGCGAATTCGCG, having adjacent Z-compatible and Z-incompatible segments. Other dodecamers are being synthesized with sequences that, hopefully, will exhibit classical B or C helix structures. These, and other carefully chosen sequence variants, should greatly assist the unravelling of the importance of solvent and other factors in stabilizing different helical types, the significance of the new left-handed structures and their ability to influence the conformation of neighbouring sequences that cannot adopt the Z or Z′ configuration.

We thank Michael Becker and Peter Dervan for many productive discussions of helix structure. This is contribution no. 6198 from the Norman W. Church Laboratory of Chemical Biology. This work was carried out with the support of NIH Grants GM-12121 and GM-24393, and NSF Grant PCM79-13959. H.D. was the recipient of a NIH Predoctoral Traineeship.

Helical periodicity of DNA determined by enzyme digestion

D. Rhodes & A. Klug

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

The periodicity of DNA has been determined by binding short, stiff pieces of DNA to a flat surface and using DNase I to probe the accessibility of the phosphodiester bonds. We have found that the distance between successive DNase I cutting sites is 10.6 ± 0.1 bases for the DNA immobilized on three different surfaces. We identify this value with the number of base pairs per turn of the DNA double helix in solution.

FOR many years it was assumed that the B form of DNA, observed in X-ray diffraction patterns from fibres at high humidity, represented the structure of DNA in solution [1-3]. The B form has 10 base pairs per turn of the helix, but recent studies have suggested a value close to 10.5 (refs 4, 5). However, the disagreement persists[6]. We describe here a new approach to the problem of the helical repeat of free DNA, which gives results of high precision.

An accurate determination of the helical periodicity of DNA in solution is required to follow in detail the folding of DNA from solution into nucleosomes, the elementary building blocks of chromatin. We have postulated[4] a change in the DNA periodicity when nucleosomes are formed, in order to reconcile the model of a nucleosome core derived from X-ray crystallographic studies, where the DNA in each nucleosome is wound into about two turns of a superhelix, with measurements of the superhelicity on closed, circular DNA extracted from SV40 chromatin, which showed a change of linkage number nearer one[7].

Our approach is based on that used previously to probe the helical periodicity of DNA on the nucleosome[8-11]. The action of DNase I (and some other nucleases) on chromatin or on nucleosome cores is to produce, after denaturation of the DNA, a set of single-stranded fragments differing in size by about 10 bases. Presumably the enzyme tends to attack the regions of the DNA backbone which are well exposed, and so will produce a spectrum of fragment sizes, which will repeat with approximately the periodicity of the DNA double helix. Liu and Wang[12] found a similar distribution of DNase I fragments when studying DNA interacting with gyrase, and also observed it in the case of DNA bound to hydroxylapatite. This work, together with the development by Lutter[9] of a high resolution gel electrophoresis

0028-0836/80/320573—06$01.00

system capable of resolving random sequence DNA fragments differing in size by a single nucleotide, stimulated the experiments described in this article.

A double-stranded DNA fragment, nominally 140 base pairs long, has been immobilized on a flat, inorganic surface, then lightly digested with DNase I and the fragments produced separated by the denaturing, high resolution gel system. The distance between successive DNase I cutting 'sites', that is the distance between neighbouring groups of accessible phosphodiester bonds, is found to be 10.6 ± 0.1 bases. Because of the simple geometry of the experiment, and because the same value is found for the DNA bound to three different inorganic surfaces, we believe that the measured distance between DNase I cutting sites directly reflects the helical periodicity of DNA free in solution.

Design of the experiment

The idea behind the experiment is that if a straight, stiff piece of DNA lies on an atomically flat surface, the access of the enzyme to one side of the DNA helix is hindered in a uniform way along its length (Fig. 1). Only the most exposed phosphodiester bonds will be accessible to the enzyme, and these will recur with the periodicity of the double helix (Fig. 2*b*). The distance between the sites of attack of the nuclease gives the helical repeat directly. In the absence of a hindering surface all phosphodiester bonds are equally accessible and no 'image' of the periodicity is seen.

There are two methods for measuring the periodicity of the nuclease cutting sites. The first is to use a piece of DNA of defined length and incorporate a radioactive label at, say, the 5' terminus. Then the length of a single-stranded fragment produced by the nuclease action gives the position of cutting from the 5' end, and the intensity of the band on the autoradiograph gives essentially the frequency of cutting at that site. A kinetic analysis of the cutting rate can be made[8]. For this method to work, all the DNA molecules must lie in the same azimuthal orientation relative to the surface, and this assumption is justified by the results. The second method, which does not require a fixed length of DNA and is independent of the orientation of the molecule, is to introduce the label after the nuclease digestion, but this gives less total information (see below).

As a source of short, random sequence, double helical DNA pieces of defined length, we have used '140-base pair DNA' extracted from nucleosome cores, actually 148 ± 2 bases long. The persistence length of DNA is about 600 Å, so this DNA behaves like stiff rods[13,14].

To immobilize the DNA on the surface, that is to stop it rolling about, inorganic crystals were chosen which naturally formed flat surfaces, and where divalent cations were present or could be supplied. To exclude the possibility of a particular surface imposing a particular periodicity on the DNA by epitaxial action, experiments were performed with three different materials having different surface structures, namely calcium phosphate, magnesium phosphate and mica. To minimize interactions between the DNA molecules, fine crystalline dispersions were used so that the binding surface areas were very large in comparison with the concentration of DNA.

Materials and methods

Double helical DNA was extracted with water-saturated phenol/chloroform (1 : 1 v/v) from preparations of nucleosome cores[8], precipitated twice with ethanol and the precipitate dissolved in 20 mM Tris-HCl, *p*H 8.0, and 20 mM NaCl. The length distribution of the single strands ranged from 146 to 150 bases with an average of 148 bases.

The 5' termini of the 140-base pair DNA were labelled with ^{32}P by incubating with [γ-^{32}P]ATP (Amersham) and T4 polynucleotide kinase (Boehringer) essentially as described by Lutter[8,9]. The efficiency of labelling was not less than 50%. When DNA was digested with DNase I before end-labelling, the DNase I fragments were labelled with ^{32}P as described elsewhere[8]. To be able to quantify the binding of ^{32}P-labelled DNA to a surface, the excess [γ-^{32}P]ATP was separated from the labelled DNA fragment on a non-denaturing, 6% polyacrylamide gel[8].

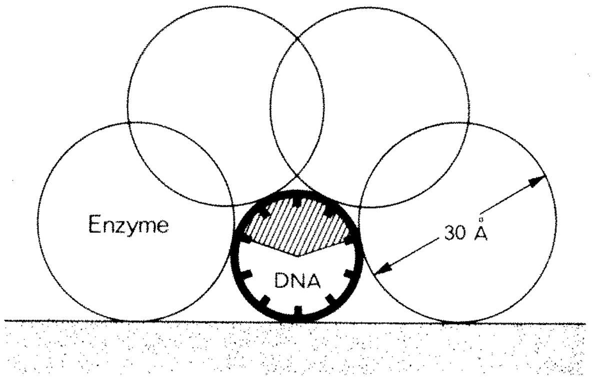

Fig. 1 Schematic drawing of the accessibility of an enzyme to DNA lying on a flat surface. The surface restricts a spherical enzyme with a diameter of 30 Å to a maximum of four accessible phosphodiester bonds. (DNase I, if spherical, would be larger than shown and have even less access to the DNA.)

The calcium phosphate and magnesium phosphate surfaces were prepared by mixing potassium phosphate with either $CaCl_2$ or $MgCl_2$ to a final concentration of 40 mM potassium phosphate and 25 mM $CaCl_2$ or 25 mM $MgCl_2$ in 50 mM Tris-HCl, *p*H 8.0. Magnesium phosphate readily forms platelet-like crystals whereas calcium phosphate forms a polycrystalline precipitate. The mica surface was prepared by grinding up mica sheets, washing and resuspending the powder at 0.2 g ml^{-1}, in 50 mM KCl, 8 mM $MgCl_2$ and 20 mM Tris-HCl, *p*H 8.0. Similar conditions were used to bind DNA to mica for electron microscopy[15].

A typical experiment consisted of adding 5 μg ^{32}P-5'-end-labelled 140-base pair DNA to 50 μl of a suspension of calcium phosphate or magnesium phosphate or mica, and leaving for 1–2 h at room temperature. The extent of binding can be monitored by pelleting the suspension and measuring the radioactivity in the pellet.

Incubations with DNase I (Worthington) were carried out in conditions where all the DNA was bound to the surface. In the experiments using calcium or magnesium phosphate, 10 U DNase I was used at 37 °C for 5–20 s, but with mica only 0.5 U DNase I was needed to obtain the same extent of digestion. Incubations were stopped by adding EDTA in excess of the divalent cation. The DNA was extracted with chloroform/isoamyl alcohol (24 : 1 v/v) and precipitated twice with ethanol. DNase I digests of the parent nucleosome cores, which were used as size markers, were carried out as reported elsewhere[9].

Samples of both DNase I-digested 140-base pair DNA and nucleosomes were fractionated by 6–10% denaturing high resolution gel electrophoresis, which is capable of resolving random sequence DNA fragments that differ in size by only one base[9].

Experiments with 140-base pair DNA

The results of a typical experiment where the 5'-end-labelled 140-base pair DNA preparation was bound to calcium phosphate, magnesium phosphate and mica, and then digested with DNase I are shown in Fig. 3, lanes a–c. In the autoradiograph a pattern of fine bands can be seen, which represent single-stranded DNA fragments differing in size by only one base. The intensities of the fine bands vary sinusoidally, showing broad maxima at regular intervals, about 10 bases apart.

The 'ladder' formed by the broad bands or maxima is an image of one side of the DNA structure as seen by the nuclease. A group of successive phosphodiester bonds, which are accessible to DNase I, give in the autoradiograph a set of intense fine bands. This set of fine bands, if unresolved, would give a broad band, or envelope, whose centre corresponds to a local maximum in the frequency of cutting on the DNA. We call this a 'site'[9].

The distance between DNase I cutting sites can be obtained by simply counting the number of fine peaks between the maxima, corresponding to sites, and then dividing by the number of sites traversed. In Fig. 4 the number of fine peaks between sites S3 and S9 is 63, giving a value of $^{63}/_{6} = 10.5$ bases. A more objective analysis of the densitometer tracings using Fourier methods, described later, gives 10.6 ± 0.1 bases as the distance between consecutive DNase I cutting sites.

Note that the absolute lengths of the fragments, which are determined by including known length markers in the gel separation (Fig. 3, lane N), and which locate the sites with respect to the 5′ end, have no role in this determination.

Interpretation of the DNase I cutting pattern

We have interpreted the above results as if most of the DNA molecules lie in the same azimuthal orientation on the surface, and also as if both DNA strands were being cut at exactly the same distance from each respective 5′ terminus.

The simplicity of the DNase I pattern in Figs 3 and 4, which show maxima with halfwidths of 4–5 bases and about 10 bases apart, suggests that these assumptions are valid. After allowing for the distribution of DNA lengths present in the original preparation[9], the width of the DNase I cutting site is only about 2 bases. This is what one might expect when the access of a molecule, with a minimum diameter of 30 Å, to the DNA helix is hindered by a flat, backing surface (Fig. 1). Moreover, as either or both of the two 5′ termini in a molecule are labelled at random, what is observed is the composite frequency of cutting on the two strands of the double helix. The two strands must be cut in a symmetrical fashion to give rise to such a clean pattern. This means that the two ^{32}P-labelled 5′ termini bear the same relationship to the binding surface, which is geometrically equivalent to saying that the unique dyad through the centre of the DNA molecule lies perpendicular to the surface (Fig. 2*b*). If this were not the case and the orientations of the molecules were random, then each 5′ end of the two strands in a molecule would give rise to its own series of bands, but displaced with respect to each other. The maxima in the cutting pattern would then be much broader than we have observed.

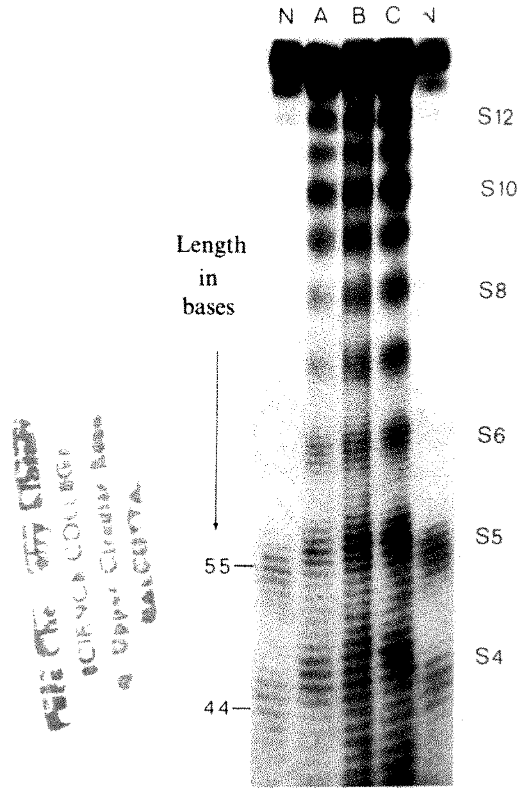

Fig. 3 Autoradiograph of DNA fragments from electrophoresis in a high resolution, denaturing gel made with 8% acrylamide and 1.35% methylene-bis-acrylamide. Lanes A, B and C contain DNA from DNase I digests of/the ^{32}P-end-labelled 140-base pair DNA preparation bound to calcium phosphate (A), mica (B) and magnesium phosphate (C). Lane N contains DNA from DNase I digests of ^{32}P-end-labelled nucleosome cores. Broad bands in lanes A, B and C, corresponding to sites of DNase I attack, are labelled S4 to S12, while the absolute fragment length in bases is indicated for lane N on the left.

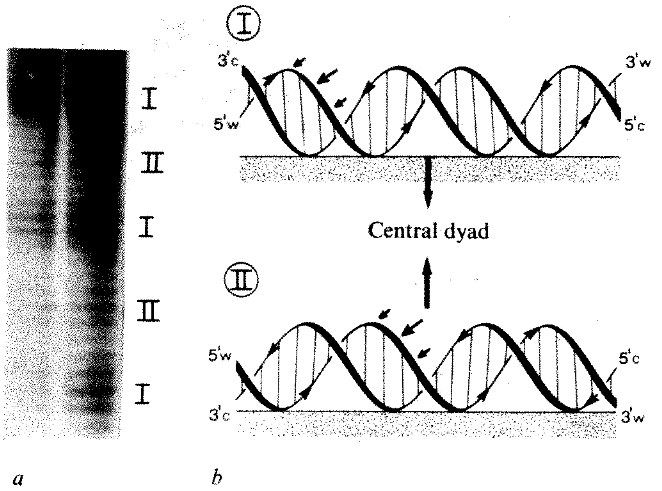

Fig. 2 Two settings of DNA on the surface. *a*, Autoradiograph from a region of a denaturing, high resolution gel electrophoresis of a sample showing two patterns of band maxima, I and II, displaced relative to each other by five bases. *b*, Schematic drawing of the two possible azimuthal orientations of a DNA molecule bound symmetrically to a surface. Setting I represents the major azimuth of the DNA, giving rise to the DNase I fragments as also observed in Fig. 3, lanes A, B and C. Setting II represents the minor azimuth of the DNA, giving rise to a set of DNase I fragments which migrate halfway between the major set of DNase I fragments. The piece of DNA in II is rotated through 180° with respect to I. A site of DNase I cutting is represented by three arrows. (This site need not occur at the most exposed position, furthest from the surface, as the enzyme need not cut at the site of binding.)

Although the results speak for themselves, it seems at first sight unlikely that all the DNA molecules would lie down in the same orientation. While clearly the bulk of the energy of binding to the surface comes from the phosphates along the length of the molecule, these would be indifferent to the orientation adopted. However, the binding of the ends of the molecule depends on the particular orientation and presumably it is the need to balance this interaction at the two ends which decides the symmetrical orientation adopted.

Further reassurance that the DNA molecules dispose themselves symmetrically on the surface comes from some experiments where a second, fainter pattern of bands can be seen lying halfway between those in the normal pattern, also repeating about every 10 bases (Fig. 2*a*). We believe the second pattern comes from DNA molecules which have rotated through 180° with respect to the first setting, so that the 5′ termini are still symmetrically disposed, and the central dyad is still perpendicular to the surface. This rotation would give an apparent translation of half of the periodicity, about 5 bases (Fig. 2*b*, I, II). When the second setting is present, never at more than about 30%, then counting between maxima becomes more difficult, but the Fourier analysis still gives the same value of 10.6 bases. That it is the ends which determine the particular orientation is made clear by an experiment in which the 140-base pair DNA preparation was treated with nuclease S1, which would remove any bases projecting at the 5′ end. This treatment results in both settings I and II appearing with equal proportion.

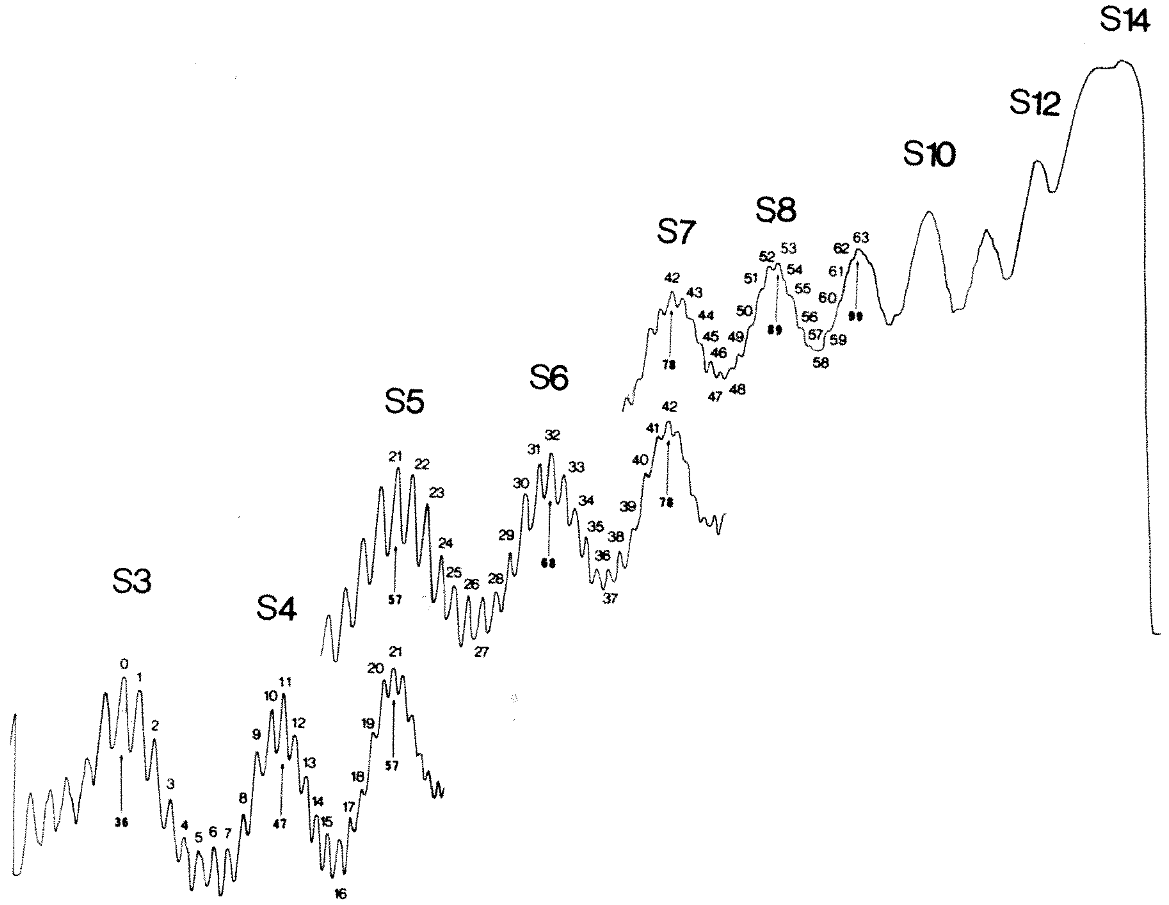

Fig. 4 Densitometer tracings of autoradiographs from the high resolution gel in Fig. 3, lane A (S5–S14), and of the same sample electrophoresed for a shorter time (S3–S5). The fine peaks, which are produced by DNA fragments differing in size by one base, have been numbered from 0 to 63 over the five bands from S3 to S9. The absolute fragment length in bases is indicated under the broad peaks in the densitometer tracing.

Probability of DNase I cutting at the sites

The probability of cutting at each site on the 140-base pair DNA can be found by cutting out the broad bands from the gels and measuring the radioactivity in each. However, the percentage of radioactivity in a band must be corrected for any cutting which might have occurred between that site and the labelled 5′ end[8].

The result is shown in Fig. 5. The probabilities of cutting at each of the 13 sites are approximately equal, but there is a clear tendency for an alternation between successive sites. This is to be expected, as in a DNA helix with a screw of 10.6 bases, there is almost an exact integral repeat after two turns. This local alternation in cutting frequency can indeed be seen directly in Figs 3 and 4, in the region of sites S9 and S13. Apart from this small modulation, analysis of Fig. 5 shows that all sites are essentially equivalent and cut at random, again justifying one of the assumptions behind the experiment.

Fourier analysis of the cutting frequency

The gel patterns may be analysed by Fourier transformation, which is more objective and accurate than simply counting the number of fine peaks between maxima, corresponding to sites. Moreover, it is the only method applicable when there are superimposed patterns with different periodicities or, what is more germane (see below), several patterns with the same periodicity but different starting points.

A Fourier transformation program applied to the amplitudes of the fine peaks in a densitometer tracing of an autoradiograph of a high resolution•gel produces a frequency spectrum of the periodicity (ies) present. The results of the method applied to such densitometer tracings as given in Fig. 4 are shown in Fig. 6. The breadth of the central maximum and the side lobes are just what would be expected from the limited length of pattern used in the analysis, in this case five repeats. The good agreement with the theoretical function expected (of the form $\sin 2\pi NX/2\pi NX$ where N is the number of bases and X the periodicity in 'reciprocal bases') indicates that a single waveform is making up the DNase I patterns of Figs 3 and 4.

The frequency spectra given by the experiments with the 140-base pair DNA bound to the three surfaces agree well with each other. The mid-points at half height are: calcium phosphate, 10.58 bases; magnesium phosphate, 10.6 bases; and mica, 10.62 bases. These values coincide well within the experimental error, which we estimate is 0.1 base. We conclude that the distance between DNase I cutting sites reflects a property of the DNA structure that is conserved when the DNA is bound to different inorganic surfaces.

Experiments with DNA of different lengths

To eliminate the possibility that the helical periodicity of 10.6 bases per turn of DNA found above could somehow depend on the particular length or end distribution of DNA used, we have also investigated a preparation of nominally 200-base pair DNA pieces extracted from nucleosomes (rather than from nucleosome cores). This contains a range of sizes, from 140 to 240 base pairs. With such a wide distribution of lengths, the external 5′ end-labelling technique loses its simplicity. The radioactive label is now introduced after the nuclease treatment, to label the new 5′ ends of the fragments produced ('internal labelling').

The result of such an experiment is shown in Fig. 7, together with that of a 140-base pair DNA preparation treated in the same way. A pattern of bands with intensity maxima at about

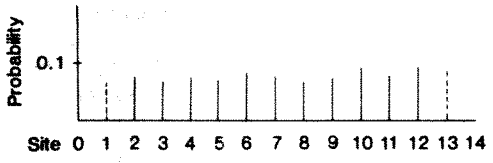

Fig. 5 The normalized probability of DNase I cutting at each site on the 140-base pair DNA fragment bound to calcium phosphate. S1 and S13 are shown dashed as these values are less accurate than the values at the other sites. The diagram is for the early stages of digestion, when the average number of cuts per single strand is 0.98.

every 10 bases is seen, but this has a higher background than the patterns shown in Fig. 3. The difference between the two experiments is that in Fig. 3 and Fig. 7, channel A, the only fragments seen are those beginning at the ^{32}P-labelled 5′ end and ending at a DNase I cut, whilst in the case of the '200-base pair DNA' (Fig. 7, lane D) all the fragments produced by DNase I are seen because the ^{32}P label was introduced after incubation with the enzyme. The pattern obtained by internal labelling does not depend on the azimuthal orientation of the DNA molecules. The first experiment gives a direct map of the cutting sites, whereas the second gives the autocorrelation function containing a superposition of similar patterns, all with different starting points.

Thus in Fig. 7, lane D the gel scans do not show a clear sinusoidal pattern, so direct counting of peaks between maxima is more difficult. The Fourier method gives a frequency of cutting of 10.8 ± 0.3 bases (not shown). This value is, however, less reliable than that given by the external 5′-end-labelling method, because it is weighted by the shorter fragments which occur in greater number than the long ones, whereas in the 'external' method all fragments occur in equal proportions (in the early stages of digestion). Even the 140-base pair DNA piece, of defined length, gives a less accurate value when the internal cuts, rather than original 5′ ends are labelled. However, in the gel, the ladder of band maxima from the 200-base pair DNA (Fig. 7, lane D) lines up well with that of the 140-base pair DNA (Fig. 7, lane E), showing that the periodicity of DNase I cutting is independent of the length of DNA used.

In these two patterns, each fragment is produced from two DNase I cuts. Thus, the distance between neighbouring DNase I cutting sites can be obtained simply by dividing the absolute length of a fragment (hitherto not required) by the fragment number (Fig. 7). This method gives a periodicity of DNase I cutting of 10.6 bases, in agreement with the results obtained from the external labelling experiment.

Consistency of absolute size of fragments and the periodicity

The ladder of broad bands produced from DNase I fragments labelled after digestion (Fig. 7, lanes D or E), lies nearly halfway between the ladder of DNase I fragments produced from the 5′-end-labelled 140-base pair DNA preparation (Fig. 7, lane A). This tells us that, for this particular length of DNA, the origin of the series of DNase I cutting sites is 4.5 bases away from its 5′ terminus (compare 2*b*, I). This value, together with the values of the absolute lengths of the fragments found in the experiment shown in Figs 3 and 4, provides a check on the helical periodicity. For instance, the centre of site S5 is at 57.3 bases (Fig. 4), which would give the origin of DNase I cutting at 57.3–5 × 10.6 = 4.3 bases, from the 5′ end, in very good agreement with the independently measured value.

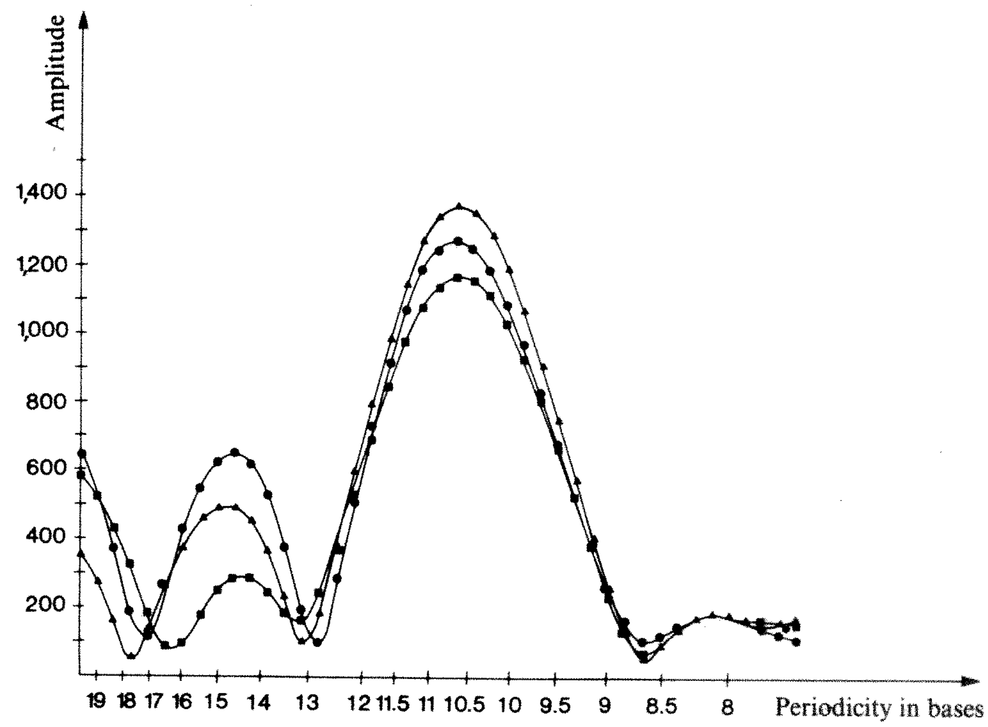
Other measurements of the helical periodicity of DNA

It has long been recognized that crystal packing tends to produce an integral number of base pairs per turn of a helix, permitting repeated regular contacts along the fibre length[16].

Prompted, in part, by the issue raised by us[4], Wang used a novel method to determine the helical repeat of DNA in solution[5]. This makes use of the effects of oligonucleotide insertions on the superhelicity of closed, circular DNA. He found a value of 10.4 bases per turn, which is close to the value of 10.6 bases we have found. Theoretical calculations by Levitt have suggested that straight DNA free in solution is most stable with 10.6 base pairs per helical turn rather than 10 (ref. 17).

The DNA fibres have been re-investigated by Zimmerman and Pfeiffer[6] who concluded, from X-ray diffraction studies, that highly swollen fibres still had the 10 base pairs per turn of the

Fig. 6 Frequency spectrum of DNase I cutting patterns computed by Fourier transformation. ^{32}P-end-labelled 140-base pair DNA fragment bound to: ▲, calcium phosphate; ■, magnesium phosphate; and ●, mica. In each case the mid-point at half height of the main peak occurs at 10.6 bases. 107 points (53 bases) were used in the analysis for all three surfaces.



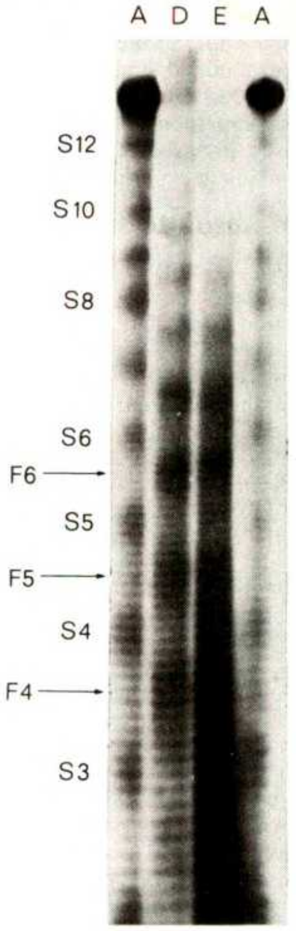


Fig. 7 Autoradiograph from a high resolution, denaturing gel made with 8% acrylamide and 1.35% methylene-bis-acrylamide. Lane A contains DNA from DNase I digests of the ^{32}P-end-labelled 140-base pair DNA preparation (external label). Lane D contains DNA fragments from DNase I digests of the 200-base pair DNA preparation, labelled after digestion (internal label). Lane E contains DNA fragments from DNase I digests of the 140-base pair DNA preparation, labelled after digestion. Broad bands in lane A corresponding to DNase I sites are labelled S3 and S12, while F4 to F6 indicate the DNase I fragments in lanes D and E. In all three experiments the DNA was bound to calcium phosphate.

helix. In our laboratory, J. T. Finch and L. C. Lutter (unpublished) have carried out X-ray studies on partially oriented gels of short stiff pieces of DNA, 150–300 base pairs long, in which the interparticle centre-to-centre distance was about 30 Å, but still found a helical repeat of 10 base pairs . Clearly these results disagree with our finding of 10.6 base pairs per turn of the DNA helix in solution. We can only conclude that in these gels or fibres of DNA, the molecules still interact, however weakly, through several layers of water and influence each other to produce an integral screw. It is relevant that structuring of water on the surface of clays appears to decay with a distance of about 10 Å (ref. 18).

Other measurements of the helical repeat are less reliable. Circular dichroism measurements and small angle X-ray scattering of DNA in solution have been used but the results are questionable because of the complexity of the data[19,20]. Griffith[21], from an electron microscope study, has reported a pitch of 10.5 base pairs, but in view of the systematic study by Vollenweider *et al.*[22] on the effects of dehydration during sample preparation, it is unlikely that the measurements made by Griffith referred to DNA in the B form.

Finally, it is known that the helical periodicity of DNA in solution is influenced, to some extent, by cation type and concentration, and temperature[23,24], but the effects on our results would amount to changes of not more than 0.1 base pair. In our experiments the cations and the ionic strength have been somewhat different, for the DNA bound to the three different inorganic surfaces, but nevertheless the same helical repeat was obtained.

Relationship to the DNA in nucleosome cores

The knowledge of the helical periodicity of DNA in solution is not only of intrinsic interest, but has important implications for the supercoiling of DNA in chromatin. To resolve the linkage number paradox, referred to in the introduction, we[4] suggested that the helical periodicity of DNA changes from 10.4–10.7 base pairs in solution to about 10 in the nucleosome. The value of 10.6 base pairs we have found for the helical periodicity of DNA in solution agrees with this prediction. However, the prediction was dependent on taking the value of 10 base pairs per turn for DNA wrapped on the nucleosome core, the value then given by Noll[25] from his DNase I digestion studies.

Ironically however, more accurate measurements show that the average distance between DNase I cutting sites on the DNA in nuclei[26] and on the nucleosome[9] is about 10.4 bases, rather than 10. Nevertheless, as pointed out in ref. 26, the periodicity of DNase I cutting, although closely related to the structural periodicity, need not be the same. This is because of the geometry of the nucleosome structure, where all the cutting sites on the DNA do not offer the same environment to the enzyme. In fact, it was concluded by Prunell *et al.*[26] that DNase I fragments from nucleosome DNA, that are multimers of 10.4 bases, could have been produced from a helical repeat of 10 base pairs. This question will be further discussed elsewhere (L. C. Lutter and A. K., in preparation).

In contrast to the case of DNA on the nucleosome, the geometry of our experiment, with the DNA lying on a flat surface, is simple. The accessibility of each turn of the double helix to the enzyme should remain constant along the length of the DNA fragment. This is confirmed by the result that the probability of cutting at successive sites is essentially the same (Fig. 5), quite unlike the results for DNA on the nucleosome[8]. We therefore conclude that the distance between DNase I cutting sites, on DNA immobilized on a surface, directly reflects the helical periodicity. Moreover, because we have found the same value of 10.6 ± 0.1 bases for three different surfaces with different atomic geometry, we identify this value with the number of base pairs per turn of the DNA double helix in solution.

We thank Drs P. J. G. Butler and R. A. Crowther for helpful discussions, and Dr. Crowther for writing the Fourier transformation program.

LETTERS

The complex radio galaxy 4C47.51 (1919+479)

J. G. Robertson

Netherlands Foundation for Radio Astronomy, PO Box 2, 7990 AA Dwingeloo, The Netherlands

An observation of the source 1919+479 with the Westerbork Synthesis Radio Telescope (WSRT) at $\lambda = 21$ cm has shown it to have a remarkable morphology, probably that of a very unusual and very large wide angle tail radio galaxy. It is situated in a cluster of galaxies at an estimated redshift of ~0.1. Although distortions of the morphology of radio sources caused by a cluster environment are well known, for example in producing normal head–tail and wide angle tail sources, the observed structure of 1919+479 is shown here to differ in several respects from previously known cluster sources.

1919+479 was included in a study[1,2] of 4C sources situated in the direction of Zwicky clusters of galaxies, in which observations at 2,695 MHz with the NRAO 300-ft telescope and the three-element interferometer (operated as a synthesis instrument) were presented. The former showed that the overall size was about 8 arc min, the latter showed a component coincident with the associated optical galaxy, and two other hot-spots. The Zwicky cluster in this case was Zw1916.8+4855 (which is of exceptionally large angular extent, nearly 20°, ref. 3). However, inspection of the optical field has shown that the galaxy identified with 1919+479 is almost certainly situated in a background cluster (see below).

The present observation was made in July 1979, at which time the WSRT consisted of 13 available telescopes along a 1.3 km east–west line. Details of the telescope and standard data reduction procedures are given elsewhere[4]. One 12 h observation was sufficient to obtain data on baselines from 36 m to 1,296 m with an increment of 36 m. This resulted in a grating ring radius of 20×27 arc min ($\alpha \times \delta$) and, with the usual tapered illumination of the aperture, a synthesized beam of 26×35 arc s. After Fourier transformation of the data, the CLEAN algorithm[5] was applied, and the resulting total intensity map is shown in Fig. 1. The noise level in this map is 0.48 mJy per beam area. The map has been corrected for the attenuation due to the primary beam of the individual telescopes; however, this is only 7% at most for the emission from 1919+479.

The galaxy previously proposed[2] as the optical identification is marked in Fig. 1. The radio structure is clearly very unusual. The diffuse region labelled F exhibits an approximately constant opening angle of ~47°, but is abruptly cut off at its far end in a straight line perpendicular to the ridge line. Connecting this component to the galaxy at C is a jet or tail which has two sharp bends. Between C and D the jet is unresolved, but in region E it has a half-power width of ~20 arc s. The western lobe of the source includes the bright component B and a 'tail' A. Although in gross morphology the lobe BA resembles an independent head–tail galaxy, and has no detectable emission connecting it with the eastern complex, it is almost certainly part of the same source. This is because inspection of the Palomar Sky Survey reveals no galaxy of $m_R \lesssim 18$ in the region of hot-spot B or its northern extension. Identification with a galaxy fainter than this limit would imply an unrealistically large size (≳4 Mpc) for the lobe. Moreover, the map of polarized intensity (prepared from the present WSRT observation) shows that the emission from region B is ~12% polarized, in contrast to the low degrees of polarization normally found near the parent object (for example, ~1% for component C). The 'head' B is also clearly extended both along the head–tail axis and perpendicular to it (the latter at region B1), unlike normal head–tail sources. Finally, the integrated flux densities of the two lobes are similar (see below). If this interpretation is correct, 1919+479 is a very unusual wide angle tail galaxy.

Of the three components shown in the NRAO interferometer map[2], two are confirmed by the present observation (B and C), while the third, located to the south-west of the weak source south of the apex of component F, is not confirmed.

No measured redshift is available for the galaxy identified with 1919+479. However, if the galaxy is assumed to have an absolute magnitude of $M_p = -21.7$ ($H_0 = 75$ km s^{-1} Mpc^{-1}), typical of the galaxies associated with wide angle tailed radio sources in clusters[6], then its apparent magnitude (on the PSS red plate) of ~14 mag implies a redshift of ~0.1. Using this estimate, the projected extent of both lobes is ~700 kpc. This places 1919+479 among the largest known cluster sources. The integrated flux densities are $S_{1412} = 0.47 \pm 0.03$ Jy and 0.61 ± 0.03 Jy for the eastern and western lobes respectively, giving a total luminosity at 1.4 GHz of 1.6×10^{24} W Hz^{-1} sr^{-1}, typical of tailed or complex sources. Integration of the contour diagram from the NRAO 300-ft observation[2] shows that $S_{2695} = 0.57 \pm 0.03$ Jy, giving a spectral index $\alpha_{1.4}^{2.7} = 1.0 \pm 0.1$ ($S \propto \nu^{-\alpha}$). The equipartition magnetic field[7] in component F is ~1.7 μG and the minimum energy density in relativistic particles and magnetic field is $\sim 2 \times 10^{-13}$ erg cm^{-3} (taking the emitting volume as a cone). If this component is confined by thermal pressure of a hot intracluster medium (ICM), then $nT \gtrsim 280$ cm^{-3} K, where n is the number density of protons in the ICM, and T is its temperature. In the diffuse component A the equipartition field is ~2.2 μG and the minimum value of nT required to confine the component laterally is ~660 cm^{-3} K. These values are typical of large diffuse radio source lobes (irrespective of whether or not the source is located in a cluster of galaxies)[8-10].

On the Palomar Sky Survey red plate the galaxy identified with 1919+479 is seen to be surrounded by a group or cluster of galaxies: there are five galaxies within 1 arc min and about 10 within 3 arc min. They are 2–3 magnitudes fainter than the radio source identification, consistent with their being typical cluster galaxies at a redshift of ~0.1, while the identified galaxy is the

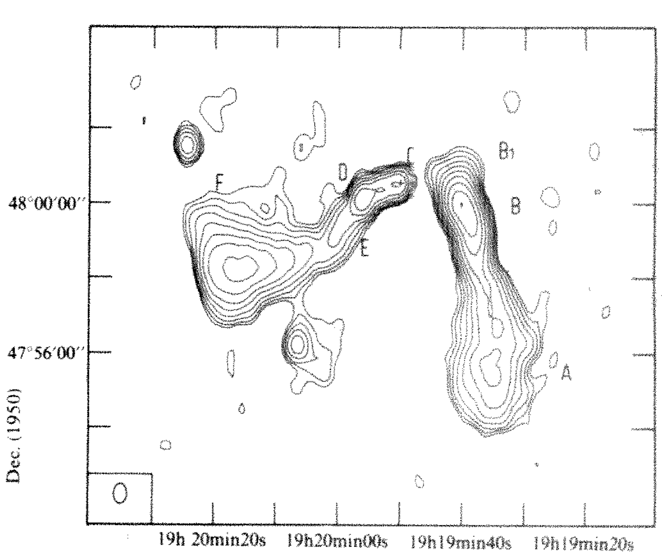

Fig. 1 Total intensity distribution of 1919+479 at 1412 MHz. The contour levels (logarithmically spaced) are 0.9, 1.5, 2.5, 4.2, 7.0, 11.5, 19.5, 32.5, 54.0 and 90 mJy per beam area. Letters identify components of the source discussed in the text; +, the position of the associated galaxy. The inset ellipse represents the half-power beam.

0028-0836/80/320579—02$01.00

dominant member of the cluster. The total extent of the cluster is difficult to determine because of the low galactic latitude (15.2°, that is well below the latitude for completeness of the Abell catalogue[11]) and because of possible confusion with fainter members of the overlying very extended Zwicky cluster. However, there are ~55 possible members within a radius of 15 arc min (the Abell radius for a cluster of redshift ~0.1). The cluster could, therefore, be as rich as Abell's[11] richness class 0 or perhaps 1, but further optical observations will be required to examine the cluster membership of the various galaxies. Radial velocity information from measured redshifts of the galaxies is also needed for more detailed modelling of the interaction of the radio source with the surrounding medium. The two small diameter radio sources to the north and south of component F have no optical identifications on the PSS.

In comparison with other complex extended sources, 1919+479 has a large size (unless the adopted redshift is a serious overestimate). With lobe sizes of ~700 kpc and an overall extent of ~1.2 Mpc, this source would considerably exceed the size of previously known large cluster sources such as IC711 (550 kpc, ref. 12), 1709+397 (460 kpc, ref. 13) or even the regions of diffuse emission in Abell 2256 (~650 kpc, ref. 8) or the Coma cluster (~450 kpc, ref. 14). Only the giant radiogalaxies such as 3C236 (~4 Mpc, ref. 15) and 3C326 (1.7 Mpc, ref. 9), which are not situated in clusters, significantly exceed the estimated size of 1919+479. The gap in the emission between the galaxy at C and the nearest part of component B/B1 is also large, although not exceptionally so. Its length is ~140 kpc, much larger than the gaps of 3–10 kpc commonly found near the heads of head–tail galaxies[16,17], and greater than that in wide angle tail sources such as 3C465 (25 kpc, ref. 18) but of the same order as the gap between the nuclear source and the western component of 1200+519 (~90 kpc, ref. 13) if the wide angle tail interpretation of the latter source is adopted. A further similarity between these two sources is the existence of a continuous tail or jet of emission extending from the galaxy to the second lobe. The physical processes responsible for the morphology of these two sources may therefore be similar, although it should be noted that the overall size of 1200+519 is only 220 kpc, and neither of its lobes is individually exceptional.

To return to the morphology of 1919+479, there are several interesting relations between the two lobes. First, a line passing through hot-spot D and the galaxy also passes perpendicularly through a noticeable protrusion B1 in the western lobe. (This feature is well above the noise level and is seen very distinctly in a map made with no tapering of the observations in the aperture plane.) This line is likely to be the axis of recent activity. Moreover, an extension of the ridge line in the triangular component F passes through the peak of the hot-spot B and is parallel to the line DCBI. This would be consistent with simultaneous ejection of the material which has given rise to the prominent components F and B, and with projected motion of the galaxy in an approximately northward direction being responsible for the overall wide angle tail morphology. The clearest problem which this source poses to interpretation within present models is the formation of the uniformly diverging region F, with its termination along a straight line. Projection effects may play a part in the appearance of this component, but for them to be a major influence the long axis of the component must lie almost along the line of sight, which would imply an extremely large physical size. An unusual three-dimensional structure seems unavoidable. Another interesting feature is the one-sided jet CDE. The presence of a surrounding medium (presumably an intracluster medium) would seem to be essential to explain the observed morphology, but making detailed models of this source will be possible only after observations at other frequencies become available, enabling the spectral index and polarization properties to be examined in detail, and after a reliable redshift is found from optical observations.

The Westerbork Synthesis Radio Telescope is operated by the Netherlands Foundation for Radio Astronomy with the financial support of the Netherlands Organization for the Advancement of Pure Research (ZWO). I thank Dr R. D. Ekers, Dr R. G. Strom and Professor Dr H. van der Laan for comments, Dr J. O. Burns for pointing out that 1919+479 lies in a background cluster, and R. Windhorst for assistance in the preparation of overlays for optical examination of the field.

IUE observations of the atmospheric eclipsing binary system ζ Aurigae

Robert D. Chapman

Laboratory for Astronomy and Solar Physics, NASA-Goddard Space Flight Center, Greenbelt, Maryland 20771

ζ Aurigae is an eclipsing binary star system with a property shared by only a few other systems. It consists of two stars in orbit around one another: a cool supergiant star (spectral type *K2* II) and a hot main sequence (spectral type *B8* V) star. The supergiant star is nearly 200 times larger than the Sun, while the main sequence star is only about seven times larger than the Sun. The Earth lies in the orbital plane of the two stars, and thus they periodically eclipse one another. When the relatively small *B* star goes into eclipse behind the cool supergiant star, its light passes through extended outer gaseous layers—the outer atmosphere—of the cool star. Thus the *B* star is an astrophysical light source which serves as a probe of the atmosphere of the *K* star. The eclipses, which occur every 972 days, have been well studied at visible wavelengths[1,2]. We report here IUE observations of the ζ Aur stellar system carried out between September 1979 and January 1980. A preliminary look at the data shows the advantage of UV observations of the system. There is strong evidence for cool, outflowing material near the primary star and hotter material farther from the primary perhaps in a shockwave. The onset of the atmospheric phase of the eclipse of the system—difficult to predict because of the irregularities of the supergiant atmosphere—began between 15 September and 1 November 1979.

As the *B* star goes into eclipse behind the *K* star, one wishes to study spectral lines produced by absorption of the *B*-star photospheric light by the *K*-star atmosphere. At roughly 4,300 Å the two stars are equally bright, and thus at this and longer wavelengths the photospheric light of the *K* star makes interpretation difficult. However, at UV wavelengths the *K* star is much fainter than the *B* star, and interpretation of the observations is greatly simplified. In the IUE case, with spectra in the wavelength range 1,200–3,200 Å, the *K*-star continuum is negligible, and we can observe spectral lines produced by the extended *K*-star atmosphere with no contamination from the *K*-star photospheric spectrum, throughout the entire wavelength range.

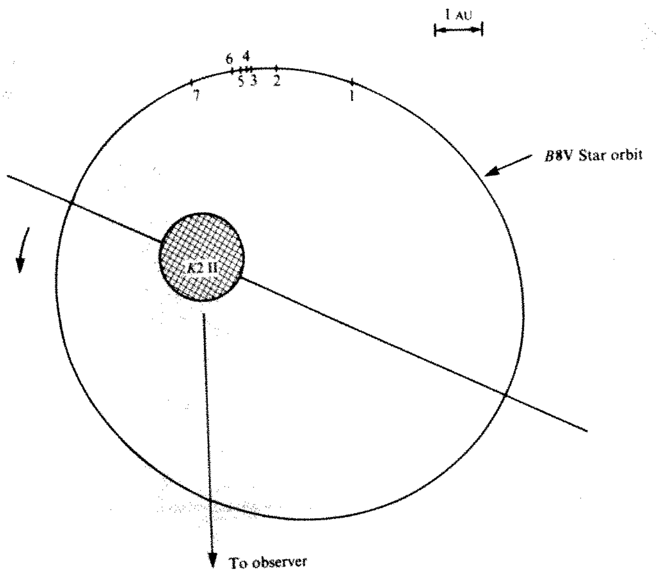

Fig. 1 Schematic diagram of the ζ Aur system.

Spectra have been obtained when the *B* star was as the positions numbered in Fig. 1. The 1979 dates of the observations are: (1) 15 September; (2) 1 November; (3) 13 November; (4) 15 November; 18 November; (6) 22 November and (7) 16 December.

The spectrum obtained on 15 September, a pure absorption spectrum, looks very similar to the spectrum of the *B*7 + *B*8 star 64 Orionis, supplied by D. S. Leckrone (see Fig. 2). The major differences between the ζ Aur spectrum and the 64 Ori spectrum is the presence of very strong multi-component absorption lines of Si II (1,260 Å, 1,264 Å), Si IV (1,394 Å, 1,403 Å), C IV (1,548 Å and 1,551 Å), and the presence of Mg II resonance doublet (2,795 Å and 2,802 Å) with strong P Cygni profiles.

The profile of the Mg II doublet Fig. 3 shows the classical P Cygni shape, indicative of an expanding shell. The absorption component of each line appears to show a reversed profile, characteristic of the strongest solar lines such as the Ca II, *H* and *K* lines. However, the appearance is undoubtedly due to two absorption lines being present, probably because of a double shell. This conclusion is supported by the spectra taken during the total phase of the eclipse. If the peak in the absorption line were chromospheric emission from the *K* star—as one finds in the case of the reversed Ca II-line profiles—then that central emission should remain visible during total eclipse even after the continuum and the absorption lines have vanished. In fact, the central emission is not present and, therefore, it must have been continuum showing between two partially resolved absorption lines.

The spectra obtained between 1 and 18 November show a large number of absorption lines not present in the 15 September spectrum. The absorption lines increase in number and strength during the time period (Fig. 4). The 1 November spectrum has been studied in some detail, and a large fraction of the absorption lines have been identified. Ionic spectra which have changed from 15 September to 1 November, showing that they arise from an extended atmosphere or dense wind region surrounding the *K* star include Al II, Al III, Cr II, Mn II, Fe II, Ni II and Ca II. This wavelength region includes the resonance lines of many of these ions. The majority of the lines correspond to lines observed in the UV solar emission line spectrum from Skylab[3,4]. The C IV, Si IV and Mg II lines observed in the 15 September spectrum are also visible in the 1 November spectrum but are very little changed in appearance. We conclude that the high ionization potential lines are formed far from the *K* star, whereas the group of low-ionization-potential lines which show significant changes are formed in cool plasma nearer to the *K* star: probably a cool wind. These cool wind lines seem to be shifted longward relative to the centre of mass of the binary system. Thus, the outflow must be dynamically influenced by the *B* star.

The high ionizations potential lines are typified by the C IV lines (Fig. 5). Each of the C IV lines consists of a narrow line, near the rest wavelength, and a longward shifted broad line. If one looks at the entire sequence of C IV lines, the narrow lines clearly remain unchanged, whereas the broad lines increase in strength into the eclipse. I believe that the narrow, constant line is probably interstellar, while the broad line is formed near the *B* star, perhaps in a shockwave produced by the *B* star moving supersonically through the *K*-star wind. Highly turbulent motion in the shockwave can account for the breadth of the absorption line.

On 22 November the *B*-star continuum had disappeared, and an emission line spectrum was present. The emission lines, which include C II, Si II, Si III, Si IV, S II, Mn II, Fe II, Ni II, correspond closely to the absorption lines observed in earlier

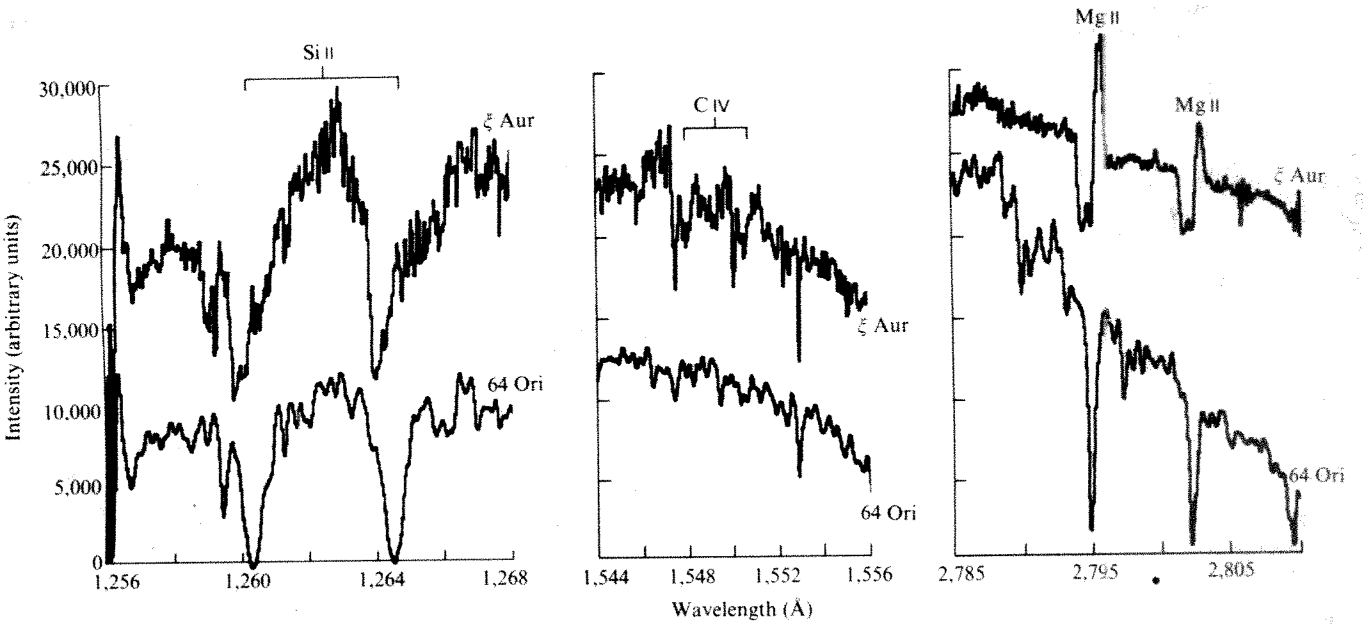

Fig. 2 Comparison between spectra of ζ Aur and the single *B*8 V star 64 Ori.

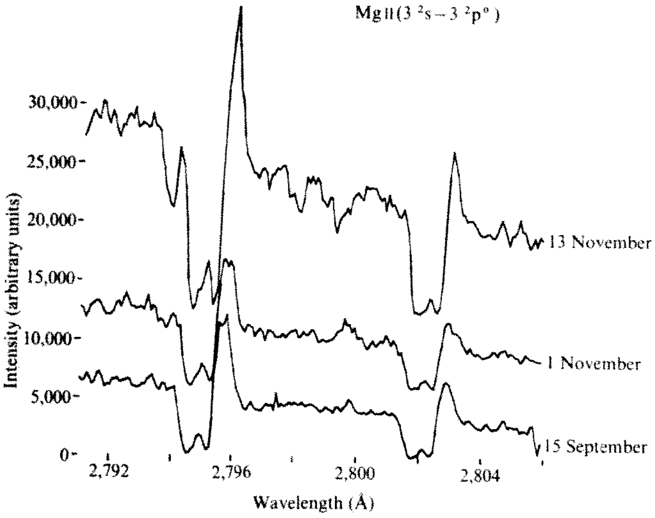

Fig. 3 The Mg II resonance doublet lines show strong P Cygni profiles. The appearances of the lines change very little with time, as can be seen from these three samples. The amplitude increase on 13 November is an exposure effect. On 22 November, the continuum level was too faint to record, and only the emission remained.

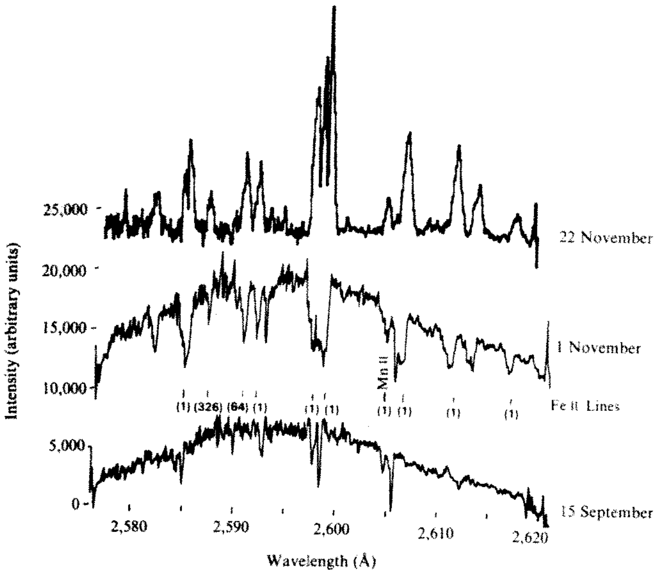

Fig. 4 Three exposures showing the region of the Fe II resonance lines. Between 1 and 22 November 1979, the absorption lines continue to increase in width. Multiplet number is indicated on figure.

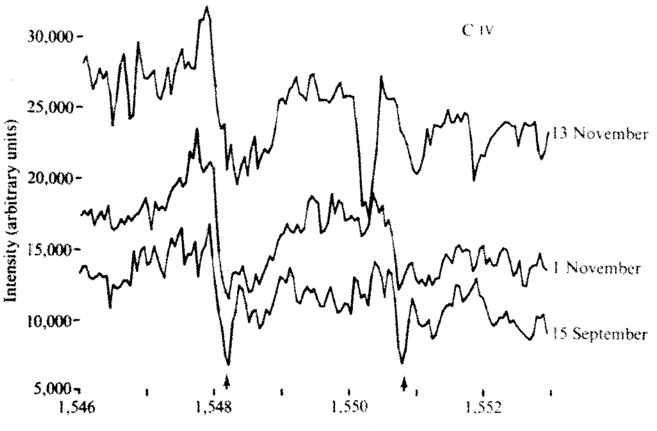

Fig. 5 The spectrum region of the C IV resonance lines. Each line seems to consist of a shortward feature and a longward feature. The longward feature is broader and shallower than the shortward. By 13 November, the features have blended together. Arrow marks laboratory wavelength.

spectra. We have searched for intercombination lines that have been observed in many stellar shell spectra, particularly in the low ionization stages of oxygen. None were found. The density of the material is therefore quite high, probably in excess of $10^{12}\,\mathrm{cm}^{-3}$.

We are now embarking on a more thorough study of the ζ Aur data, including additional observations during total eclipse and egress. Full details will be published elsewhere.

We thank the project scientist and observatory administrator for the opportunity to carry out this project, and the resident astronomers and staff of the IUE observatory at the NASA-Goddard Space Flight Center for practical assistance.

A long-lived (>32 min) persistent meteor train has been observed with a low light television camera which was sensitive only to radiation between wavelengths of 700 and 900 nm. The peak emission from the train was about 2×10^{17} photons $\mathrm{s}^{-1}\,\mathrm{m}^{-1}$ and the meteor which produced the train had a magnitude corrected to the zenith of about −6. It is suggested here that this IR emission arises from the excitation of the atmospheric band of molecular oxygen ($b^1\Sigma_g \rightarrow X^3\Sigma_g$) by the sodium catalytic process, a process which Baggaley[1–3] has previously proposed to be responsible for the visible radiation from persistent meteor trains.

The persistent train was recorded between 01.30 and 02.02 UT on 19 September 1979 from the Jungfraujoch Observatory in the Swiss Alps (46°33′N, 7°59′E, 3,570 m). The train was observed with an image isocon television camera used in integration mode to image structure in the near IR airglow. A picture was produced every half second and was recorded on a time lapse video tape recorder. A camera tube with a photocathode having an extended red (S-25) photocathode spectral response was used and a Schott RG715 filter was placed over the front of the camera lens to eliminate visible light. Thus the effective spectral region of the camera was confined to a region between 700 and 900 nm as shown in Fig. 1 (obtained by combining manufacturers' specifications).

The meteor which produced the train appeared at 01.30.14 (±1 s) UT. The luminous trail started outside the field of view, entered at the upper edge (elevation 17°) and ended in the middle of the field (elevation 12°). The range of the meteor from the camera may be estimated at 300 ± 50 km. As the meteor travelled 2.9° in 0.5 s at the estimated range of 300 km the velocity $v \gtrsim 30\,\mathrm{km\,s}^{-1}$. Comparing the brightness of the meteor with Jupiter recorded under similar conditions gave m_v of −3 for the brightest part, which was at an elevation of 14°. Using the correction given by Lovell[4], the magnitude of the meteor adjusted to the zenith was about −6.

The train which persisted after the passage of the meteor originated from a part of the meteor trail at elevations between 14.0 and 14.5°. Taking the range as 300 km it follows that the train lay between 15 and 20 km above the end height of the meteor. Assuming that the end height lay between 70 and 80 km suggests that the train lay at heights between 85 and 100 km.

During the period of observation the persistent train moved eastwards across the field of view. The upper and middle parts of the train moved very rapidly. By 02.02 UT they were 18° east of the original azimuth which indicates a drift velocity of 50 ± 10 m s^{-1}. The lower part of the train became drawn out behind the main body of the train and parallel to the drift direction. The drift velocity of the trailing edge of the train was estimated to be about 20 m s^{-1}. Thus there was considerable wind shear at the lower end of the train. This shear and the comparatively high velocity above it suggest that the train lay well above the mesopause and confirm the range of heights deduced from elevation measurements.

The brightness of the train was estimated by comparison with field stars of spectral class A. At the beginning, the brightest part of the train was comparable to a star of magnitude +5 but by the end of the period of observation it was barely visible above the limiting magnitude +7. To convert stellar magnitudes into photon emission rates we assume that the stars radiate as black bodies. Thus in our spectral passband a fifth magnitude star of class A_0 gives a photon flux at the camera of 2×10^8 m^{-2} s^{-1}. As we used a fairly narrow spectral passband, we neglect the differences between the spectra of the stars and the train and take the photon flux from the train to be 2×10^8 m^{-2} s^{-1} at the camera. This flux came from a portion of the persistent train which corresponded to a single resolution element in the picture (about 0.2° of angular extent, equivalent to 1 km at the estimated range of 300 km). By assuming that the meteor train was at right angles to the line of sight we obtain a line emission rate from the persistent train of 2×10^{17} photons s^{-1} m^{-1}. This estimate will be seriously in error only if the meteor were travelling in a direction close to the line of sight. This seems unlikely as the meteor train was of significant angular extent (>6°).

The depth of the Earth's shadow[5] in the region of the train at the time of observation was about 1,000 km so the light was generated in the train rather than being scattered sunlight. The light from such self luminous trains is thought to be generated by a cyclic chemical process first suggested by Chapman[6,7]:

$$O_3 + M \rightarrow MO + O_2 \qquad (1)$$

$$O + MO \rightarrow M + O_2 \qquad (2)$$

Metal atoms (M) released by the meteoroid catalyse the conversion of atomic oxygen and ozone to diatomic oxygen. If the reactions are sufficiently exothermic the products may be in excited states and emit photons as they decay to their ground states. The process may continue almost indefinitely as the metal atoms are recycled and the energy is extracted from the atmosphere. Baggaley has studied the case of sodium[1-3] for which both reactions have high rates[8]: a significant proportion of the sodium atoms produced by reaction (2) are in the excited ^2P state which decays by D line emission. Baggaley[3] estimated the production rate for the ^2P state from data on the sodium nightglow and found that to produce a clearly visible persistent train (one emitting $>5\times10^{15}$ photons s^{-1} m^{-1}) a meteor of $m_v > -2$ is required. Because almost all persistent trains (>96%) are produced by meteors brighter than $m_v \sim -2$ Baggaley concludes that the visible light emission from persistent trains can be explained solely by this process—the sodium catalytic process.

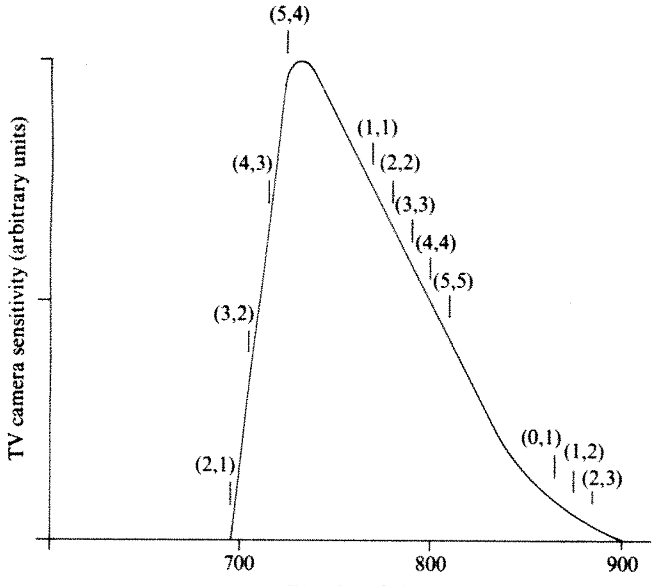

Fig. 1 The effective spectral response of the television camera and the positions of the vibrational bands of the atmospheric system of O_2.

The present radiation detected from the persistent train cannot be sodium light. We therefore consider whether the oxygen molecules in reactions (1) and (2) may be produced in excited states. The $b^1\Sigma_g$ state of molecular oxygen, in the absence of quenching, decays to the ground state emitting radiation in a band between 700 and 900 nm, as shown in Fig. 1. (The (1,0) and (0,0) bands are not shown as these connect with the vibrational ground state of O_2 and so are lost to a ground-based observer by absorption in the atmosphere.) The transition is foribdden for electric dipole radiation and so it has a long radiative lieftime of 12 s (ref. 9). The quenching of O_2 ($b^1\Sigma_g$) proceeds mainly by collision with N_2 and has a rate constant[9] $K = 2\times10^{-21}$ m^3 s^{-1}. This leads to significant quenching[10] only at heights below 85–90 km. It follows that the molecular oxygen emissions will not be quenched at the heights of the train reported here.

The production of O_2 ($b^1\Sigma_g$) is permitted in reactions involving many elements but because of the high reaction rates, the most favourable case is sodium. If we study reaction (2) for sodium, we find that, with an energy[1] for the reaction of 2.5 ± 0.2 eV, there are four variations of the basic reaction which are energetically and spin allowed:

	energy required	
$NaO\,(X^2\pi) + O\,(^3P) \rightarrow Na\,(^2S) + O_2(X^3\Sigma)$	0 eV	(3a)
$Na\,(^2S) + O_2(a^1\Delta)$	0.98 eV	(3b)
$Na\,(^2S) + O_2(b^1\Sigma)$	1.63 eV	(3c)
$Na\,(^2P) + O_2(X^3\Sigma)$	2.09 eV	(3d)

For reactions (3b) and (3c) the energy required is that needed to excite the lowest vibrational level ($v = 0$) in the upper electronic state. The total energy available from the reaction is much more than this so the higher vibrational levels may be excited (up to $v = 5$ for the $b^1\Sigma_g$ state). Reaction (3d) produces the sodium D line emission discussed by Baggaley and reaction (3c) produces molecular oxygen emission in the near IR. If the reaction were to take branch (3c) as often as (3d) we may expect a photon emission rate from molecular oxygen comparable to the photon emission rate from sodium. This gives an emission rate[3] of 5×10^{15} photons s^{-1} m^{-1} for a $m_v \sim -2$ meteor which extrapolates to 2×10^{17} photons s^{-1} m^{-1} for a meteor of $m_v \sim -6$. This is in good agreement with the emission rate from the train reported here. Thus the near IR emission from the persistent train may be explained in terms of the sodium catalytic process.

I thank M. J. Taylor for help wth the observations and Miss P. Rothwell for valuable discussions. The use of the Hochalpine Forschungsstation Jungfraujoch during September 1979 is gratefully acknowledged.

Photoelectrochemical conversion using reaction-centre electrodes

Solar Energy Research Institute, Golden, Colorado 80401

Recent reports have demonstrated the possibility of using photoactive, biological membrane components in photoelectrochemical cells[1]. Such systems have produced small photovoltages and photocurrents. The present studies in our laboratories have led to the attachment of a much simpler biological complex, the bacterial photosynthetic reaction centre isolated from *Rhodopseudomonas sphaeroides*, directly onto an SnO_2 electrode. The light-induced, primary-charge-separation processes which occur across the reaction-centre macromolecule have been coupled to the electrode, and in a two-electrode configuration photovoltages of 70 mV and photocurrents of 0.3 μA cm^{-2} have been observed in an external circuit. The phenomena are not due to Dember effects, and 'reactor-centre electrodes' may serve as a model system for future photovoltaic devices.

Photoelectrochemical cells have used chloroplast membranes[2], chloroplasts[3,4], photosystem-I particles[5], purple-membrane fragments containing bacteriorhodopsin[6,7], and bacterial reaction centres[8]. In most cases, the biological component was incorporated into liposomes or bilayer lipid membranes, and in some cases the stability was enhanced by using polymers or lipid-impregnated filters. Because the interiors of liposomes are inaccessible to contemporary electrodes, definitive electrochemical studies are very difficult. Lipid bilayers often trap solvents and have small working surfaces. Furthermore, the geometry necessitated by lipid bilayer systems (two half-cells separated by the bilayer) would be quite cumbersome in a solar energy conversion device. In contrast, chloroplast membranes[2,3] have been deposited directly onto the surface of an electrode, thus forming a simpler photoelectrochemical cell.

Bacterial reaction-centre complexes are the simplest biological units that carry out the primary photochemistry of photosynthesis. They have been isolated from photosynthetic bacterial membranes and are relatively stable at high concentration in room temperature and light conditions. A reaction centre[9] is an 80,000–100,000 molecular weight complex containing three protein subunits and six chlorophyllous chromophores, and it carries out a multistep charge separation process with a quantum efficiency of one. In the case of *Rhodopseudomonas sphaeroides* reaction centres, 15.2% of the incident solar energy (air mass 1.2) is available as the chemical potential of charge separation at the level at which the bacteriochlorophyll dimer donor ($BChl_2$) is oxidized and the iron/quinone acceptor (X) is reduced[10]. This estimate assumes that the sample is of sufficient optical density to absorb all incident light between 380 and 865 nm. Several investigators[11,12] have suggested that reaction centres might be deposited onto electrodes as model systems for future solar energy conversion devices. The first successful direct electrical coupling of an isolated photosynthetic reaction centre to an electrode is described here.

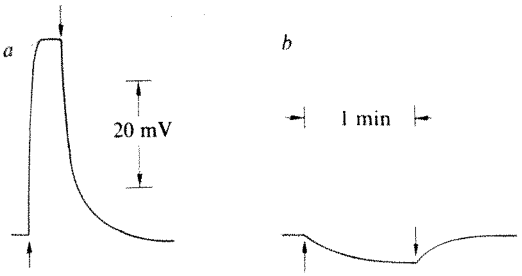

Fig. 1 The open-circuit photovoltage produced by a reaction-centre-coated, SnO_2 electrode exposed to red light (~40 mW cm^{-2}) in an electrochemical cell. *a*, Freshly-coated electrode. The electrode acts as a photocathode since the midpoint potential of the X acceptor in the reaction centre is more oxidizing than the flat-band potential of SnO_2. The kinetics of the photovoltage can vary with the sample. *b*, Autoclaved electrode. Upward and downward arrows indicate light on and light off, respectively. The photovoltage produced by an uncoated, SnO_2 electrode in these conditions was <1 mV.

Using the method of Dutton *et al.*[13] we isolated reaction-centre complexes from the purple, non-sulphur photosynthetic bacterium *Rhodopseudomonas sphaeroides* R-26 (a mutant strain of ATH 2.4.1 lacking highly unsaturated carotenoids). The complexes were suspended in 10 mM Tris-HCl buffer (*p*H = 8.0) at a concentration of 266 μM. Reaction centres were transferred to working electrode surfaces by dipping the electrodes into the concentrated, reaction-centre suspension. Excess liquid was removed from the lower part of the electrodes and the electrodes were dried in the dark. Platinum electrodes were platinized using standard methods, and SnO_2-coated glass was from Corning Glass Works. The experimental cell consisted of a working electrode and either a platinized platinum or SnO_2 counter electrode. The electrolyte was 0.1 M Na_2SO_4 and 0.05 M hydroquinone in water or Tricine buffer (*p*H = 7.1). The light source was a tungsten lamp (Unitron Instruments), and the light passed through both a Corning CS2-62 red filter, which cuts off light below 600 nm, and a 7-cm water filter. Photovoltages and photocurrents were measured in the external circuit with a Keithley Instrument Model 177 multimeter, using various load resistors connected in parallel or series with the meter. Absorbance spectra were obtained with a Cary 219 spectrophotometer. Action spectra were measured at very low light intensity using a tungsten light source focused through a 0.25-m Bausch and Lomb monochromator (6-nm bandwidth). The reciprocal of the quantum flux necessary to elicit a 10-μV response across a 10-kΩ resistor was plotted as a function of the wavelength.

Platinized platinum was the first working electrode material we investigated. Table 1*a* presents the photovoltages and photocurrents obtained when reaction-centre complexes were dried as a thin film on this surface. Small open-circuit photovoltages and short-circuit photocurrents were observed routinely, and the photoeffects lasted for at least several days. If these phenomena were due to the light-induced charge separation associated with the primary processes of photosynthesis, electrodes coated with inactive reaction centres would not be expected to produce photo-induced voltages and currents. Autoclaved reaction-centre-coated platinum electrodes (Table 1*b*) exhibit photoeffects of the same order as unautoclaved

Table 1 Photoeffects in reaction-centre-coated, platinized platinum electrodes

Working electrode condition	Open-circuit photovoltage (mV)	Short-circuit photocurrent (μA)
a. Freshly coated electrode	2.1	1.07
b. Autoclaved electrode	3.65	0.32

The total irradiated area of the electrode was about 0.25 cm^2 in each case.

electrodes, indicating that biologically active electron transfer is not involved. Dember effects[1] could account for the phenomena shown in Table 1.

The absence of any coupling of the primary charge separation to the electrode could be due to rapid back reactions from the electrode to the oxidized reaction centres or to quenching of excitation by energy transfer from excited reaction centres to the metal[14]. If this is the case, the use of semiconductor electrode materials might overcome the problem. Consequently, we made reaction-centre electrodes using SnO_2-coated glass. Figure 1*a* shows that a reaction-centre-coated SnO_2 electrode can typically generate an open-circuit photovoltage of 37 mV. The maximum value observed thus far is 70 mV. A maximum photovoltage of about 495 mV is possible (the difference between the midpoint redox potential of the $BChl_2$ primary donor, +450 mV, and that of the X acceptor, −45 mV, because $BChl_2$ and X are located on opposite sides of the reaction-centre molecule). Mismatching of the energy levels of the reaction-centre molecules with the energy levels of the SnO_2, charge recombination within the reaction-centre film, and a lack of reaction-centre orientation could account for the small photovoltages. Typical short-circuit photocurrents observed are $\sim 0.3\ \mu A\ cm^{-2}$. The residual photovoltage after autoclaving indicated in Fig. 1*b* is probably due to a Dember effect.

If electrons pumped across the reaction centre during the primary photoact of photosynthesis do equilibrate with the electrode, the action spectrum of the photocurrent measured in the external circuit should correspond to the absorbance spectrum of the reaction centres. Figure 2 compares the solution absorbance spectrum, the absorbance spectrum of a thin reaction-centre film, and the action spectrum of the photocurrent. The absorbance spectrum of the film is distorted with respect to the solution spectrum due to the effects of light scattering. The action spectrum, however, follows the solution spectrum closely. The peaks in the spectra at around 800 and 860 nm are due to bacteriochlorophyll absorption, while the peak at 760 nm is due to bacteriopheophytin absorption. The quantum yield (absorbed photons) for the production of electrons by 800-nm photons was 0.002.

We conclude that charge separation generated across the reaction-centre molecule as a result of the primary photochemistry of photosynthesis can be electrically coupled directly to semiconductor electrode materials (although inefficiently yet). Such reaction-centre electrodes can be used in a photoelectrochemical cell to generate photovoltages and photocurrents in an external circuit. Similar results have been obtained using electrodes on which chlorophyll or chlorophyll analogues have been deposited[15–18]. These electrodes may lead to new methods of probing the primary photochemistry of photosynthesis and may also serve as model systems for future inorganic or organic photoelectrochemical devices.

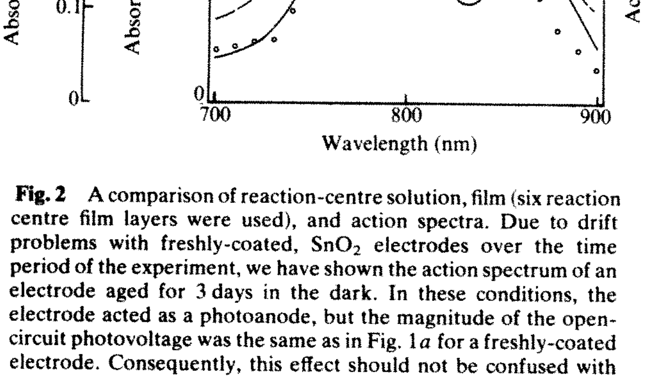

Fig. 2 A comparison of reaction-centre solution, film (six reaction centre film layers were used), and action spectra. Due to drift problems with freshly-coated, SnO_2 electrodes over the time period of the experiment, we have shown the action spectrum of an electrode aged for 3 days in the dark. In these conditions, the electrode acted as a photoanode, but the magnitude of the open-circuit photovoltage was the same as in Fig. 1*a* for a freshly-coated electrode. Consequently, this effect should not be confused with the small photoanodic effects of autoclaved electrodes (Fig. 1*b*). The action spectra of freshly-coated electrodes show the same peaks as aged electrodes, but the relative peak heights are distorted. The action spectra of autoclaved electrodes have no peaks in the 700–900 nm range.

Cross-polarization ^{13}C NMR spectroscopy of whole soils

The ideal tool for the analysis of soil organic matter would enable structural group analysis to be performed on whole soil samples in a non-destructive manner. However, up till now, there have been no adequate techniques available to characterize the structure of amorphous humic compounds in the solid state. Moreover, it has not been possible to dissolve all the organic material from the soil and obtain soluble material for analysis without chemical alteration during solvent extraction or pyrolysis. Although conventional NMR spectra of amorphous solids reveal no structural information due to large dipolar interactions, the use of high power cross-polarization (CP) techniques[1] has overcome difficulties in obtaining ^{13}C NMR spectra of solids to the extent that spectra can be obtained in much shorter times and organic functional groups partly resolved. We now report the first recorded ^{13}C NMR spectra of whole soils and show that this technique has the potential for structural analysis of organic matter in solid soil samples.

Although the ^{13}C cross-polarization technique has been well documented[1,2], a brief description is necessary here. Its major advantages over conventional ^{13}C NMR are a reduction of the time required to obtain a usable spectrum which, in turn, is better resolved owing to the elimination of heteronuclear dipolar broadening. The increased sensitivity to ^{13}C is achieved in two stages: the first by the transfer of polarization from the more polarized and more abundant ^1H spins to the ^{13}C spins. The maximum possible enhancement due to this effect is given by the ratio of the two gyromagnetic ratios, $\gamma_H/\gamma_{^{13}C}$, which is about 4. The second, and more significant, contribution results from the ^{13}C spin–lattice relaxation now occurring at the spin–lattice relaxation rate of the proton population which, in general, is an order of magnitude faster than the conventional ^{13}C rate. Thus the frequency with which data may be accumulated is greatly increased. In the presence of the high power heteronuclear decoupling field, the remaining line widths of the order of 0.2–2 kHz are due predominantly to residual ^{13}C chemical shift anisotropy (CSA)[2] and are not removed by the CP technique. However, the reduction in line widths is sufficient to allow partial resolution of many of the ^{13}C resonances from different functional groups with amorphous solids. The ^{13}C technique is used in the present study to determine the relative abundance of different functional groups in the organic matter in a range of soils.

To obtain this information, a number of experimental conditions must be satisfied. For example, it must be established that all carbon types approach the same degree of polarization enhancement during the CP process. This requirement is satisfied if the proton population is assumed to relax with a uniform spin temperature according to a single time constant, $T_{1\rho}$, as a result of spin-diffusion. Although the efficacy of spin-diffusion is quite short range on the time scale of the relaxation rates encountered in the soils studied here, this assumption has been widely used in the interpretation of spectra obtained from closely related coal samples which possess similar proton relaxation rates[3,4]. A second consideration is the r_{CH}^{-6} (where r_{CH} is the internuclear distance between carbon and hydrogen) dependence of the cross-polarization rate. Clearly the non-protonated carbons will cross-polarize at a slower rate than protonated carbons[3,4], setting a lower limit to the contact time used to achieve adequate cross-polarization. Finally, the delay between repeating the pulse sequence must be sufficiently long to allow for the spin–lattice relaxation of the proton population.

Unfortunately, as the polarization enhancement to which the ^{13}C spin system is approaching decreases with length of contact at the rate of the ^1H $T_{1\rho}$, over-allowance in the choice of contact time will lead to reduced enhancement and increased accumulation time. Also, over-allowance in the choice of pulse repetition time will lead to increased accumulation time. Because soils have low carbon contents (<25%), both the contact and pulse repetition times must be optimised for maximum time efficiency as well as equal response of different carbon types to the CP process.

To estimate the optimum conditions for this study, Maungatua silt loam, details of which are shown in Table 1, was examined using a range of contact and recycle times. Recycle times of 0.5–2 s resulted in no apparent differences in the total signal or those parts of the signal pertaining to specific carbon types, indicating that spin–lattice relaxation is very efficient for all carbon types ($T_1 < 0.1$ s). The ^{13}C–^1H contact time was varied from 0.25 to 2 ms with maximum enhancement occurring in the range 0.5–1 ms. No change in relative enhancement of different carbon types was evident for contact times greater than 0.5 ms. Hence, cross-polarization rates are fast and the ^1H $T_{1\rho}$ is short (<10 ms), as has been found in coals[3,4]. Thus the spectrum of Maungatua soil could be semiquantitatively interpreted using a contact time of about 1 ms and a recycle time as short as 0.5 s. All other soils were examined using a single contact of 1 ms duration with a recycle time of 1 s except for Taupo C horizon clay where a recycle time of 0.5 s was used due to the low carbon content.

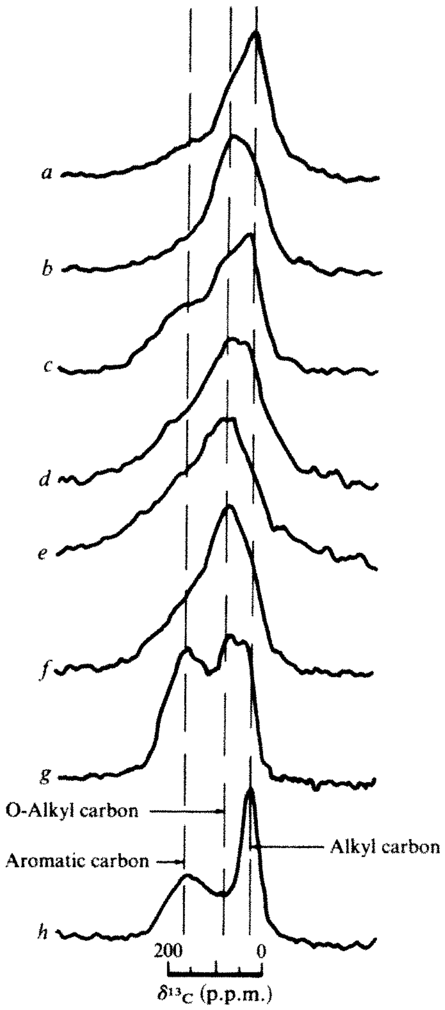

Fig. 1 CP-NMR spectra of soils and coals obtained with a Bruker CXP-100 spectrometer operating at 22.63 MHz for ^{13}C and a Bruker z-22v ^{13}C-[^1H] double resonance probe. ^1H irradiation fields of 28 and 7 G for ^{13}C and ^1H respectively were used to satisfy the Hartmann–Hahn condition[2] necessary for cross-polarization. The number of free induction decays collected ranged from 2×10^4 to 2×10^5. *a*, Maungatua humic silt loam. *b*, McKerrow fine sandy loam A_1 (clay-size fraction <0.02 μm, 23% organic matter) isolated by ultrasonic dispersion of soil in water and subsequent separation into sand-, silt- and clay-size material. *c*, Te Kopuru sand B_h horizon. *d*, Te Kopuru sand A horizon. *e*, Taupo C horizon clay concentrate (<0.2 μm, 6.3% organic matter). Conditions of isolation have been described elsewhere[6]. *f*, Taupo B horizon clay concentrate (<0.2 μm, 13.2% organic matter). Conditions of isolation have been described elsewhere[6]. *g*, Yallourn coal (woody brown coal). *h*, Wandoan coal (sub-bituminous black coal).

Table 1 Properties of Maungatua humic silt loam

New Zealand classification[5]	Podzolized upland yellow-brown earth	
Horizon	A_1	
%C	22.1	
Cation exchange capacity *me*%	39.0	
Total exchangeable bases *me*%	1.1	
Parent material	Thick schist over comminuted schist	
Vegetation dominants	Canopy:	
	Chionochloa rigida	35%
	Dracophyllum longifolium	35%
	Celmisia coriacea	15%
	Ground layer:	
	Astelia linearis	
	Celmisia gracilenta	
	Cladonia aggregata	

Figure 1 shows typical spectra of soils and soil fractions, together with spectra of brown and black sub-bituminous coals for comparison. Details of the other soils used in these experiments have been reported previously[5–7]. ^{13}C CP spectra of coals normally consist of a relatively sharp resonance due to alkyl carbons and a broader, unsymmetrical peak to lower field, due to aromatic carbons[3,4]. The spectrum of Wandoan coal (Fig. 1*h*) is typical of this. The Yallourn xylitic brown coal spectrum (Fig. 1*g*) exhibits an additional resonance indicative of carbons α- to oxygen in ethers and alcohols (O-alkyl), and is also obviously more aromatic. In contrast, in Maungatua soil (Fig. 1*a*), the dominant carbon type is alkyl with a significant amount of O-alkyl carbon also present. The aromatic carbon content seems much lower than in either coal. Figure 1*c*, *d* show the spectra obtained from the B_h and A horizons of the Te Kopuru sand. The B_h horizon of Te Kopuru sand is clearly more aromatic than the Maungatua soil and is also possibly slightly more aromatic than the A horizon of Te Kopuru sand. Similarly, more of the aliphatic carbon in the A horizon is bound to oxygen than in the B_h horizon. Thus, the chemical structure of the soil organic matter may vary with profile depth as well as soil type.

Humic and fulvic extracts of soils usually contain carboxylic acid carbon[8–14] but no distinct signals were obtained downfield of the aromatic carbon signal. It is possible that the signal is hidden by the large chemical shift anisotropies of aromatic and carboxylic carbons[1]. The use of the 'magic angle spinning' technique (MAS)[2], which removes the CSA broadening, in conjunction with the CP process should clarify this point. The brown coal spectrum exhibits a shoulder on the low field side of the aromatic signal which is possibly due to carboxylic carbon.

In the soils with low carbon content, we were able to obtain spectra by physically separating the carbon-rich clay fractions. As found for the Maungatua soil, the clay fraction of the A horizon of McKerrow fine sandy loam (Fig. 1*b*) is highly aliphatic, but it is also apparent that more of the aliphatic carbon is bound to oxygen. We have also obtained spectra from the $<0.2\ \mu m$ clay fractions of the B and C horizons of Taupo sandy soil (a vitric andosol developed on pumice) (Fig. 1*e*). The C horizon fraction contained only 6% carbon and required 2×10^5 scans at 0.5 s pulse repetition to obtain the spectrum. At the field strength used (21.1 kG) the technique is probably limited to soils or soil fractions of about this carbon content or greater.

Early workers believed that humic substances were highly aromatic polycyclic materials[13]. However, recent workers have proposed different structures. Schnitzer has suggested that humic materials are highly substituted monocyclic materials in which some of the substituents are polymethylene chains of fatty acids[14]. Other workers[9–12] have suggested that humic materials are more aliphatic than previously thought. Grant[15] has shown that polymethylene can comprise as much as 30% of the organic matter in a particular soil, while Anderson and Russell[16] have offered evidence which suggests that polymaleic acid-like polymers may be important constituents of humic substances. In the soils we have investigated, our results indicate the variation in the nature of the organic matter present, from highly aliphatic to moderately aromatic.

We are continuing our studies of soil organic matter by the ^{13}C CP technique with the aim of correlating the variation in structure with soil forming factors, in particular, vegetation. The combination of the 'magic angle spinning' technique with the CP process will provide more detailed and quantitative information.

We thank R. Tyler and N. Russell for coal samples and Drs A. Campbell and K. Goh for some of the soil samples. Support to P.F.B. was provided under the National Energy Research, Development and Demonstration program administered by the Commonwealth Department of National Development.

Harmattan dust deposition in northern Nigeria

Grant McTainsh

School of Earth Sciences, Macquarie University, North Ryde,
New South Wales 2113, Australia

Studies of atmospheric dust deposits originating from Africa, within Atlantic Ocean sediments[1,2], have provided useful indirect information on Quaternary environments, but dust studies in Africa are rare. Here Harmattan dust deposition measurements at Kano, northern Nigeria during the 1978–79 season are reported. A relation between dust deposition, visibility, solar radiation and wind speed is defined, which deteriorates during the latter half of the Harmattan season. A probable explanation of this deterioration is the local remobilization of existing dust.

The dust is thought to originate from the Faya Largeau area in the Chad Basin[3] (Fig. 1). From there the dust plume travels WSW at an altitude[4] of 600–900 m reducing visibility, relative humidity, solar radiation and temperatures along its path. The Harmattan season extends from October to April though it may vary considerably from year to year.

The dust collection technique was designed to measure the amount of Harmattan dust falling onto the ground from suspension in the atmosphere. A dust trap was set up 9 m above ground level on the roof of a building on the campus of Bayero University, Kano, isolated from local soil dust movements. The trap was a basin of distilled water 20 cm deep exposing a water surface of 0.27 m^2 for collecting dust. Water level was maintained daily 10 cm below the top. To prevent bird contamination of the dust trap a second basin was kept full for birds to use. The dust laden water was evaporated in laboratory ovens weekly and the residue weighed. Collections were made during three Harmattan seasons, 1976–79.

Casual observations during the Harmattan season suggest a close association between visibility and dust deposition but the

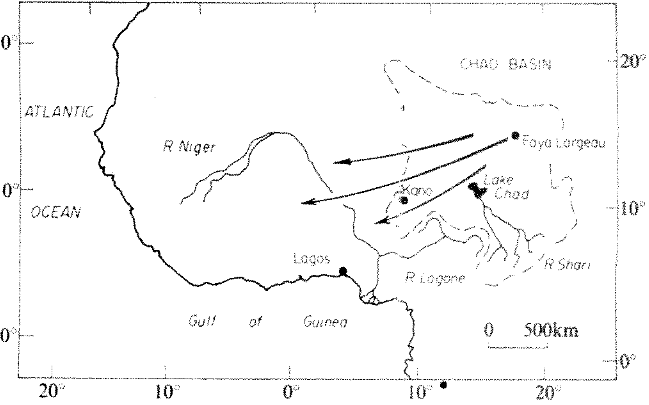

Fig. 1 The Harmattan wind in West Africa.

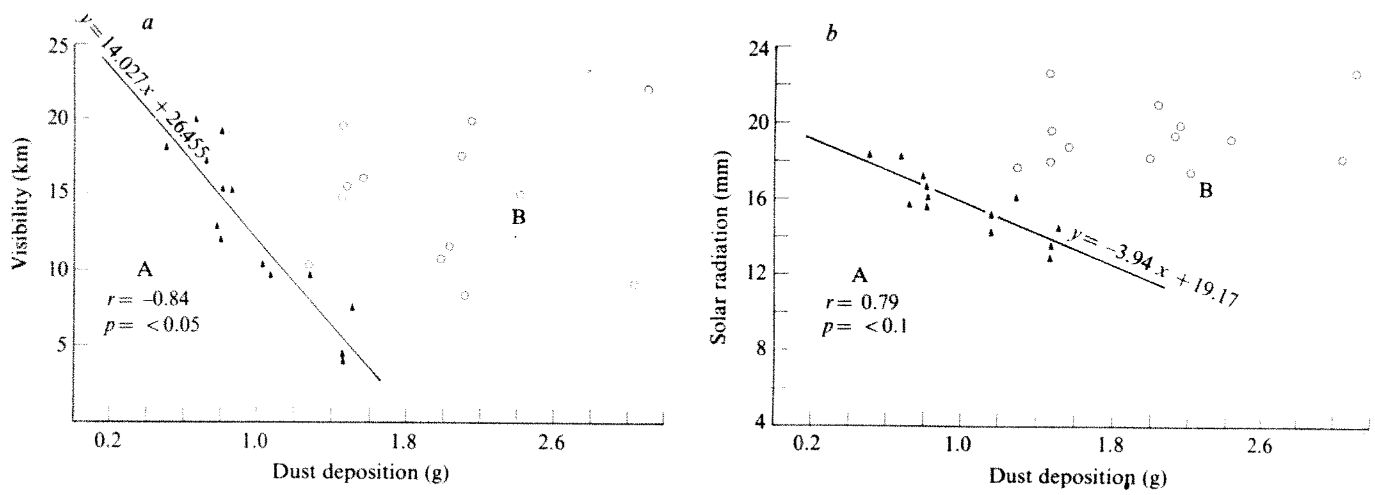

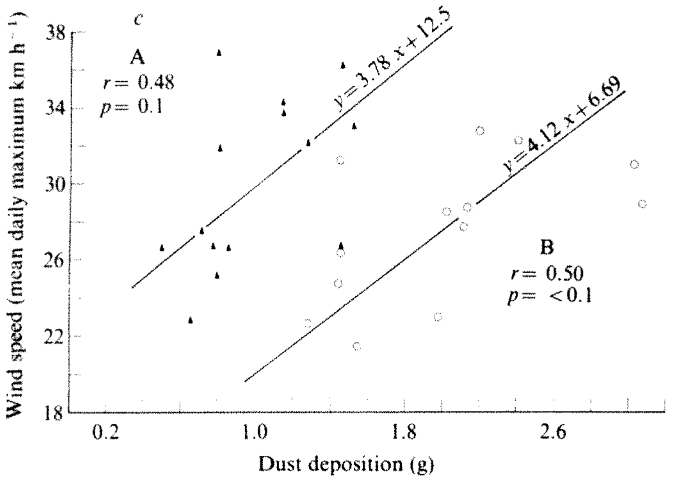

Fig. 2 *a*, The relation of visibility to Harmattan dust deposition—weekly mass of dust settling over 0.27 m of distilled water (see text); *b*, the relation of solar radiation to Harmattan dust deposition; *c*, the relation of wind speed to Harmattan dust deposition. ▲, Time period A (October–January); ○, time period B (January–April). *r* is the correlation coefficient and *p* is the significance level found in a test of the hypothesis $r = 0$ against $r \neq 0$.

monitored rates indicate a more complex relationship. During the first part of the season periods of low visibility are associated with high dust deposition. As the season progresses measured deposition was far greater than observed visibility would suggest. Data on visibility, solar radiation (Gunn Bellani) and wind speed obtained from Kano International Airport were averaged over each of the 28 weekly dust measurement periods of the 1978–79 season. Relationships with deposition are shown in Fig. 2.

The data consistently fell into two time periods, here termed A (12 October–12 January) and B (13 January–27 April). During A a close relation emerges between visibility and deposition and between solar radiation and deposition ($r = -0.84$ and -0.79 respectively, Fig. 2*a*, *b*). During B these relations deteriorate to statistical insignificance. The relation of wind speed to deposition remains at a lower but stable level throughout the season ($r = 0.48$ and 0.50, Fig. 2*c*).

A probable explanation of these differences is local remobilization and secondary deposition of the dust during B, increasing the measured deposition and upsetting the expected relationships with visibility and solar radiation. As the remobilized dust is not derived from high altitudes the expected relations with visibility and solar radiation are disrupted, whereas during A primary deposition is dominant.

Wind speed data support this view. During A, increases in Harmattan wind speed are accompanied by greater dust deposition. During B the amount of dust deposited is higher than wind speed might suggest (Fig 2*c*) as wind is remobilizing and redepositing dust.

The start of the Harmattan season coincides with the end of the wet season so that during A tall grasses abound and relative humidity levels are high thus minimizing dust remobilization. As the grasses die off, relative humidity decreases and the total amount of deposited dust increases, conditions become conducive to remobilization and secondary deposition. This process might be accentuated by grass burning during the latter part of the dry season adding coarser particles to the measured deposition. These particles may have relatively little influence on visibility.

Therefore, measured dust deposition rates during B (after mid January) overestimate the Harmattan dust influx. The visibility–deposition regression line (Fig. 2*a*) is taken to indicate primary Harmattan dust deposition. Visibility data for each week during B are used to predict the expected deposition for each week. The difference between expected and measured deposition I assume to be secondary deposition.

When the corrected data are derived, total Harmattan dust deposition at Kano during 1978–79 is 99.1 g m^{-2}. This figure represents a reduction in total measured deposition of 41.7% which is the amount of secondary deposition. Based on measured dust bulk density of 0.85 g cm^{-3} the 1978–79 Harmattan dust influx represents a layer of dust 0.116 mm thick.

Harmattan dust deposition measurements made by Bromfield[5] in the same area during 1969–72 amount to 22.6 g m^{-2} which is far lower than rates given here, and surprising during a time of drought. Bromfield collected dust in a dry deposition gauge (B.S. 1747 Part 1 1961) which can seriously underestimate deposition[6].

Published[7] dust accumulation rates measured on land vary from 6.6 to 20,100 mm kyr^{-1} which could in part reflect different collection and calibration techniques. A standardized method for monitoring dust is urgently needed.

With respect to historic fluctuations in dust deposition, the visibility–dust deposition relation defined here could be used to estimate dust deposition over the period for which meteorological data are available, thus providing a sensitive index of environmental change in historic times within the Sahel.

I thank Innocent Ukenna for help with the dust collections and note the recent and tragic death of Dr M. P. S. Collins of the Bayero University Harmattan Research Group. Thanks go to Bayero University for financial aid and Martin Williams for discussion.

Coupled effects of atmospheric N_2O and O_3 on the Earth's climate

Wei-Chyung Wang & Nien Dak Sze

Atmospheric and Environmental Research, Inc., 872 Massachusetts Avenue, Cambridge, Massachusetts 02139

Increased application of nitrogen fertilizer[1] could perturb the atmospheric nitrogen cycle and might lead to a possible increase[2-6] in atmospheric N_2O. N_2O plays an important role in stratospheric chemistry[7-9] as well as in the global radiation budget[10-12]. Recent studies[13-15] suggest that perturbation of local ozone could also significantly affect the global climate. Here we show that a doubling in the present day N_2O level might significantly perturb the distribution of O_3 and HNO_3, and that the associated climatic feedbacks from O_3 and HNO_3 perturbations could contribute as much as 0.23 K warming of the surface temperature, in addition to 0.44 K directly caused by N_2O doubling.

Nitric oxide (NO) is formed in the stratosphere mainly by the reaction of $O(^1D)$ with N_2O (refs 7–9),

$$O(^1D) + N_2O \rightarrow 2NO \qquad (1)$$

and may serve as a catalyst for O_3 removal[16,17] mainly by

$$NO + O_3 \rightarrow NO_2 + O_2 \qquad (2)$$

and

$$NO_2 + O \rightarrow NO + O_2. \qquad (3)$$

In the lower stratosphere ($z < 30$ km), NO and NO_2 may, however, couple with stratospheric odd hydrogen (HO_x) and odd chlorine (ClX) mainly through reactions

$$NO + HO_2 \rightarrow OH + NO_2 \qquad (4a)$$

$$NO_2 + OH + M \rightarrow HNO_3 + M \qquad (4b)$$

$$NO + ClO \rightarrow Cl + NO_2 \qquad (5a)$$

and

$$NO_2 + ClO + M \rightarrow ClNO_3 + M \qquad (5b)$$

Note that while addition of NO may enhance O_3 removal through reactions (2) and (3), it may reduce the efficiency of both the HO_x cycle ($OH + O_3 \rightarrow HO_2 + O_2$; $HO_2 + O_3 \rightarrow OH + 2O_2$) and the ClX cycle ($Cl + O_3 \rightarrow ClO + O_2$; $ClO + O \rightarrow Cl + O_2$) as sinks for O_3, particularly in the region below 30 km. Thus, an increase in stratospheric NO (or N_2O) may lead to O_3 depletion in the upper stratosphere and to O_3 increase in the lower stratosphere and upper troposphere. (For reviews of current understanding of stratospheric chemistry see refs 18–22).

Table 1 Calculated surface temperature change ΔT_s(K) caused by a doubling of the present day atmospheric N_2O abundance, 320 p.p.b.v.

Case	Model	ΔT_s(K)
A	N_2O	0.44
B	$N_2O + O_3$	0.62
C	$N_2O + O_3 + HNO_3$	0.67

Case A considers the sole effect due to N_2O increase. Case B includes the additional effect of O_3 perturbation (Fig. 2). Case C represents the combined effect associated with N_2O increase, including the feedbacks from perturbation to O_3, HNO_3 and NO_2. The effect of NO_2 increase is mainly to increase the absorption of solar radiation in the atmosphere[24], with possible greenhouse effect as it has IR bands[30]. However, the calculated surface cooling due to the associated NO_2 increase is small, ~0.01 K. For the constant cloud temperature parameterization[26] with ice-albedo feedback[27], the calculated surface temperature change should be multiplied by a factor of 2.

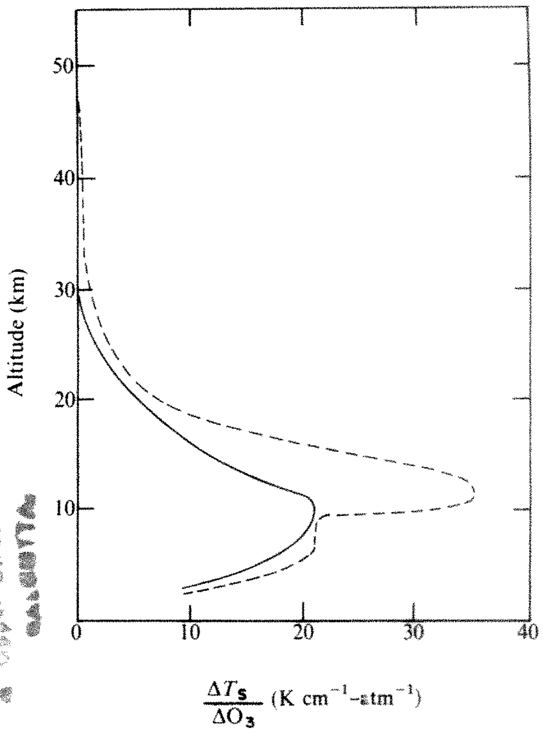

Fig. 1 Sensitivity of surface temperature change ΔT_s(K) to changes in local O_3 amount for mid-latitude (solid line) and tropical atmospheres (dashed line) (after ref. 15).

Besides its dominant role in the stratospheric chemistry, N_2O has strong IR absorption bands at 4.5, 7.78 and 17 μm, and thus contributes to the 'greenhouse effect'. Calculations[10-12] indicate that an increase in the atmospheric N_2O abundance due to the increased application of nitrogen fertilizer[2-6] might directly influence the troposphere climate.

We consider here some of the indirect climatic effects that might be associated with the compositional changes caused by N_2O increase. For instance, because of the strong photochemical coupling between N_2O, O_3 and other trace species, changes in atmospheric N_2O may perturb the O_3 distribution which also has an important role in maintaining the stratospheric thermal structure and the Earth–troposphere radiative energy balance[13-15,23]. Figure 1 shows the calculated sensitivity[15] of surface temperature T_s to changes of local O_3. Note that the maximum sensitivity occurs at around 12 km.

Furthermore, because N_2O is the precursor (reaction (1)) to stratospheric NO_x (NO, NO_2, HNO_3, NO_3, N_2O_5, $ClNO_3$), changes in N_2O would cause similar changes in HNO_3 and NO_2. Note that HNO_3 has IR absorption bands[13] at 5.9, 7.5, 11.3 and 21.8 μm while NO_2, primarily absorbs solar radiation in the UV and visible[24]. Consequently, changes in HNO_3 and NO_2 may also affect the global radiation budget. The combined climatic effects to be expected from a large increase of N_2O are therefore due, in part, to direct greenhouse effect of N_2O as discussed by Wang *et al.*[10] and, in part, to the perturbation of atmospheric chemical composition (for example, O_3, HNO_3 and NO_2) caused by the interaction of N_2O with other trace species.

Figure 2 shows the calculated changes in the vertical thermal structure and the O_3 profile resulted from a doubling of the present day atmospheric N_2O abundance, 320 p.p.b.v. (parts per 10^9 by volume). Note that while the calculated perturbation to column O_3 amount is relatively small (~2% increase), the changes in local O_3 amount are relatively large, up to ~+18% at 12 km and −19% at 38 km. The increase in O_3 below ~26 km is

0028-0836/80/320589—02$01.00

mainly attributed to the strong coupling between NO_x, HO_x and ClX while the decrease above 28 km to reactions (2) and (3). The calculated changes in O_3 profile (Fig. 2) are sensitive to the choice of diffusion coefficients and the stratospheric OH concentrations which are uncertain by at least a factor of 2 or 3. In view of such large uncertainties, the quantitative aspect of the results presented in Fig. 2 should be taken with caution. The calculated changes of the column abundance of HNO_3 and NO_2 resulted from a N_2O doubling are +85% and +75% respectively. These results, on the other hand, are relatively model independent.

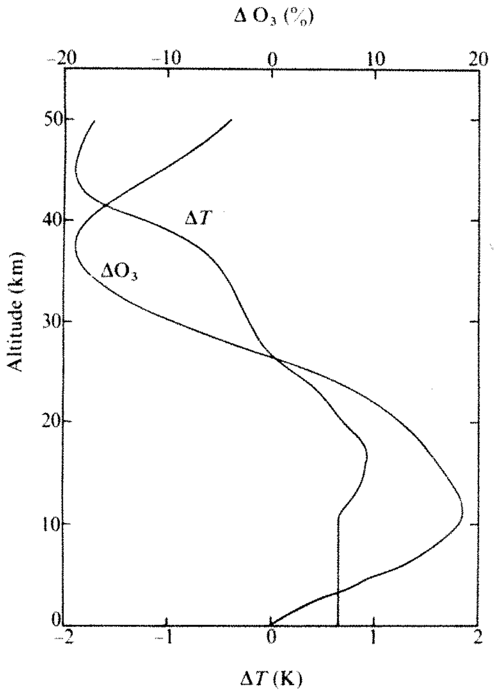

Fig. 2 The calculated changes in thermal structure and O_3 profile due to a doubling of present day N_2O abundance of 320 p.p.b.v. The calculations were based on iterative runs between the one-dimensional radiative-convective model[10] and the one-dimensional photochemical-diffusive model[25]. In the one-dimensional radiative-convective model, we used: (1) 6.5 K km^{-1} as the critical lapse rate[23]; (2) constant relative humidity parameterization[23]; (3) constant cloud altitude parameterization[26]; and (4) fixed surface albedo[27] (that is, no ice-albedo feedback). In the one-dimensional photochemical-diffusive model, transport was treated by using the expedient concept of eddy diffusion with the diffusion coefficients taken from ref. 28. The rate data for the oxygen-hydrogen-nitrogen-chlorine chemistry were taken from ref. 22. The stratospheric H_2O mixing ratio f_{H_2O} was assumed to be constant with altitude and with f_{H_2O} set equal to 4.5 p.p.m.v. (ref. 22). The mixing ratio of ClX at 50 km was 2.2 p.p.b.v., which corresponds to the contributions of various known chlorocarbons to the present stratospheric chlorine level.

The combined climatic effects of the changes in N_2O, O_3, HNO_3 and NO_2 are to decrease the temperature above ~26 km and to increase below. The stratospheric cooling is mainly associated with the local O_3 depletion because the solar radiative heating is reduced. Note that the decrease in solar heating is partially compensated by a warming effect associated with the absorption of upwelling thermal emission from a higher tropospheric temperature of about 0.67 K. The warming effect, however, seems less effective at higher altitude, as reflected by the feature that the calculated maximum cooling occurs at considerable higher altitudes than the region where O_3 depletion peaks. On the other hand, the stratospheric warming with temperature increase up to 1 K can be attributed to the increases in both the local O_3 and the solar radiation reaching the region as a result of O_3 reduction in the upper stratosphere.

Table 1 shows the computed surface temperature change ΔT_s associated with N_2O doubling. In contrast to the partial surface cooling effect caused by the CFMs-induced O_3 perturbation[15,29], the effect of the N_2O-O_3 coupling provides a significant positive feedback and increases the surface temperature from 0.44 K (case A) to 0.62 K(case B). The 30% enhancement in ΔT_s is mainly caused by the calculated increases of O_3 in the lower stratosphere and upper troposphere, a region where the response of T_s to O_3 changes is maximum, as shown in Fig. 1. The associated increase in HNO_3 produces an additional positive feedback effect and increases the surface temperature further, to 0.67 K (case C). The combined climatic effect seems quite significant when compared with the one-dimensional model predicted[27] 2 K global surface warming due to a doubling of the present day atmospheric CO_2 concentration.

Note however, that the foregoing calculations are based on one-dimensional models in which uncertainties are large. The sources of uncertainties may arise from: (1) the inadequacies[31] in the basic formulation of one-dimensional models; (2) the treatment of humidity, clouds and the use of critical lapse rate to approximate the vertical transport of heat by atmospheric motions[22], (3) the complexity of the stratospheric chemical reactions where those involving peroxy(HO_2) are particularly not well understood[20,21], and (4) the lack of present knowledge of the atmospheric N_2O cycle. Thus, the present uncertainties make it difficult to quantify the errors associated with the calculated climatic effect due to N_2O increase. Presumably some of the uncertainties discussed here may be narrowed when more atmospheric data and sophisticated models become available. Nevertheless, it seems clear that should we study the climatic effect due to a change of atmospheric 'greenhouse' material (such as N_2O) which can also influence the atmospheric chemical composition, feedback from compositional changes should be considered.

W.C.W. thanks J. E. Hansen and A. A. Lacis who initiated and participated in the development of the one-dimensional radiative-convective model. We also thank F. M. Luther for the NO_2 absorption data. This work was supported by grant NAS1-15943 from NASA Langley Research Center and by the Chemical Manufacturers Association.

Plio-Pleistocene reversal of displacement on the North Anatolian fault zone

P. L. Hancock & A. A. Barka

Department of Geology, University of Bristol, Queen's Building,
University Walk, Bristol BS8 1TR, UK

Fault plane solutions[1] and the offset of geomorphic and man-made features[2–4] show that present-day displacements on the North Anatolian fault zone are right-lateral (Fig. 1). The present analysis of some of the mesoscopic faults and joints cutting Upper Neogene–Lower Pleistocene continental sediments in intermontane basins between Cerkes and Erbaa indicates that there was left-lateral motion on the fault zone during part of its neotectonic evolution. The structures include conjugate reverse faults striking north-west, conjugate normal faults and joints striking north-east, and conjugate vertical joints enclosing an acute angle about a north-east trending bisector (Figs 2 and 3).

The ~1,200 km arc of the North Anatolian fault zone is generally interpreted as an early Neogene intracontinental transform boundary separating the Black Sea and Anatolian plates[2,5] (Fig. 1*a*). As part of a study of neotectonic structures associated with the fault zone, we have surveyed fractures of mesoscopic scale cutting Neogene–Quaternary continental sediments in five intermontane basins between Cerkes and Erbaa (Fig. 1*b*). The basins are situated astride or adjacent to fault breaks which developed during six westwards migrating, large magnitude earthquakes. The aim of investigating the mesofractures was to infer directions of compression and extension related to shear along the fault zone. Other studies of mesofractures have demonstrated their value in the kinematic analysis of major fault zones[6,7].

Although Neogene–Quaternary successions are different in each basin, those older than the late Pleistocene are regarded as belonging to the Pontus Formation[8] or its lateral equivalents. The ~500 m Lower Pontus Formation (Upper Miocene–Lower Pliocene) comprises lacustrine gravels, sands and clays passing laterally and upwards into fluviatile sediments. The 300 m Upper Pontus Formation (Upper Pliocene–Lower Pleistocene) also consists of fluvio-lacustrine sediments but passes laterally into colluvium in the Cerkes region. Unlike the mainly marine Neogene successions bordering the Aegean, the minor divisions of the Pontus Formation have not been dated precisely; the continental sediments have yielded few fossils of biostratigraphical value.

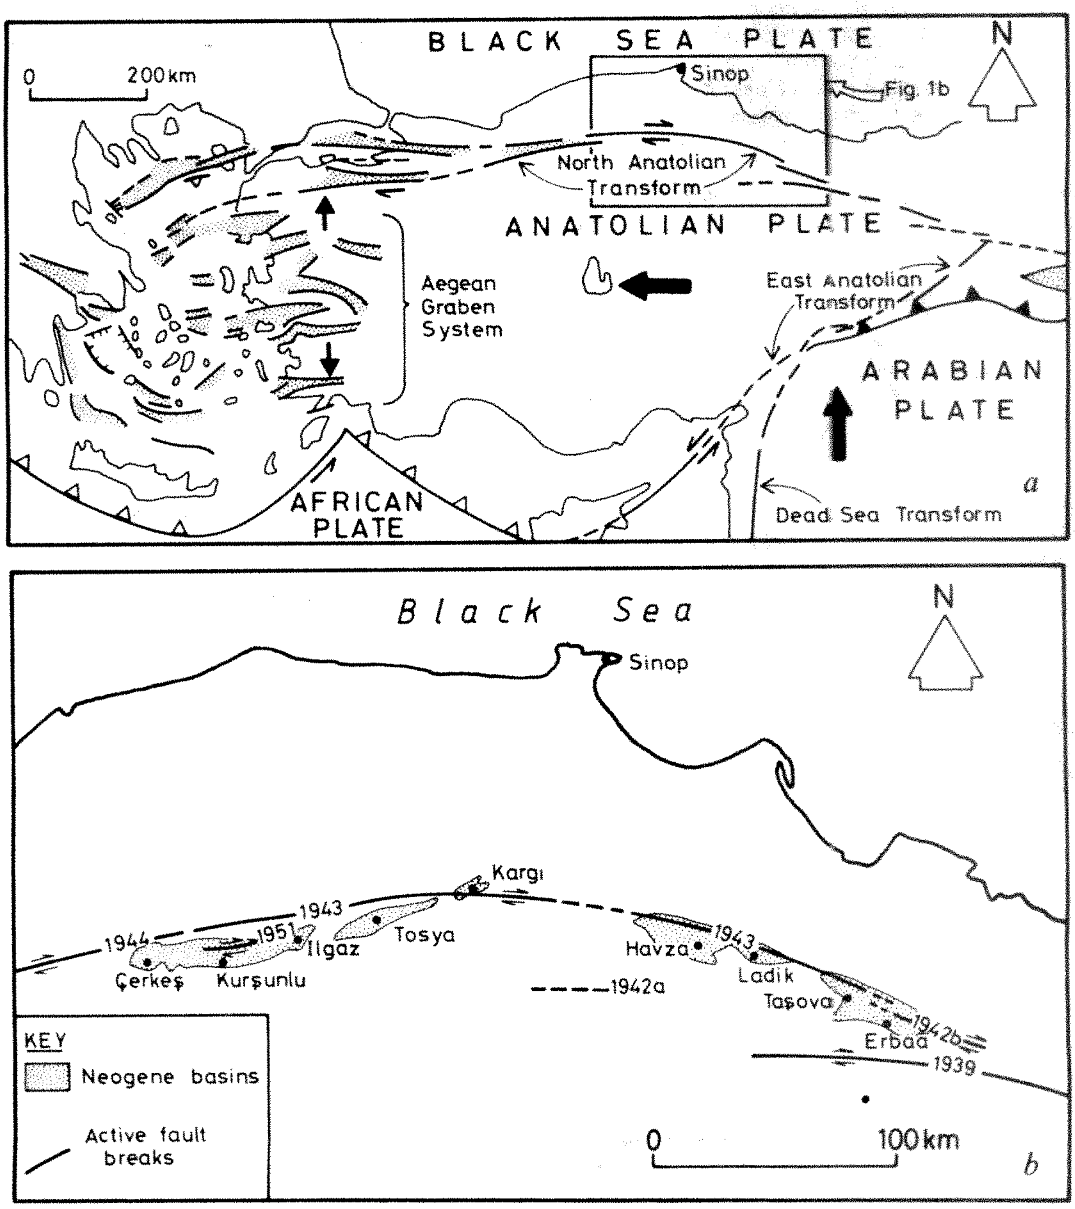

Fig. 1 *a*, Plate setting of the studied segment of the North Anatolian transform fault zone (after ref. 2). *b*, Locations of the sampled Neogene basins. The traces of active fault breaks generated during six large magnitude earthquakes are also shown.

Tasova–Erbaa				Conjugate faults	325–145			Conjugate shear joints	344–164	120
Number of analysed fractures		20		65		65		380		

σ_1 (maximum principal stress direction) and σ_3 (minimum principal stress direction) are given as horizontal projections of those directions.

Where growth faults and/or contemporaneous (intrasequence) erosion surfaces truncate fault planes, it is possible to distinguish between synsedimentary and post-sedimentary faults. However, because the movements responsible for generating the fractures were approximately identical during basin filling and later tectonism, the distinction between the two categories of faults is of less kinematic significance than in rocks where the time interval between deposition and subsequent tectonism is longer. Synsedimentary and post-sedimentary faults occur throughout the Pontus Formation and it is not possible to recognize horizons corresponding to particular tectonic events. Both faults and joints are less frequent in the Upper Pontus Formation.

The structures sampled during the full survey of mesoscopic-scale fractures are either joints (85%) or faults (15%). The latter are rarely greater than 20 m^2 in area and show displacements generally not exceeding 2 m. The orientations of 1941 mesofractures at 142 localities were measured. Twenty-seven per cent of these fractures are interpreted as being related to left-lateral shear. Figure 2 shows the morphology of some of them, of which 14% are faults and 86% are joints. At each sample locality, the sediments are horizontal or uniformly dipping and orientation data were collected from small, structurally homogeneous domains of 15 m^2 area. Because the majority of analysed faults cut horizontal sediments and show vertical offsets, and because the intersects between conjugate faults are

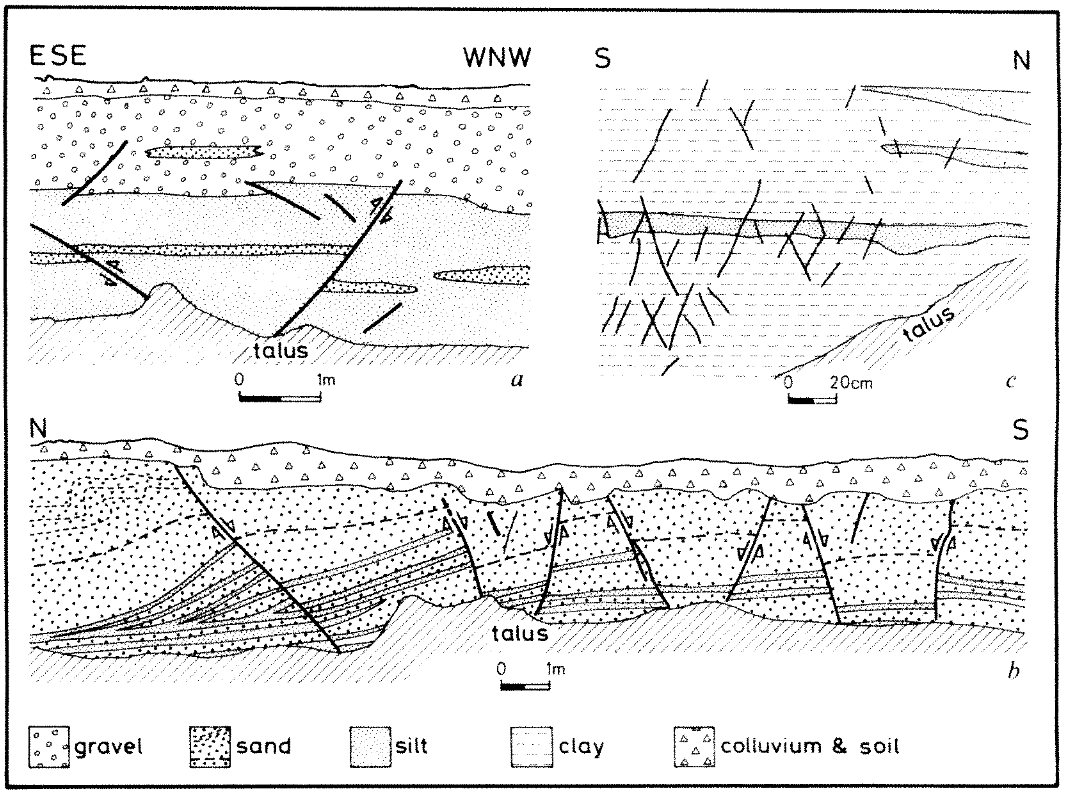

Fig. 2 Sketches from photographs of the analysed structures. *a*, Conjugate reverse mesofaults displacing gravels, sands and silts in the Lower Pontus Formation about 5 km west of Kursunlu. *b*, Conjugate normal mesofaults displacing cross-bedded sands and silts in the Lower Pontus Formation at Kursunlu. Synsedimentary folds are exposed at the north end of the section. *c*, Conjugate normal shear joints cutting silts interbedded with clays in the Lower Pontus Formation about 3 km south-east of Tosya.

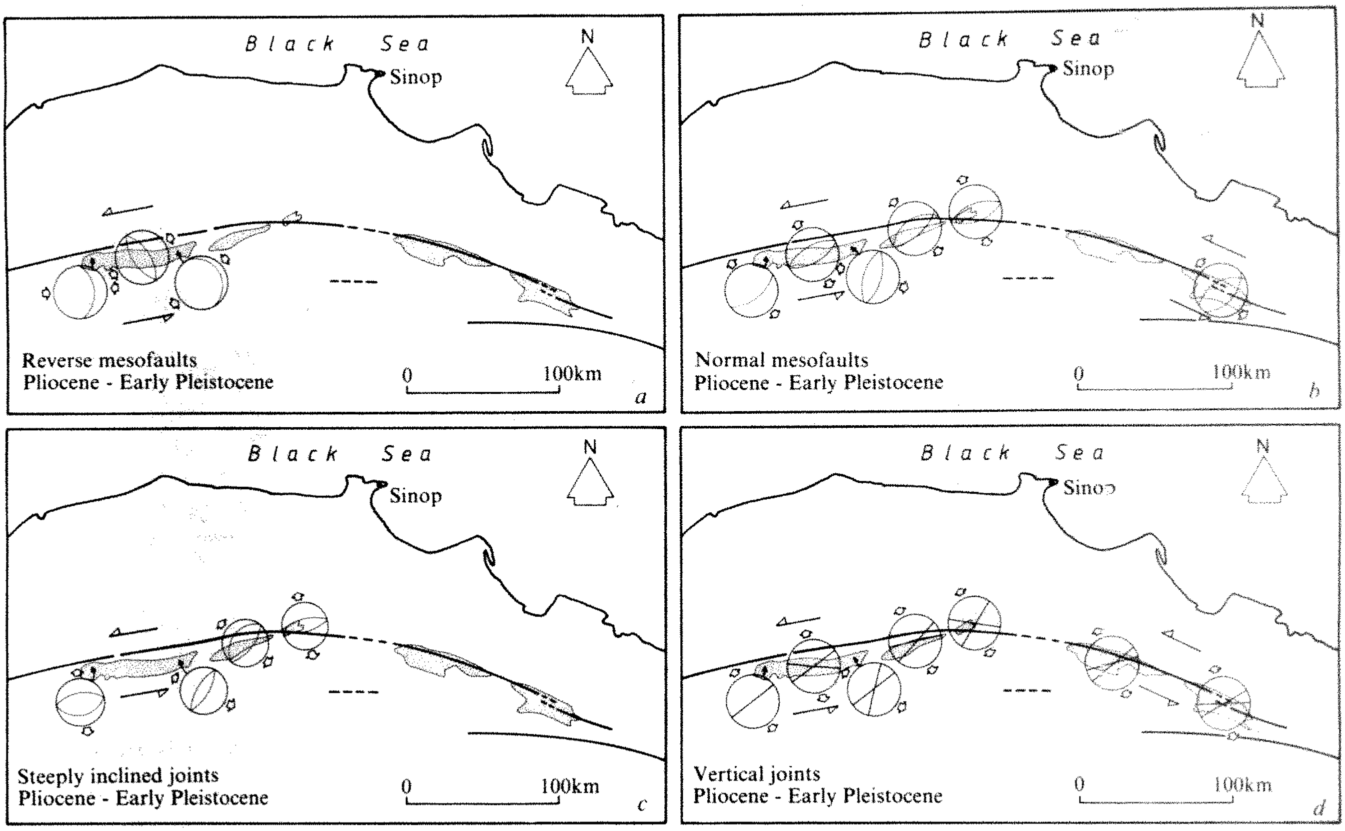

Fig. 3 Mean cyclographic traces of mesofracture sets of Pliocene–early Pleistocene age and from which a left-lateral sense of displacement on the North Anatolian fault zone may be inferred. Stereograms are lower-hemisphere Lambert plots of sets in either horizontal sediments or tilted sediments imagined to be restored to the horizontal. Pairs of arrows immediately outside each plot show horizontal directions of compression or extension inferred from the fractures, and believed to be related to the influence of left-lateral shear along the fault zone. See Fig. 1*b* for names of basins and dates of earthquake fault breaks. *a*, Reverse mesofaults. *b*, Normal mesofaults. *c*, Steeply inclined joints. *d*, Vertical joints.

horizontal or gently plunging, we conclude that displacements were dominantly dip-slip, either reverse or normal.

The fractures were analysed by determining the mean orientations of sets, field relationships being used to decide whether they are conjugate. Although conjugate faults are not present at all localities, it was possible to allocate single fault sets to an appropriate system by comparing their geometry with that of parallel joints belonging to conjugate sets. Approximate orientations of principal stress directions (Table 1) were determined from geometrical analysis of conjugate sets or single extension fracture sets. It was not possible to use the more precise technique of analysing striations on failure surfaces to determine either the orientations of principal strain axes[9] or stress axes[10] because only 11% of the faults are striated, and because many of the analysed structures are joints, which by definition cannot be lineated. It was unrealistic to determine the orientations of strain axes because, to get any regional meaning from them, an areal knowledge of the total slip on each set is required; unless the total slip on both conjugate sets is equal, the preferential development of one set rotates the X and Z axes. There was no evidence for more than one episode of displacement on any fault which is probably due to the mesoscale nature of the fractures. The determination of stress directions from conjugate shears is valid theoretically only when the fractures cut mechanically isotropic rocks. However, as field studies[6,11] demonstrate, many rock masses contain numerous sets of symmetrically arranged mesofractures, and hence as Couples[12] states "... the ordered orientations of fractures indicate that the formation of one crack, and even the formation of many fractures, does not appreciably alter the orientation of the causative stresses, otherwise, the ordering would not be obtained".

The ~27% of mesofractures from which it is possible to infer that there was some left-lateral shear on the North Anatolian fault zone belong to four categories: reverse mesofaults; normal mesofaults; steeply inclined joints; and vertical joints (Fig. 3). Whereas fractures related to right-lateral shear are abundant in both the Pontus Formation and the overlying Upper Pleistocene–Holocene sediments, those related to left-lateral shear are restricted to the Pontus Formation. The number of localities at which mesofractures related to different shear regimes intersect each other is limited. Most of those interpreted as being related to left-lateral shear are cut by those related to right-lateral shear.

North-west trending reverse mesofaults are the least abundant fractures (Fig. 3*a*), being observed only in the Cerkes–Kursunlu–Ilgaz basin where they are relatively common in the Lower Pontus Formation in the region of Kursunlu (Fig. 2*a*). Normal mesofaults (Figs 2*b* and 3*b*) strike between NNE and ENE. They are equally abundant in both the Upper and Lower Pontus Formations, but as Fig. 3*b* shows, they are restricted to the western basins with the exception of Tasova–Erbaa. Figure 3*c* shows the distribution of joint sets at mean inclinations between 50 and 74°. These fractures, which are commonly parallel or subparallel to nearby normal mesofaults, are interpreted as conjugate normal shear joints (Fig. 2*c*). Their distribution is restricted to the three western basins in which they are more abundant in the Lower Pontus Formation. Vertical joints are common in both divisions of the Pontus Formation in the three western basins, but are restricted to the Lower Pontus Formation in the two eastern basins. Except for the western subarea of the Cerkes–Kursunlu–Ilgaz basin, where the system is represented by a single set of extension fractures, the vertical joints form conjugate sets (Fig. 3*d*). They enclose a mean dihedral angle which is 41°, suggesting that they are mainly surfaces in the shear–extension fracture transition.

Although mesofractures in Neogene basins external to the fault zone were not sampled in detail, a reconnaissance survey suggests that they are significantly less abundant than within the basins associated with the fault zone. Thus, we believe that the neotectonic mesofractures described above are restricted to the fault zone and are not part of a regional system.

The restriction of mesofractures related to left-lateral shear to sediments of the Pontus Formation, together with the observation that both synsedimentary and post-sedimentary structures are represented, suggests that the movements responsible for their generation occurred, possibly intermittently, during the late Miocene–early Pleistocene interval but did not continue after that. The greater abundance of the fractures in the west (79% of analysed surfaces) may indicate that left-lateral shear was more along the western part of the fault zone.

The difficulty of dating divisions of the Pontus Formation prevents the recognition of individual phases of compression or extension. The attitudes and displacement senses on the mesofractures are consistent with their development as secondary structures within a zone along which there was left-lateral displacement, a sense of shear which is the reverse of that along the North Anatolian fault zone at present.

A comprehensive explanation for the inference that there was some left-lateral shear on the fault zone is beyond the scope of this letter. Left-lateral shear may have been a consequence of either or both: a reversal of motion, possibly related to reversals detected in the Aegean region[13]; or the effect of local mechanical constraints caused by, for example, anti-Riedel[14] overlaps of faults.

Fieldwork was funded by M.T.A. of Ankara and A.A.B. acknowledges that institute for a post-graduate award. We thank Nicholas Ambraseys for his comments about the North Anatolian fault zone and his advice. Jean Bees drafted the figures.

Sr isotopic geochemistry of voluminous rhyolitic ignimbrites and related rocks, Batopilas area, western Mexico

Marvin A. Lanphere*, K. L. Cameron† & Maryellen Cameron†

* US Geological Survey, Menlo Park, California 94025
† Board of Earth Sciences, University of California, Santa Cruz, California 95064

The middle Tertiary ignimbrites of the Sierra Madre Occidental of western Mexico form the largest continuous rhyolitic province in the world. Minor amounts of intermediate lavas occur interlayered with the ignimbrites, and Sr isotope data on the complete range in rock compositions must be considered when evaluating hypotheses for the origin of the rhyolites. Initial ^{87}Sr/^{86}Sr ratios of andesites, dacites and rhyolites from the Batopilas region of western Chihuahua lie in the range 0.7042–0.7050, showing no systematic variation with rock composition. The data reported here support a crystal fractionation hypothesis for the origin for the voluminous rhyolitic ignimbrites.

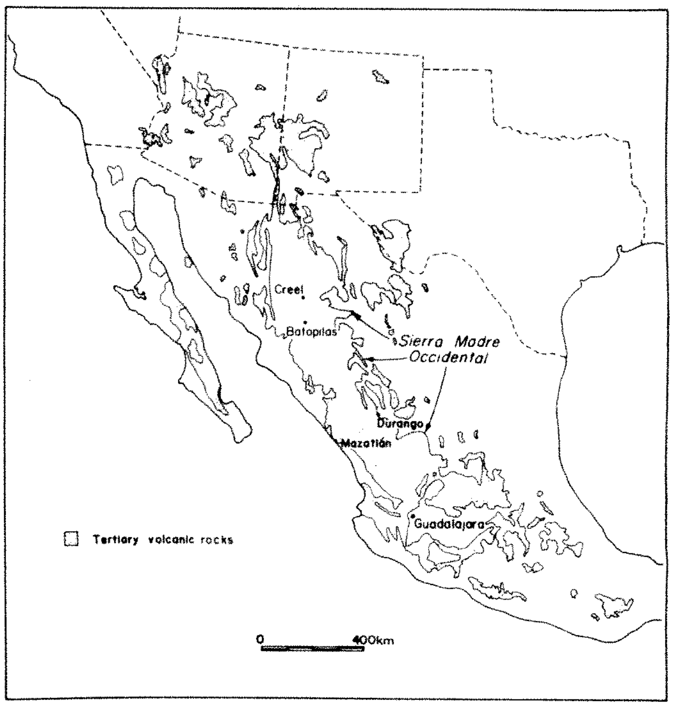

Fig. 1 Distribution of Tertiary volcanic rocks in Mexico and the adjacent US.

A high volcanic plateau, the Sierra Madre Occidental, parallels the west coast of Mexico for 1,200 km (Fig. 1). The plateau is capped by a thick section of middle Tertiary extrusive rocks, predominantly rhyolitic ignimbrites (ash-flow tuffs), referred to informally here as the Upper Volcanic sequence. These ignimbrites, most of which were erupted between 34 and 27 Myr ago, cover at least 200,000 km^2 in western Mexico and have an average thickness[1–3] approaching 1,000 m. An eastward-dipping subduction zone was active off the west coast of Mexico when these rocks were erupted[4]. The volcanic deposits occur as a belt parallel to the western continental margin (Fig. 1), suggesting that they represent a middle Tertiary magmatic arc associated with that subduction[5]. The Sierra Madre Occidental contains a larger volume of rhyolitic rocks than do better known ignimbrite provinces such as the Central Andes (>70,000 km^3, ref. 6), North Island, New Zealand (>15,000 km^3, ref. 7) and Central America (>10,000 km^3, ref. 8). The total original volume of rhyolitic ignimbrites in the western US may have exceeded that of Mexico, but much of that has now been removed by erosion or covered by more recent deposits.

Most of the samples described here are from the Batopilas region of western Chihuahua (Fig. 1). Data on a few samples of rhyolite from the Creel area (Fig. 1), about 100 km north of Batopilas, are also reported. The Upper Volcanic sequence near Batopilas was erupted ~30 Myr ago[3]. More than 80% of the sequence is composed of rhyolitic ignimbrites, but rhyolitic, dacitic and andesitic lava flows occur interlayered with the ignimbrites. The andesite-to-rhyolite series is calc-alkalic and contains ~1% K_2O at $SiO_2 = 60\%$ (refs 3, 5); the ignimbrites typically contain 71–75% SiO_2 and 0.5–1.5% normative corundum. The present study compared the Sr isotopic compositions of the voluminous rhyolites with those of the associated intermediate lavas. The only previously published Sr isotopic data on rocks of the Upper Volcanic sequence were on eight samples of rhyolite collected along a transect between Durango and Mazatlan (Fig. 1), some 400 km south of the Batopilas area, and three samples from near Cuauhtemoc, ~175 km north-east of Batopilas[9]. The initial ^{87}Sr/^{86}Sr ratios of these samples range from 0.7033 to 0.7062.

Rb and Sr concentrations were determined by X-ray fluorescence. The uncertainties in concentration measurements are estimated to be ~3% based on replicate analyses of USGS rock standards. Sr isotopic composition was measured on samples dissolved in HF and $HClO_4$; Sr was separated using ion-

‖ 40 km south of Creel.

exchange chromatography. Mass spectrometry was done with an automated 30.48-cm-radius 90°-sector single-collector instrument using a triple-filament source and digital data acquisition. A typical Sr-composition determination consists of 24–36 measurements of each mass. The uncertainties in isotopic composition (Table 1) are standard deviations of analytical precision.

The initial $^{87}Sr/^{86}Sr$ ratios for 13 samples of andesitic to rhyolitic rocks of the Upper Volcanic sequence from the Batopilas area range from 0.7042 to 0.7050 (Table 1). There is no systematic variation in initial ratios with SiO_2 content (Fig. 2), Sr content or Rb/Sr ratio. The Pearson correlation coefficient, r, between the initial $^{87}Sr/^{86}Sr$ ratio and SiO_2 content, Rb content, and Rb/Sr ratio are −0.20, 0.05, and −0.15, respectively. The correlation coefficient between initial $^{87}Sr/^{86}Sr$ ratio and Sr content is 0.40 (Fig. 3). However, the null hypothesis that these two variables are linearly related is rejected at the 5% level of significance. That is, there is no significant correlation between the $^{87}Sr/^{86}Sr$ ratio and the Sr content of the analysed samples. Upper Volcanic rhyolites from Creel are more radiogenic than those from Batopilas, with initial ratios ranging from 0.7055 to 0.7074 (Table 1). Initial ratios reported by McDowell *et al.*[9] for eight samples of rhyolite from the Durango-Mazatlan area range from 0.7033 to 0.7062.

Rocks of the Upper Volcanic sequence from the Sierra Madre Occidental have somewhat higher $^{87}Sr/^{86}Sr$ ratios than Quaternary andesites of the Trans-Mexico volcanic belt (0.7036–0.7043, ref. 10). The ignimbrites from Mexico are similar in Sr isotopic characteristics to Cenozoic ignimbrites from Nevada[11] and Central America[12] but are less radiogenic than ignimbrites from Chile[13]. The middle Tertiary andesite-to-rhyolite series of the San Juan Mountains volcanic field of Colorado, shows an increase in initial $^{87}Sr/^{86}Sr$ ratio from about 0.7054 to 0.7070 with increasing SiO_2 content[14]. This increase was interpreted[14] to reflect interaction of the silicic magmas with Precambrian upper crust enriched in radiogenic Sr. In contrast to the San Juan ignimbrites, there is no evidence in the Sr isotopic data that the Batopilas rhyolites interacted with radiogenic crust. The nature of the crust beneath the region is uncertain, but Anderson and Silver[15] reported that the southern limit of the Precambrian craton probably lies about 200 km to the north. McKee *et al.*[16] reached a similar conclusion for the origin of early Miocene (21–27 Myr old) rhyolitic ash-flow tuffs in the northwestern part of the Great Basin, US. Initial $^{87}Sr/^{86}Sr$ ratios ranging from 0.7042 to 0.7062 were interpreted to reflect only small amounts of contamination of mantle-derived magmas by crustal material.

The Sr isotopic data reported here support the fractional crystallization model proposed recently by Cameron *et al.*[17] for the origin of the Batopilas rhyolites. The rare-earth element patterns of the ignimbrites can be modelled closely using associated andesites and dacites as parents (K.L.C. and G. N. Hanson, unpublished data). The fractionating assemblage was dominated by plagioclase (>60%) and contained ~10% magnetite with the remaining phases being pyroxene and/or hornblende. The ultimate parent was probably a basaltic magma of mantle origin. Th–Sr variations within the andesite to rhyolite series are inconsistent with a hypothesis that the series were derived by different degrees of melting of similar crustal sources (M.C., K.L.C. and W. C. Bagby, unpublished data). The rhyolites of the Sierra Madre Occidental are heterogeneous isotopically as shown by a comparison of the Batopilas and Creel data (Table 1) and the analyses reported by McDowell *et al.*[9]. Some of the silicic magmas may have interacted with radiogenic

crust. Nevertheless, the Sr isotope data from the Batopilas region establish that no such interaction was required to produce the voluminous rhyolitic ignimbrites of the Sierra Madre Occidental.

Fieldwork was supported by NSF Grant EAR 77-09006. We also acknowledge partial support from the Donors of the Petroleum Research Fund, administered by the American Chemical Society. We thank W. C. Bagby for several of the samples, and A. L. Berry for making the Sr isotopic measurements at the laboratories of the US Geological Survey in Menlo Park.

Ancient Archaean supracrustal rocks from the Limpopo Mobile Belt

Peter C. Horrocks

Department of Geology, University of the Witwatersrand,
Jan Smuts Avenue, Johannesburg 2001, South Africa

A preliminary study has been made to establish pressure, temperature and water activity parameters for the high-grade metamorphism of the early Archaean supracrustal rocks exposed in the Limpopo Mobile Belt near Messina, South Africa. The results reported here indicate that a significant orogenic crustal thickness up to ~30 km was developed before ~3,100 Myr ago in the region.

The high-grade and poly-deformed supracrustal gneisses studied occur south-east of Messina in the Central Zone[1] of the Limpopo Mobile Belt (Fig. 1). They are thought to have been deposited at least partly on a sialic basement made up of the ~3,800 Myr old Sand River Gneisses[2], which are cut by 3,570 Myr old tholeiitic dykes[2] that have not been recognized in the supracrustal gneisses. The supracrustal gneisses were intruded by the anorthositic, gabbroic and peridotitic gneisses of the Messina layered intrusion[3] probably ~3,270 Myr ago (J. M. Barton Jr, work in preparation). Subsequently, an important event of igneous and metamorphic activity affected all of these rocks ~3,150 Myr ago[4], and a second suite of ~3,060 Myr old tholeiitic dykes were intruded[2].

The supracrustal gneisses are predominantly quartzo-feldspathic, but contain numerous interlayers and lenses of pyroxenitic amphibolite, quartzite, magnetite quartzite, garnet–cordierite gneiss, calc-silicate gneiss and marble. The mafic lithologies commonly preserve othopyroxene + clinopyroxene + amphibole + plagioclase + quartz + magnetite ± garnet assemblages, and frequently show prograde metamorphic textures in which orthopyroxene has replaced and overgrown amphibole, while some localities show coexisting clinopyroxene and garnet. Kelyphitic coronas predominatly made up of plagioclase are developed around the garnet in lithologies with abundant amphibole, and in some samples, the garnet is almost completely replaced, or remains only as a few scattered optically continuous remnants in the centres of these reaction coronas. Thus, these kelyphitic textures are thought to be the result of retrograde processes (ref. 5, and P.C.H., in preparation), and not due to a second prograde metamorphism as has been described for previously metamorphosed rocks with a resulting low water partial pressure[6]. The metapelitic lithologies contain garnet + cordierite + biotite + sillimanite (±kyanite) + plagioclase + quartz ± K-feldspar ± amphibole ± orthopyroxene. The garnet is commonly distinctly zoned with more inclusion-filled cores, which are more pyrope-rich, overgrown by thin more almandine-rich and inclusion-poor rims (work in preparation). Some localities preserve kyanite overgrown by sillimanite[7–9].

SMZ = Southern Marginal Zone

Fig. 1 A simplified geological map of part of southern Africa showing the location of Messina and the Limpopo Mobile Belt.

Peraluminous and magnesia-rich rocks within these metapelitic gneisses consist of corundum + spinel + sapphirine + cordierite + garnet + phlogopite ± orthopyroxene ± gedrite, and these undersaturated assemblages apparently represent metamorphic residua after the extraction of minimum melt granitic anatectic liquids[10,11]. Symplectitic coronas about garnet are developed in places where the garnet is replaced by an intergrowth of radial orthopyroxene grains in plagioclase (Fig. 2). This garnet is relatively unzoned, and it is not obvious whether this reaction is prograde or retrograde. However, some samples preserve only spherical 'knots' comprising myrmekitic orthopyroxene grains in plagioclase suggesting the complete breakdown and

replacement of garnet probably by a retrograde process similar to that which is thought to have produced the kelyphitic coronas.

Electron microprobe analyses of the above mineral assemblages mean that several thermodynamic techniques can be used to estimate some of the pressure, temperature and water activity parameters of the high-grade metamorphism these rocks have experienced. The analytical technique used natural and synthetic standards, and was routinely able to repeat known international standards typically to within 2% for all relevant elements. Temperature estimates have been calculated using the following equilibria:

$$\underset{\text{opx}}{Mg_2Si_2O_6} = \underset{\text{cpx}}{Mg_2Si_2O_6} \tag{1}$$

$$\underset{\text{cpx}}{CaMgSi_2O_6} + \underset{\text{opx}}{Mg_2Si_2O_6} = \underset{\text{opx}}{CaMgSi_2O_6} + \underset{\text{cpx}}{Mg_2Si_2O_6} \tag{2}$$

$$\underset{\text{garnet}}{Mg_3Al_2Si_3O_{12}} + \underset{\text{opx}}{3CaMgSi_2O_6} = \underset{\text{garnet}}{Ca_3Al_2Si_3O_{12}} + \underset{\text{opx}}{3Mg_2Si_2O_6} \tag{3}$$

$$\underset{\text{garnet}}{Mg_3Al_2Si_3O_{12}} + \underset{\text{cpx}}{3CaFeSi_2O_6} = \underset{\text{garnet}}{Fe_3Al_2Si_3O_{12}} + \underset{\text{cpx}}{3CaMgSi_2O_6} \tag{4}$$

$$\underset{\text{garnet}}{Fe_3Al_2Si_3O_{12}} + \underset{\text{biotite}}{KMg_3AlSi_3O_{10}(OH)_2} = \underset{\text{garnet}}{Mg_3Al_2Si_3O_{12}} + \underset{\text{biotite}}{KFe_3AlSi_3O_{10}(OH)_2} \tag{5}$$

$$\underset{\text{cordierite}}{3Fe_2Al_4Si_5O_{18}} + \underset{\text{garnet}}{2Mg_3Al_2Si_3O_{12}} = \underset{\text{cordierite}}{3Mg_2Al_4Si_5O_{18}} + \underset{\text{garnet}}{2Fe_3Al_2Si_3O_{12}} \tag{6}$$

The geothermometers derived from these equilibria[12–19] are based on experimental data and calculated values are typically within 50 °C of the experimental condition. Thus the maximum practical resolution of these techniques is probably about ±50°C and about ±100 °C at worst. Fe^{3+} was estimated in pyroxene and garnet by a stoichiometric method[20] and was found to cause generally a lowering of the temperature estimates by not more than 50 °C in most cases, and usually much less than 50 °C. Pressure estimates were made from equilibria (3) and (6), and these geobarometers[12,16,21], also based on experimental data, have given more inconsistent results[22], mainly due to the problems surrounding Al solution in pyroxene. At worst, these barometers reproduce the experimental values to within 5 kbar (ref. 12) and to within 1.5 kbar (ref. 16) for the garnet–cordierite equilibrium. Typically, the best resolution for practical purposes is probably limited to ±3 kbar (ref. 21). The water activity was calculated using equilibrium (7) (S. Richardson, personal communication) in the mafic lithologies:

$$\underset{\text{tremolite}}{Ca_2Mg_5Si_8O_{22}(OH)_2} = \underset{\text{diopside}}{2CaMgSi_2O_6} + \underset{\text{enstatite}}{3MgSiO_3} + SiO_2 + H_2O \tag{7}$$

together with certain thermodynamic approximations[23] based on hydrothermal equilibrium data. The results from these calculations are summarized in Table 1 and Fig. 3.

The P–T field thus suggested for the supracrustal rocks in the region (Fig. 3) supports the petrographical evidence of this study and that of other studies in the region[7–9], particularly with regard to the association of enstatite + kyanite + quartz[7], sillimanite overgrowths on kyanite[7–9], prograde othopyroxene replacement of amphibole (that is, granulite facies metamorphism), retrograde kelyphitic coronas about garnet in the mafic rocks, and the garnet zonation in the pelitic rocks. The early phase of this metamorphism which produced the orthopyroxene-bearing assemblages in the mafic rocks, and the pyrope-rich garnet and corundum in the pelitic rocks (work in preparation), was characterized by temperatures in excess of 800 °C and probably pressures up to 10 kbar (Fig. 3). Water activities in the mafic rocks were low, with H_2O making up ≤10% of the fluid present during the high-grade phase of the metamorphism. CO_2 was probably the most abundant fluid present during this time, based on a comparison with a study of liquid inclusions in granulites from southern Norway[24]. A subsequent retrogression to a lower temperature–pressure regime is recorded by the development of the kelyphitic rims about garnet in the mafic lithologies, the almandine-rich garnet overgrowths and the spinel + sapphirine + cordierite association (work in preparation) in the pelitic rocks, and probably also the production of the symplectitic textures about garnet (Fig. 2). Here, pressures of between 5 and 7 kbar were attained at temperatures of ~600–700 °C (Fig. 3).

The early phase of this metamorphism suggests that the supracrustal stratigraphy, deposited sometime between 3,570-Myr ago and the emplacement of the Messina layered intrusion ~3,270 Myr ago, was subjected to rapid burial to depths probably greater than 30 km into regions of the lower crust either by subsidence or tectonic means. An earlier study of an enstatite + kyanite + quartz association from Zimbabwe[7] also suggested pressures in excess of 10 kbar and temperatures close to 950 °C with the enstatite having an Al_2O_3 content of over 5.5%. These data suggest that this metamorphism reflects an average geothermal gradient during the peak of the metamorphic event of less than about 30 °C km^{-1} in the lower regions of the crust. This compares favourably with other suggested Archaean geotherms[25–28]. The metamorphic and igneous activity about 3,150 Myr ago, which reset the Rb–Sr isotopic ratios in the rocks of the Messina layered intrusion[3] probably reflects the peak of this phase of the metamorphism. Subsequent orogenic events occurred during the interval from ~3,100 Myr ago to ~2,400 Myr ago[4] during which minimum melt granitic anatectic liquids were extracted[29] and intense polyphase deformation was imposed on the lithologies[9]. Although temperature and pressure data currently available do not provide sufficient evidence in themselves, these events could probably represent a continous progression of tectonism and metamorphism[8,9] during the

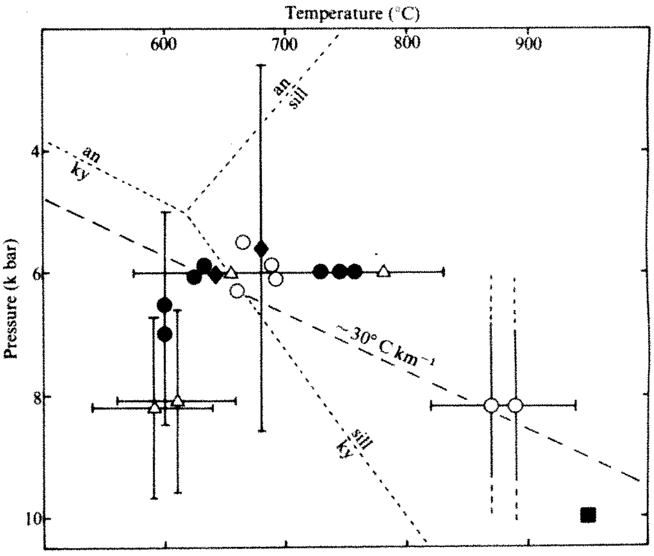

Fig. 3 A pressure–temperature diagram showing the results given in Table 1: ○, mafic rocks; ●, pelitic lithologies; △, sapphirine-bearing samples; ◆, symplectite sample; ■, enstatite + kyanite + quartz[7] association discussed in the text. an, andalusite; ky, kyanite; and sill, sillimanite.

erosional and/or tectonic excavation of the supracrustal rocks and the resulting pressure and temperature changes. The exhumation of these gneisses would cause waning pressures at maintained temperatures, probably adiabatically, and may explain the retrogression as manifest by the kelyphitic textures and garnet zonation. The end of high-grade metamorphism and the onset of comparative tectonic stability are evidenced by a fabric-free dolerite dyke of ~2,200 Myr in age[30]. This ancient basement-supracrustal event of high-grade metamorphism may not predate the development of the greenstone–grandodiorite–tonalite terrains which comprise much of the Earth's shield areas, but perhaps represents a contemporaneous development at lower crustal levels now only exposed in limited zones of the ancient shields. The geometry of these zones (or 'belts') is probably superimposed, and not a result of the intrinsic metamorphic history.

Evidence for pre-Devensian glaciation in the northeastern Lake District

J. Boardman

Department of Humanities, Brighton Polytechnic, Falmer, Brighton, East Sussex BN1 9PH, UK

In the northeastern English Lake District two major till units occur. The upper unweathered unit is clearly the product of late-Devensian glaciation[1]. The lower till has undergone severe humid temperate chemical weathering and contains palaeosol features. It must pre-date the Ipswichian interglacial[2]. Pre-Devensian weathering profiles of an interglacial character have not previously been described in northern England. There has been scant previous evidence for a pre-Devensian glaciation of north-west England[3,4]. No date has been assigned to 'Early Scottish' till which has been located around Carlisle. Till in Low Furness is recorded beneath 'interglacial beds', but this was described in the nineteenth century and cannot be relocated[1,3]. It has generally been accepted that erosion during the Devensian effectively removed pre-existing deposits and it has been assumed that the landforms of the Lake District, including the major erosional features, are the product of the last glaciation[5,6]. I show here that, in the Vale of Threlkeld, this is not the case.

In the valleys of Mosedale and Thornsgill Beck, two south bank tributaries of the Glenderamackin (Fig. 1), 10 km east of Keswick, a sequence of glacigenic, glacifluvial and periglacial deposits overlie thinly-cleaved mudstones of Ordovician Skiddaw Group[7]. The surface tills form drumlins and till hummocks, and glacifluvial sands and gravels locally form kames. All these features are considered to be of late Devensian age[1]. The Mosedale Beck valley was eroded by high meltwater discharges released by the corrie glacier at Wolf Crags which last developed in Younger Dryas time[4]. In places, such as on Threlkeld Common, stone-banked solifluction lobes disturb the till and these are probably of Younger Dryas age.

The recently discovered succession in the area[2] reveals weathered till at the base, overlain by fresh unweathered till or unweathered sands and gravels. Four representative sites are considered in Fig. 2.

At Carel Gully and site D, yellowish-brown weathered till is overlain by a grey till which incorporates, at its base, lenses of the weathered material. At two sites, D and N, a weathering profile exists—the severely weathered till grading down into fresh till. In the weathered till manganese staining is frequent, clasts are soft and friable, and surface textures on quartz grains, examined by scanning electron microscopy, indicate severe chemical weathering and an absence of glacial processes (P. Wilson, personal communication). At site E, the weathered till unit is dissected by a channel which is filled with similarly weathered sands and gravels. This in turn is overlain by coarse unweathered gravels which form a terrace fragment of Younger Dryas age.

At N, the upper part of the site is obscured but it is probable that unweathered Devensian material completes the sequence, as it is exposed at nearby sites. In places, a gleyed horizon is developed in a silty clay band at the base of the severely weathered till. The dominant colour is orange (7.5YR 6/8) but it contains many irregular mottles of low chroma (5Y 7/1). In thin section these are seen to be iron-depleted areas (albans). Channels and chambers reflect biological activity[8], and in some cases, are lined with translocated clay and silty clay. Gleying, translocation of clay, and biological activity are characteristic of the B horizon of certain soils.

The chief characteristics of the weathered till in the area are: (1) high proportion of soft and friable clasts that can be crushed by hand; (2) typical bright yellowish-brown (10YR 6/6) clast colour and yellowish-brown (10YR 5/8) matrix colour which differ from greenish-grey (7.5GY 5/1) and dark grey (N 3/0) respectively of the fresh materials; (3) low silt and clay percentages, 13 and 7% for the weathered till samples, in contrast to values of 23 and 20% for unweathered equivalents; (4) clay mineral suites dominated by illite and vermiculite which are typical of many weathering products of acid igneous rock types (R. Merriman, personal communication).

The weathering profile is interpreted as having formed in a period of protracted weathering on a stable land surface such as is typical of a vegetated temperate interglacial environment.

The sequence of events can be summarized as: (1) deposition of the lower till and glacifluvial sands and gravels; (2) severe chemical weathering under humid temperate conditions; (3) deposition of the upper till incorporating lenses of the pre-existing weathered till unit; (4) deposition of terrace gravels in Mosedale and corrie glaciation at Wolf Crags.

0028–0836/80/320599—02$01.00

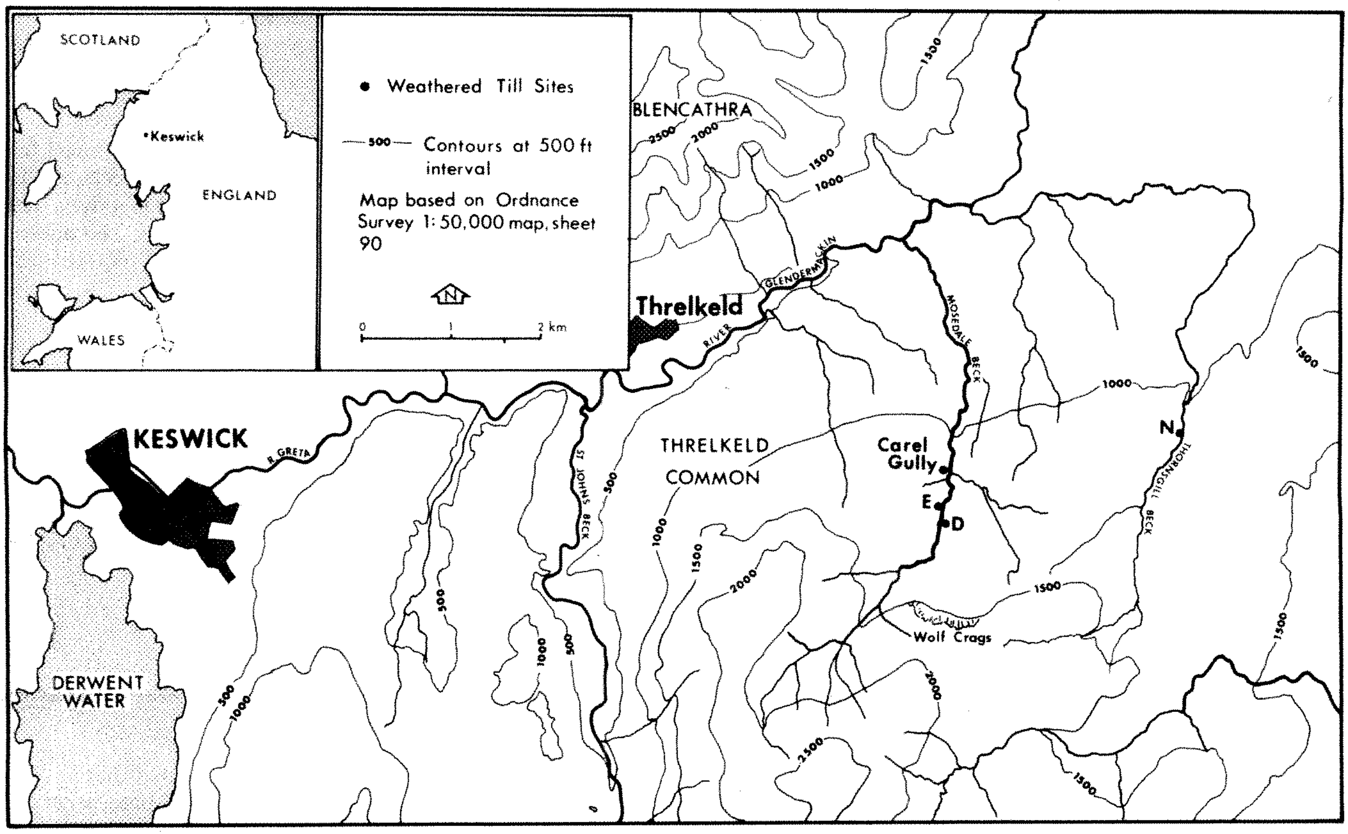

Fig. 1 Location of sites.

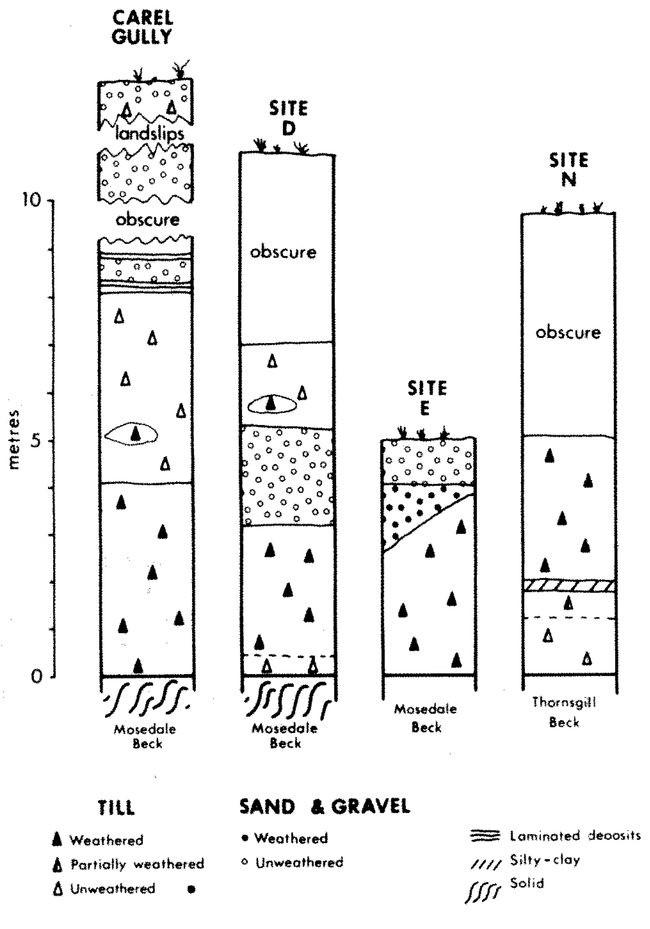

Fig. 2 Stratigraphy of sites.

With reference to the established British Quaternary stratigraphy[9], the upper till and associated glacial landforms is Devensian, the weathering profile is most likely to be Ipswichian, and the weathered till unit is probably Wolstonian. Till of that age has been described from East Yorkshire and Lincolnshire[10], and a possible Wolstonian till containing Lake District erratics occurs in the Peak District[11]. However, in the Lake District, a maximum age cannot be assigned to the till: it may be of greater antiquity.

Preservation of unconsolidated sediments beneath till is rare in highland Britain, and in the northeastern Lake District seems to be the result of irregular bedrock topography. The survival of deposits at several sites suggests that Devensian erosion had a limited impact on the Vale of Threlkeld. Classic glacial features in the area such as the truncated spurs of Blencathra (Fig. 1) are therefore likely to be pre-Devensian in age. By implication, other major glacial troughs in the Lake District may also have been in existence at the onset of the last glaciation.

I thank Dr P. Bullock for advice on pedological aspects and Dr J. Catt for comments, Mr J. Rose, who discovered the weathered till in Mosedale, for discussions and comments. Mr S. Frampton drew the diagrams. The Central Research Fund, University of London, financed the cutting of thin sections.

Gene frequency changes and adaptation in marine cockles

Elizabeth Gosling

Zoology Department, University College, Galway, Ireland

When closely related species overlap geographically, a change of character state may occur in one species which is directly attributable to the presence in the same environment of an ecologically similar species[1,2]. Most reports of this phenomenon—called character displacement—have been concerned with divergence, rather than convergence, in morphologial characters between species in the zone of sympatry. There has been only one report on genetic displacement at the allelic level[3]. In this, Murphy observed a divergence in allele frequency at a leucine aminopeptidase locus in sympatric species of marine limpets which he interpreted as allelic accommodation in response to interspecific competition[3]. I report here a study of two closely related species of cockles, *Cerastoderma edule* and *Cerastoderma glaucum*, in which *C. glaucum* exhibits a convergence in allele frequency at the phosphoglucomutase (Pgm) locus when it is found intermixed with *C. edule*.

In the British Isles, *C. edule* is widely distributed intertidally whereas *C. glaucum* is found in stagnant saline pools isolated from tidal influences[4,5]. However, occasionally the two species are found together intertidally, apparently occupying identical ecological niches[6]. The two species are morphologically very similar and were separated using the characteristics outlined by Boyden[7]—shell shape, ligament length, shape of ribs, digestive gland coloration and internal shell pigmentation.

Pgm is coded at a single locus with three electrophoretic alleles, Pgm^A, Pgm^B and Pgm^C, present in *C. glaucum* and Pgm^C, Pgm^D, Pgm^E and Pgm^F present in *C. edule*. The allele Pgm^C is common to both species (Fig. 1). Because of the different electrophoretic mobilities of Pgm allozymes in *C. glaucum* and *C. edule*, the Pgm system can therefore be used in conjunction with morphological characteristics to separate the two species. In this study, unispecific samples of *C. edule* were collected from the intertidal region of the shore whereas all unispecific samples of *C. glaucum* were taken from stagnant saline pools where the cockles were permanently submerged. Table 1 presents allele frequency data in two unispecific populations of *C. edule* and *C. glaucum*. To date, all unispecific populations of either species from Irish and British sites exhibit little geographical variation in allele frequency at this locus (unpublished results). In addition to the above samples, mixed populations of the two species were collected intertidally from two Irish sites (Keeraunnagark and Shannon Estuary) and two British sites (the Fleet, Dorset, and Hullbridge Ferry, Essex). At these sites, *C. glaucum* experiences quite different environmental conditions from the lagoon habitat, such as exposure to air, exposure to wave action and tidal amplitude. In the case of each mixed population, an attempt was made to collect unispecific populations of *C. glaucum* and *C. edule* from sites situated close to the mixed population. The results of the Pgm allozyme analyses of these samples are shown in Fig.2. In some cases (see Fig. 2 *c*, *d*), it was not possible to collect unispecific samples from sites which were geographically close to a mixed population. However, the result was the same for each *Cerastoderma* assemblage, that is, allele frequency in *C. glaucum* was consistently nearer to that of *C. edule* in mixed populations of the two species by a statistically significant ($P<0.05$) amount. Allele frequency in *C. edule* from unispecific populations, or from populations where it was mixed with *C. glaucum*, showed no significant ($P>0.05$) difference.

Table 1 *Pgm* allele frequencies in allopatric populations of *C. edule* and *C. glaucum* from W. Ireland

		Allele frequency							
	N	*A*	*B*	*C*	*D*	*E*	*F*	χ^2	
C. edule Shannon Estuary	80	—	—	0.09	0.34	0.54	0.03	2.43	NS
C. glaucum Carna, Galway	95	0.0	0.68	0.32	—	—	—	2.81	NS

N, no. of individuals analysed. χ^2, Goodness-of-fit of observed to expected frequencies from Hardy–Weinberg equilibrium. NS, not significant, $P>0.05$.

Cross-fertilization can be ruled out as an explanation for the observed convergence in allele frequency. First, no Pgm enzyme genotypes indicative of hybridization were observed. Second, hybridization between these species is, in any case, unlikely. Although individuals with apparently intermediate morphological characteristics occur in mixed populations and cross-fertilization can take place in the laboratory[7,8], attempts[8] to rear hybrid larvae have met with little success. In general, attempts have been less successful between species originating from mixed populations than between species taken from different geographical locations[8]. In addition, displacement in spawning times occurs in mixed populations[9], thereby ensuring effective reproductive isolation between the two species.

The results of the present study suggest that the genetic displacement, that is, the change in allele frequency which occurs only when *C. glaucum* coexists with *C. edule*, is a genetic consequence of adaptation to the intertidal habitat. Previous reports[3,10-12] have implicated interspecific competition as the cause of character displacement in the zone of sympatry. There is no evidence in the literature to suggest that the two cockle species compete in the zone of contact. If interspecific competition is occurring, one might expect the observed difference in

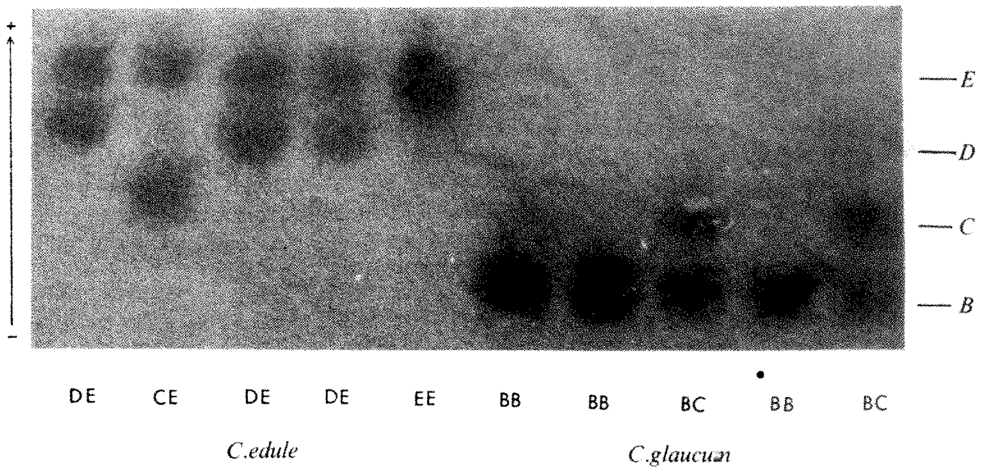

Fig. 1 *Pgm* alleles in *C. edule* and *C. glaucum*. Mixed samples of *C. edule* and *C. glaucum* together with unispecific samples of *C. edule* were collected from the intertidal region of the shore; unispecific samples of *C. glaucum* were collected from non-tidal lagoon sites. A portion of the foot was excised from living individuals and homogenized manually in approximately two volumes of 50 mM Tris-HCl buffer, *p*H 7.8 (1:1w/v). Electrophoresis was carried out at 2 °C in horizontal starch gel (Connaught) using the Tris/EDTA/maleic buffer system, *p*H 7.4, of Spencer *et al.*[13]. Gels were run for 14–16 h at 6.5 V cm^{-1}. Sliced gels were stained for Pgm using the paper overlay method described by Scopes[14].

0028–0836/80/320601—02$01.00

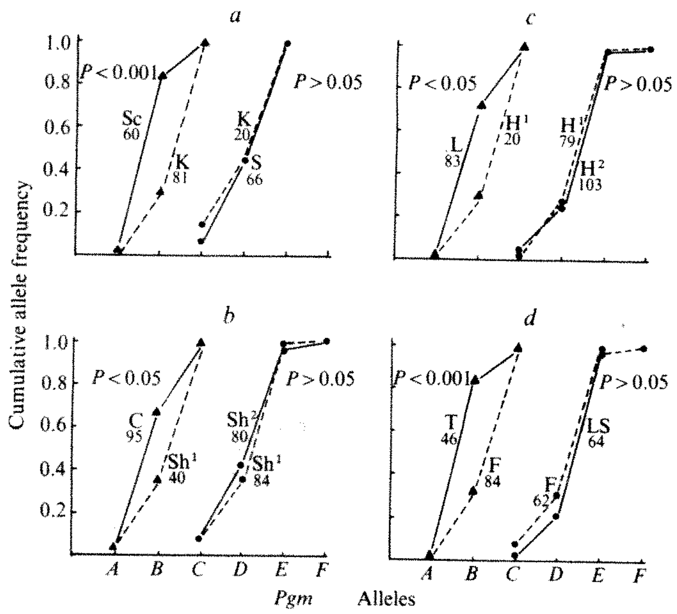

Fig. 2 Cumulative frequency of *Pgm* alleles in allopatric (———) and sympatric (– – – –) populations of *C. glaucum* (▲) and *C. edule* (●). Samples were collected from four habitats that supported mixed populations of *C. glaucum* and *C. edule* and in each case a unispecific populations of *C. glaucum* and *C. edule* was collected from a site situated as close as possible to the mixed population. Results for each *Cerastoderma* assemblage are presented separately in *a*, *b*, *c* and *d*. *P* was derived from a two-tailed Kolmogorov–Smirnov two-sample test of the H_0 that the distribution of alleles in allopatric and sympatric populations of *C. edule* and *C. glaucum* are identical. *a*, S: Silverstrand, Galway; K: Keeraunnagark, Galway; Sc: Screebe, Galway. *b*, C: Carna, Galway; Sh^1, Sh^2: Shannon Estuary, Limerick. *c*, L: Lady's Island, Wexford; H^1, H^2: Hullbridge Ferry, Essex, UK. *d*, T: Tacumshin, Wexford; F: The Fleet, Dorset, England; LS: Leigh-on-Sea, Essex. Numbers beneath each site abbreviation indicate size of sample.

allele frequency to vary depending on the proportions of *C. glaucum* and *C. edule* present in mixed samples. This was not the case, as is evident from Fig. 2*a* and *c*, where the ratio of *C. glaucum* to *C. edule* in the two samples was 4 : 1 and 1 : 4 respectively. In the sample from Fleet, Dorset, individuals of *C. glaucum* were not actually intermixed with *C. edule* but were separated from them by a geographical distance of about 0.5 km. However, *C. glaucum* shows the characteristic shift in allele frequency which indicates that sympatry of the two species is not necessary to produce this effect.

We conclude that, although character divergence or convergence in sympatry can occur in response to interspecific competition there must also be occasions, for example in this study, when it occurs for reasons not directly connected with the presence of another species.

I thank N. P. Wilkins and J. McKay for useful discussions and the following people who helped in the collection of samples: D. McGrath, B. Healy, G. O'Sullivan, A. Beaumont, G. Pickett, B. Dawson and D. Seaward. This work was supported by a grant from the National Board of Science and Technology, Ireland.

Juvenile hormone mimics the photoperiodic apterization of the alate gynopara of aphid, *Aphis fabae*

Jim Hardie

Agricultural Research Council Insect Physiology Group,
Department of Zoology and Applied Entomology,
Imperial College, London SW7 2AZ, UK

Extensive investigations of the environmental factors influencing the alate–apterous dimorphism of the summer, parthenogenetic, virginoparous generations of aphids have shown that crowding has a major influence on the development of the alate morph, although temperature and nutrition are also important[1,2]. These factors may act prenatally, postnatally or both, depending on the species. However, the physiological control of this dimorphism within the individual has not been elucidated. As the apterous adult and the larvae share certain morphological features[3] it has been suggested that the hormone controlling larval–adult metamorphosis, juvenile hormone (JH), also influences development of apteriform characteristics[4,5]. Indirect evidence from measurements of corpus allatum (CA) volumes and CA nuclei were believed to support this theory[6] and early experiments with topically applied JH extracts and analogues seemed to divert alate development towards the apterous condition[2,5]. Attempts to obtain more direct evidence have been negative or inconclusive[6]. Recently, Lees[7] has questioned this hypothesis, citing the following evidence: (1) examination of more extreme forms produced by topical application of JH mimics to middle instar alatae shows them to be developing towards a fifth instar, supernumerary larva (that is juvenilization) rather than towards an apterous morph (that is apterization); (2) in an autumn, short-day-induced alate morph of *Aphis fabae*, namely the gynopara (see below), authentic apterization can be effected by postnatal exposure to long photoperiods, the first larval instar being most sensitive to this treatment. By contrast, it was the late second and the third instars that were most sensitive to juvenilization following topical application of JH analogues. It is shown here that larger doses of a more active hormone (JH1) will closely mimic the photoperiodic apterization of these gynoparae but that apterization is not due to the neotenic action of JH. Evidence is also presented suggesting that the alate-apterous dimorphism in summer, long-day generations is not controlled by JH.

In many host-alternating aphid species a separate alate, viviparous morph is produced in response to short days and gives birth to the sexual females (the oviparae). In *Aphis fabae* these gynoparae (Fig. 1*a*) are morphologically very similar to the alate virginoparae but may differ in the number of secondary rhinaria (placoid sensilla) on the antennae[8]. The major differences between the two alates lie in their behaviour [8] and in the morph of their progeny.

In the experiments described below, *A. fabae* [from a clone originally isolated in 1946 (ref. 9)] were reared on germinating tick beans (*Vicia faba*) at 15 °C. Long day (LD) conditions were 16 h light : 8 h dark and short day (SD) conditions 12 h light : 12 h dark. When progeny of an apterous virginopara from an LD stock culture are reared in isolation in SD conditions they develop as apterous adults and their progeny, that is the second generation in SD, are mainly alate gynoparae but include a few late-born males and apterous virginoparae. If only the progeny born before the appearance of the males are reared at a density of between 1 and 10 per germinating bean in SD conditions then 99.8% (1,140 in 1,142) develop as gynoparae. Initially the germinating beans are 1–1.5 cm tall.

As mentioned earlier, the development of the adult alate gynopara of *A. fabae* also depends on the postnatal environ-

0028–0836/80/320602—03$01.00

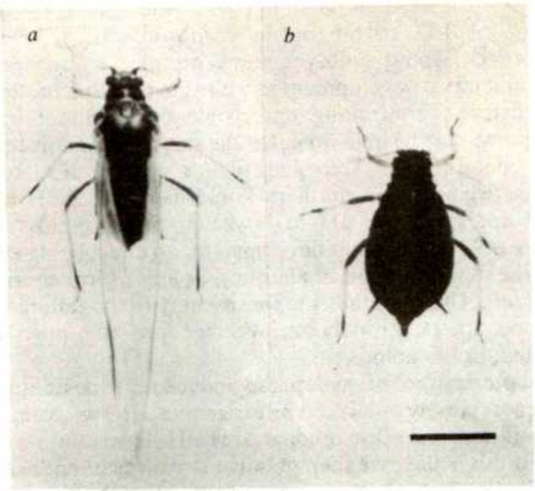

Fig. 1 *a*, The alate gynopara of *Aphis fabae* which produces sexual females (oviparae). *b*, A presumptive gynopara which has been completely apterized by topical application of 0.1 μg JH1 during the first instar. This aphid was reared in short-day conditions; similar apterae are produced when presumptive gynoparae are reared from the first instar in long-day conditions. As far as is known they are morphologically identical to apterous virginoparae. Scale bar, 1 mm.

ment[7]. If presumptive gynoparae complete larval development in LD conditions after transfer from SD during the first or early second instar a number develop into adult apterae or alate/apterous intermediates, that is apterization occurs. In extreme cases this is complete and the adult morph is identical to the apterous virginopara (see Fig. 1*b*). The proportion of adults showing various degrees of apterization is maximal if transfer to LD is effected during the first 24 h of postnatal development and decreases with the age of transfer (Fig. 2).

Lees[7] has previously shown that by examination of fifth instar (normally adult) individuals it is possible to distinguish the more extreme forms of juvenilized alate gynoparae induced by treatment with JH mimics juvenilization and presumptive gynoparae which have been diverted along an apterous developmental pathway by postnatal exposure to LD (apterization). Less extreme apterized and juvenilized alate fifth instar individuals—those designated as 25% morphological effect—are difficult to distinguish. This category is, however, rare in the LD, 'authentic' apterization (12 of 1,017 insects transferred to LD between days 1 and 4 of postnatal development) and so when observed in the following JH experiments it was assumed to be an indication of juvenilization rather than apterization.

It was found that photoperiodic apterization could in fact be mimicked by JH (Figs 1*b*, 2). JH1 (0.1 μg, Calbiochem) in 0.1 μl acetone was applied topically to the abdomen of presumptive gynoparae, postnatal development continuing in SD conditions. The numbers of insects showing apterous characters was less than that obtained by transfer to LD conditions at the same stage of development except on the fourth day after birth. However, the response profile was similar in both apterizing treatments. Presumptive gynopara controls either, untreated or treated with 0.1 μl of acetone, and reared in SD at <10 per bean were almost all alate adults (0.2% of individuals showed apterous characters).

JH-treated insects that were not apterized often showed juvenilization are the second and third instars, an observation for the degree of juvenility the total effect was calculated after Lees[7] (Fig. 3). The developmental stages most sensitive to juvenilizations are the second and their instars, an observation also reported by Lees[7]. Thus the apterizing effects and the juvenilizing effects of JH treatment show different sensitivity profiles, a finding which indicates that separate target sites exist and that apterization is not due to the neotenic action of JH.

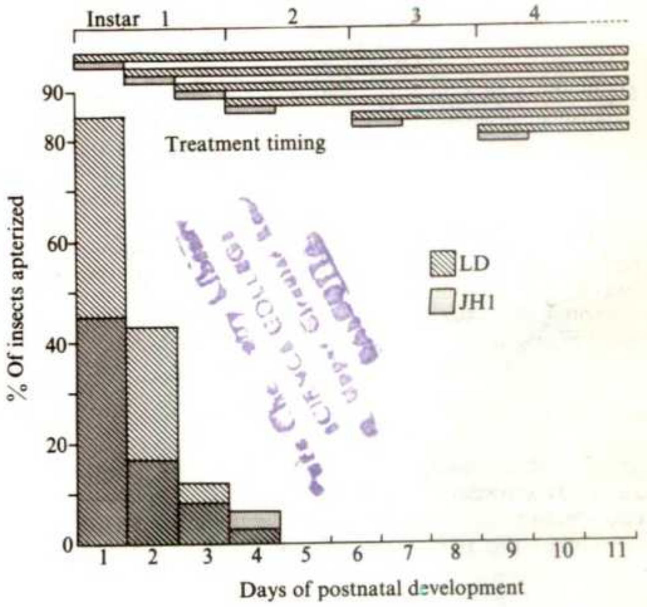

Fig. 2. The percentage of presumptive gynoparae which showed some degree of apterization when either transferred to LD conditions (hatched) or treated with a single application of 0.1 μg JH1 (stippled) at different stages during postnatal development. The JH-treated insects were reared in SD conditions throughout development. All insects were reared with an initial population of 10 per germinating bean but due to the increased mortality in JH-treated individuals there was often less than 10 for much of development. Number of insects tested in the LD treatment were: day 1, 193; day 2, 148; day 3, 143; day 4, 94; first day of the third instar, 61; first day of the fourth instar, 102. Only the survivors of the JH treatment could be scored and survival depended on the age when treated. Survivors per number treated were: day 1, 67/210; day 2, 24/454; day 3, 37/389; day 4, 77/103; first day of the third instar, 65/70; first day of the fourth instar, 102/104. Of controls dosed on day 1 with 0.1 μl acetone and reared in SD 27/30 survived; all survivors were alate gynoparae. Of untreated controls reared in SD 99.8% (971/973) were alate when reared at a density of between 2 and 10 individuals per germinating bean while 100% (142/142) were alate when reared at one per bean. These alatae are induced by the pre- and postnatal SD treatment, not by crowding.

Table 1 The apterizing effects of 0.1 μg JH1 on presumptive gynoparae less than 24 h after birth, compared with the alatizing effect of crowding. Development continued in SD conditions

Crowding intensity	Control survival	Experimental survival	% Insects showing apterization Controls	JH-treated
a Relatively uncrowded (10 aphids per germinating bean)	(404/410) = 98.5%	(67/210) = 31.9%*	0.5%	44.8%
b Crowded (200 aphids per bean stipule)	(166/250) = 66.4%	(13/250) = 5.2%	0%	0%

The crowding intensity was increased in *b* compared with *a* not only by increasing the number of aphids in the colony but also by using a bean stipule (growing tip removed). These plants showed retarded growth during the experiments when compared with the germinating beans. The increase in density of crowding leads to a decreased survival in both control and experimental animals. Control animals are untreated.

* These values are the same as those of day 1, JH-treated insects in Fig. 2.

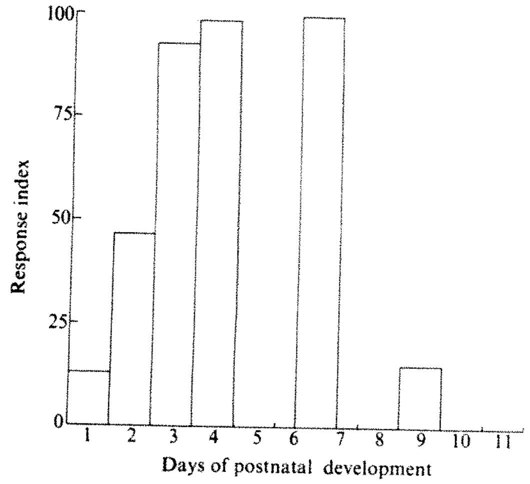

Fig. 3 The total degree of juvenilization exhibited by aphids that were not apterized by JH treatment in Fig. 2. The response index was calculated after Lees[7], each insect being assigned to one of five groups of 'morphological effect' namely 0, 25, 50, 75 and 100%. 0% was a normal alate while 100% was a fifth instar supernumerary nymph, the other groups falling between these extremes. The response index was calculated as $\Sigma(\% \, ME \times n)/N$; ME, morphological effect; n, number showing this grade of response; and N, total number of individuals. Due to the different mortalities and apterization caused by the treatments the N varied as follows: day 1, 37; day 2, 20; day 3, 34; day 4, 72; first day of the third instar, 65; first day of the fourth instar, 102.

In LD, virginoparous aphid generations wing production is induced by crowded conditions, postnatal crowding being a predominant factor in *A. fabae*[10]. It was therefore of interest to test whether the LD apterization of presumptive gynoparae observed in relatively uncrowded conditions (10 per germinating bean) could be opposed by the alatizing effect of crowding. In one experiment where day 1 presumptive gynoparae were crowded on to a single bean stipule (growing tip removed) and transferred to LD, 100% (126 of 126) of the adult survivors were alatae, in a second experiment 88% (83 of 94) were alatae. In uncrowded conditions only 15% (28 of 193) were alatae (Fig. 2). Thus the apterization induced by LD could be cancelled out by crowding.

Experiments were also designed to test the effectiveness of apterization by exogenous JH against the alatizing effect of crowding. Fifty first-day presumptive gynoparae were treated with 0.1 μg of JH1 and placed on a bean stipule with 50 first-day control aphids marked by the removal of the left antenna. After leaving these insects to settle overnight a further 100 first-day larvae with the right antenna removed were added to the same stipule to act as an additional crowding agent. This crowded colony was allowed to develop in SD conditions and scored for alate/apterousness in the fourth or fifth instar. Due to the large residual effects of the JH1 during the larval instars most sensitive to juvenilization, the fifth instar individuals, in these experiments, were all supernumerary nymphs. However, alate individuals could easily be distinguished from apterized insects. Table 1 summarizes the results of five such experiments (*b*) in comparison with a similar uncrowded series (*a*). It can be seen that the increase in intensity of crowding decreases the survival of both control and JH-treated individuals but all survivors in the crowded JH-treated experiments were alatae while 45% were apterized in uncrowded experiments. Control experiments showed there to be no differential mortality between alate and apterous morphs. Thus the apterization of alate gynoparae induced by either LD or JH treatment may be cancelled out by crowding.

Recent examination of the role of JH in controlling aphid polymorphism, as investigated by topical application of JH or analogues, indicates that in addition to influencing larval–adult metamorphosis it has a possible role in the embryonic determination of LD parthenogenetic morphs as opposed to oviparae[11,12]. Aphid embryogenesis occurs paedogenetically throughout larval development as well as in the adult mother, so that JH levels controlling embryonic development in LD virginoparae may be high except at the stage when adult characters are determined. According to this view both alate and apterous virginoparous mothers would have raised JH levels. Topical application of JH to larvae of these aphids would influence only larval–adult development, no effect being expected on the determination of alatiform or apteriform characters of the adult. This hypothesis is consistent with the failure of JH to induce aptera production, whether pre- or postnatally controlled, in LD aphids[6,12].

The apterization of gynoparae induced by postnatal LD treatment is closely mimicked by exogenous JH, suggesting that LD conditions increase endogenous JH levels in *A. fabae* larvae. If this is the case then putative low titres of endogenous JH induced by SD exposure would promote both wing development and the embryonic development of oviparae. Both LD- and JH-induced apterization involves a switch in embryonic development from oviparae to parthenogenetic viviparae (ref. 7 and unpublished results). The observation that crowding can cancel out the apterization induced by either LD or JH points to the existence of a separate factor which controls the alate–apterous dimorphism in LD, virginoparous aphids.

I thank Professors A. D. Lees and B. Johnson for advice and Professor J. S. Kennedy for comments on the manuscript.

Two distinct patterns of visual evoked response asymmetry in human albinism

W. M. Carroll, B. S. Jay, W. I. McDonald & A. M. Halliday

The National Hospital for Nervous Diseases, Queen Square, London
WC1 3BG and Moorfields Eye Hospital, City Road,
London EC1, UK

Results are presented which confirm that in human albinos each cerebral hemisphere receives a predominantly monocular input from the contralateral eye, giving rise to an asymmetry of the visual evoked potential (VEP) to whole-field stimulation which is similar to that for stimulation of the temporal half-field in the same individual. The further finding of two distinct, and in some respects opposite, types of topographical asymmetry raises the possibility that there are two anatomically distinct variants in the retinocortical projection in human albinism, as there are in the Siamese cat.

Albinism is associated with a peculiar anatomical anomaly of the visual pathways resulting from a misrouting of the retinogeniculate projections. In the extensively studied Siamese cat, not only is the whole of the temporal half-field of each eye projected to the opposite hemisphere, but also up to 20° of the nasal half-field. Each hemisphere therefore receives a predominantly monocular input from the contralateral eye, with only the more peripheral parts of the nasal field represented

0028–0836/80/320604—03$01.00

ipsilaterally[1]. A similar anomaly appears to be associated with albinism in all the mammalian species so far studied, including albino rats, guinea pigs, rabbits, and mink[2–7]. There is now also evidence for a similar anomaly in man[8].

The misrouting of the retinocortical projection results in a partial disorganization of the normal cortical retinotopic representation in the contralateral occipital lobes, and it appears from anatomical and electrophysiological studies in Siamese cats that the visual system deals with the abnormal projection from the nasal field of the contralateral eye in two distinct ways. In one, the 'Boston' pattern, the anomalous central 20° of the nasal field has a separate representation in V1 and V2 (areas 17 and 18) interpolated on either side of the 17/18 border, so that the representation of the fixation point or the area centralis is shifted away from the common border of areas 17 and 18 by the abnormal input[9]. In the other variant, the 'mid-Western' pattern, the area centralis is still positioned, as in the normal cat, at the 17/18 border, and the abnormal input from the contralateral temporal hemiretina overlies it, so that mirror-symmetrical points to either side of the fixation point go to almost identical positions on the cortex, rather as the homologous points from homonymous half-fields in each eye converge in the normal cat[10]. A further feature of the mid-Western pattern is the 'suppression' or reduced number of cortical units in the area of cortex receiving the abnormal input. There has been some evidence suggesting that in some cases both types of anomaly may co-exist in the same individual[11].

Creel *et al.* have recorded the visual evoked potential in human albinos and report that up to 70% of individuals have an abnormal response with evidence of missing components from the hemisphere receiving the uncrossed visual pathway[12–14]. Since pattern reversal VEPs have proved particularly consistent in normal healthy subjects, and the responses from each half-field show a characteristic asymmetry in all normal individuals[15,16], we have recorded the VEPs in 15 human albinos to reversal of a black-and-white checkerboard pattern of 50′ checks, using a multi-channel montage to examine in detail the topographical distribution of the response over the back of the head. Three had X-linked, and five had autosomal recessive ocular albinism and seven were oculocutaneous albinos (tyrosinase positive in six). The visual acuities were 6/36 or worse bilaterally in nine subjects and the remainder had best monocular acuities of between 6/9 and 6/24. No differences were found in the size of the central nasal and temporal visual fields and all but three had varying degrees of pendular or jerk nystagmus when the eyes were in the primary position. In all, the nystagmus diminished considerably during VEP recording. Recordings where fixation (monitored throughout) was judged inadequate or nystagmus excessive or which were not reproducible were rejected.

All the monocular responses to a circular stimulus of 16 degree radius showed a marked asymmetry which clearly distinguished them from those of normal subjects (Fig. 1). This whole-field response asymmetry invariably resembled the asymmetry produced by stimulation of the temporal half-field in the same eye. However, two quite distinct, and in some respects opposite, types of asymmetry were encountered in the albino group. In five subjects the $\overline{\text{P100}}$ component (major positivity) was ipsilateral to the stimulated eye or temporal half-field, being similar in distribution to the $\overline{\text{P100}}$ of the temporal half-field response of the normally pigmented subject. In nine others the distribution of the $\overline{\text{P100}}$ was the reverse of that found in normal subjects with this component appearing in the channels contralateral to the stimulated eye. One individual showed a mixture of the two patterns, the $\overline{\text{P100}}$ being ipsilateral for the left eye responses and contralateral for the right eye responses. In both groups of subjects the $\overline{\text{P100}}$ to nasal half-field stimulation showed an almost identical distribution to that for the temporal half-field and whole-field responses from the same eye. In general, the amplitude of the nasal field $\overline{\text{P100}}$ was smaller than the temporal field $\overline{\text{P100}}$, this difference being most marked in the first group of five subjects. There was, however, no

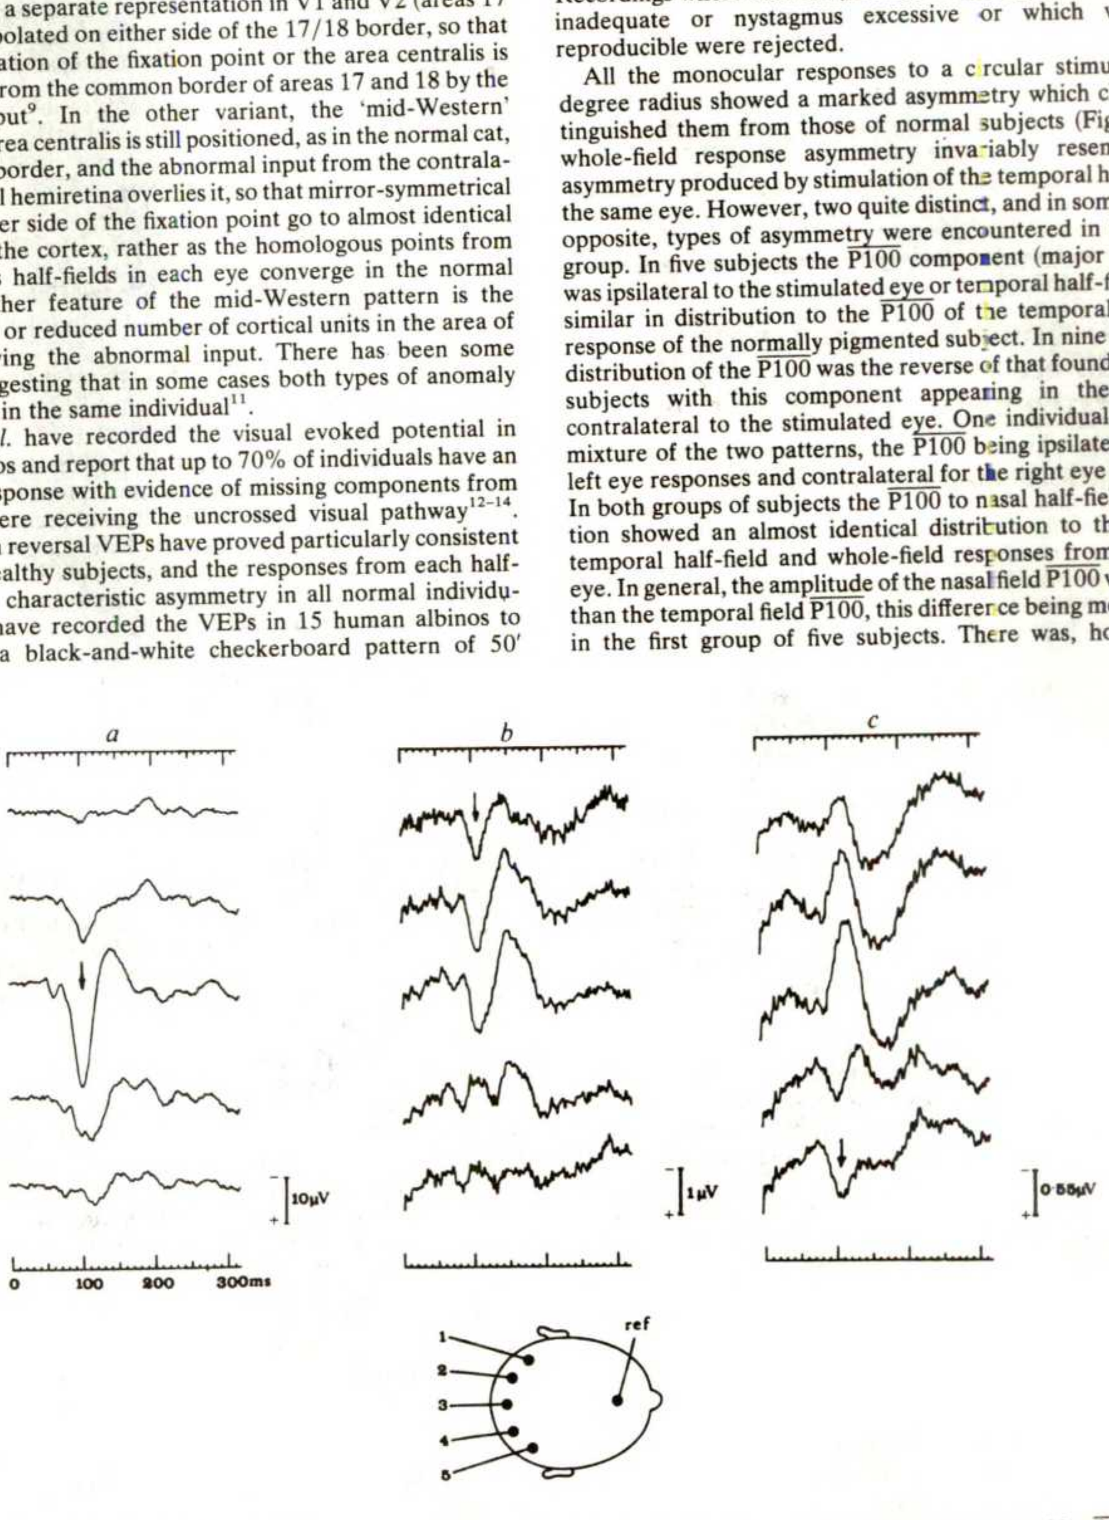

Fig. 1 Left eye whole-field (16 deg radius) VEPs from: *a*, a normal subject; *b*, the grand average of the 5 albino subjects with a $\overline{\text{P100}}$ (arrow) distribution ipsilateral to the stimulated left eye and *c*, the grand average of the 9 albino subjects with a contralateral $\overline{\text{P100}}$ (arrow) distribution. Note in the normal subject the larger amplitude and symmetrical distribution of the $\overline{\text{P100}}$ about the midline. The midline electrode of the transverse chain of 5 is situated 5 cm above the inion.

obvious association between the various types of albinism and the two patterns of VEP asymmetry. The mean amplitude of the VEPs to all fields of stimulation in the albinos was significantly smaller than in the normal population, in line with the lowered visual acuity characteristic of this group.

Ethyl β-carboline-3-carboxylate shows differential benzodiazepine receptor interaction

Mogens Nielsen & Claus Bræstrup*

Psychopharmacological Research Laboratory, St Hans Mental Hospital, Department E, DK-4000 Roskilde, Denmark
* Research Laboratories, A/S Ferrosan, Sydmarken 1-5, DK 2860 Soeborg, Denmark

High-affinity binding of ^{3}H-diazepam and ^{3}H-flunitrazepam has provided evidence for the presence of benzodiazepine receptors on brain neurones[1–6]. Pharmacological evidence showing a clear correlation between receptor affinity and *in vivo* pharmacological potency for several benzodiazepines[7] and a link between benzodiazepine receptors and GABA (γ-aminobutyric acid) receptors at the molecular level[8,9], indicates that these receptors are relevant to the pharmacological and clinical effects of benzodiazepines. In searching for possible endogeneous ligands for benzodiazepine receptors we have recently isolated ethyl β-carboline-3-carboxylate (β-CCE) from human urine and brain, and shown that β-CCE has a higher affinity than diazepam for brain benzodiazepine receptors[10]. β-CCE itself is probably not present in the brain, but may be closely related to an endogenous benzodiazepine receptor ligand[10]. We report here that β-CCE, in contrast to benzodiazepines, can distinguish clearly between benzodiazepine receptors in cerebellum and hippocampus. This result strongly indicates that benzodiazepine receptors are not a single class of non-interacting entities. It has not been possible to determine whether two distinct receptors are present and/or whether true negative cooperativity exists among hippocampal, but not cerebellar, benzodiazepine receptors.

Purification of human urine, including treatment with hot ethanol, yielded 1.78 mg β-CCE[10], which was stored in 50% ethanol at 0–4 °C for more than 2 months without loss of activity. Its identity was confirmed by *de novo* synthesis and crucial experiments were repeated with synthetic material (A/S Ferrosan). Crude membrane fractions from different brain regions were prepared by homogenization by an Ultra Turrax homogenizer in 10 vol of ice-cold 25 mM potassium phosphate buffer, *p*H 7.1, followed by dilution to 100 v/w original tissue. Aliquots of 500 μl were used directly in binding experiments. β-CCE test solution (25 μl) was added to assays just before ^{3}H-flunitrazepam (25 μl, 87 Ci mmol^{-1}, NEN) and samples were incubated at 0 °C for 40 min. Specific ^{3}H-flunitrazepam binding was estimated by conventional filtration techniques[2] using 3×10^{-6} M diazepam to assess nonspecific binding.

The first indication that β-CCE did not interact like a simple competitive inhibitor on a single class of benzodiazepine receptor came from Scatchard analysis of ^{3}H-flunitrazepam binding to rat forebrain. These plots were curvilinear in the presence of β-CCE[10] whereas plots without β-CCE never (>200 experiments) exhibited curvatures. A regional study on rat brain revealed that the curvature was most pronounced in the hippocampus and that no curvature was detected in cerebellum (Fig. 1). Other brain regions, such as frontal cortex, occipital cortex, striatum, hypothalamus and thalamus all exhibited curvilinear Scatchard plots for ^{3}H-flunitrazepam in the presence of β-CCE (data not shown).

Ethyl β-carboline-3-carboxylate
(3-carboethoxy-9H-pyrido [3,4-b] indole; β-CCE)

Fig. 1 Ethyl β-carboline-3-carboxylate (3-carboethoxy-9H-pyrido[3,4-b]indole; β-CCE).

Benzodiazepine receptors can exist in several conformations which exhibit different affinities. Various proportions of alternative conformational states in different brain areas might account for the observed difference between cerebellum and hippocampus. Mixed type inhibition by β-CCE, however, was consistently seen in hippocampal synaptosomal membranes which had been prepared in various ways known to favour different conformational states—for example, membranes prepared in sucrose[2]; in membranes washed five times (Tris-citrate)[11]; in washed membranes which were 'activated' by 3×10^{-5} M GABA[8,11,12]; in membranes treated with Triton X-100 (0.1%)[13]; in partially heat-inactivated membranes (Tris-HCl; 15 min at 60 °C)[14]; in crude membranes prepared in a physiological buffer (122 mM NaCl, 4.8 mM KCl, 0.97 mM $CaCl_2$, 1.2 mM $MgSO_4$, 16 mM phosphate, 1 mM ascorbic acid, 11 mM glucose) and in crude membranes activated by 30 mM potassium iodide[15] (data not shown). These data indicate that curvilinear Scatchard plots were not dependent on any previously described conformational heterogeneity.

Besides the induction by β-CCE of curvilinear Scatchard analysis, hippocampal benzodiazepine receptor binding differed from cerebellar binding in the displacement potency of β-CCE for ^{3}H-flunitrazepam. The IC_{50} value for β-CCE, which is the concentration displacing 50% of specific ^{3}H-flunitrazepam binding, was only 0.36 ng ml^{-1} (range 0.22–0.57 ng ml^{-1}, Hill coefficient 0.95 ± 0.02, mean ± s.e.m., $n=4$) in cerebellum compared with 2.7 ng ml^{-1} (range 1.7–3.6 ng ml^{-1}, Hill coefficient 0.75 ± 0.04, mean ± s.e.m., $n=4$) in hippocampus (Fig. 2). β-CCE was more potent in displacing ^{3}H-flunitrazepam in cerebellum than in hippocampus irrespective of the membrane preparation used (see above, data not shown). Furthermore, cerebellar and hippocampal tissue from mouse and pig exhibited about the same difference in affinity for β-CCE as did rat brain tissue (data not shown).

The almost sevenfold higher affinity of β-CCE for cerebellar than for hippocampal ^{3}H-flunitrazepam binding does not unequivocally show that β-CCE possesses higher affinity for cerebellar receptors because IC_{50} values depend on the K_D value for the ^{3}H-ligand. The K_D value for ^{3}H-flunitrazepam binding was, however, quite similar in cerebellum ($K_D = 1.40\pm0.08$ nM; mean ± s.e.m., $n=10$) and hippocampus ($K_D = 1.34\pm0.04$ nM; mean ± s.e.m., $n=16$), excluding regional differences in the affinity for ^{3}H-flunitrazepam as a major contributor to the observed regional differences.

0028–0836/80/320606—02$01.00

The present results clearly show that benzodiazepine receptors in cerebellum and hippocampus are not identical. One interpretation would be that one class of receptor is most abundant or exclusively present in cerebellum and that this class exhibits high affinity for β-CCE. Two or more classes of receptors are present in hippocampus; at least one of them exhibits reduced affinity for β-CCE. The observation of Hill coefficients below unity is compatible with the presence of more than one receptor species in the hippocampus with different affinities. The possible occurrence of receptor heterogeneity in the central nervous system was proposed, based on experimental evidence showing biphasic dissociation curves[14], polyphasic heat inactivation curves[14] and flat ^{3}H-diazepam displacement curves with Hill coefficient below unity for some new triazolopyridazines[14]. Furthermore, curvilinear Scatchard plots for ^{3}H-diazepam were found in the brain of lower vertebrates[16]. Direct evidence for benzodiazepine receptor heterogeneity in hippocampus has been obtained in photoaffinity labelling experiments using ^{3}H-flunitrazepam. SDS-electrophoresis of these irreversibly radiolabelled receptors showed two molecular species with different molecular weights (MWs) (W. Sieghart and M. Karobath, personal communication).

An alternative explanation for the present results that is compatible with both the curvlinear Scatchard analysis and the Hill coefficients below unity would be that benzodiazepine receptors in hippocampus, in contrast to cerebellar receptors, exhibit true negative cooperativity. Solubilization of benzodiazepine receptors reveals MWs of either 50,000 (ref. 17), 200,000 (ref. 18) or 110,000 (C.B. *et al.*, unpublished), depending on the procedures applied, indicating the possible presence of dimers or tetramers. Receptors composed of polymer subunits in hippocampus might possess mutually interacting sites, so that binding of β-CCE (but not of a benzodiazepine) to one site decreases the affinity of the adjacent receptor site for benzodiazepines. Apparent negative cooperativity has previously been observed for the interaction of a neurotransmitter agonist with receptors identified by labelled antagonists[19,20]. It is tempting to speculate that β-CCE is an 'agonist' to 'antagonistic sites' labelled by benzodiazepines. Studies of several drug receptors show that GTP changes the affinity of agonist binding to antagonist sites[21,22]. We found no effects of GTP (10^{-5}–10^{-4} M) on the affinity of β-CCE in hippocampus or cerebellum (data not shown), indicating that any cooperative interaction is not dependent on GTP-dependent coupling of the benzodiazepine receptor to adenylate cyclase.

Much work has gone into developing benzodiazepine derivatives with more selective pharmacological actions. Clinically available benzodiazepines apparently always exhibit anxiolytic, hypnotic and anticonvulsant properties in accordance with their lack of selectivity for any particular class of benzodiazepine receptors. New classes of drugs, such as triazolopyridazines[23] and derivatives of β-carboline-3-carboxylic acid, may interact preferentially with particular classes of receptor and exhibit new profiles of action.

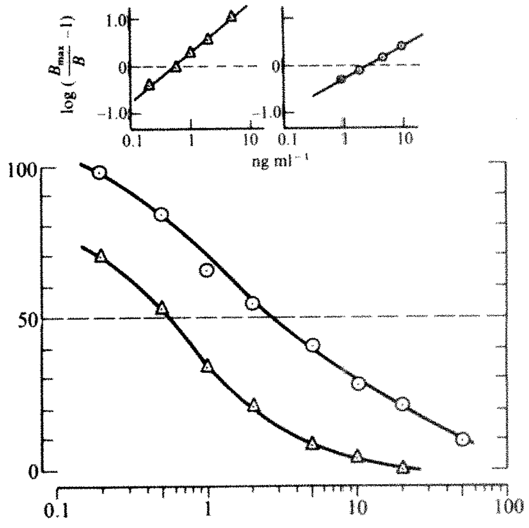

Fig. 3 Inhibition of ^{3}H-flunitrazepam binding (1 nM) to crude membrane fractions of rat hippocampus (○) and cerebellum (△) by increasing concentrations of ethyl β-carboline-3-carboxylate (0.2–50 ng ml^{-1}) added in duplicate. Total binding in hippocampus and cerebellum was 16,200 and 11,600 c.p.m. per assay, respectively. Nonspecific binding was 6–11% of total binding. Plots are representative of four separate experiments. Inset: Hill plots of the above data. Hill coefficients were 0.95±0.02 and 0.75±0.04 (mean±s.e.m. of 4 values) for cerebellum and hippocampus, respectively.

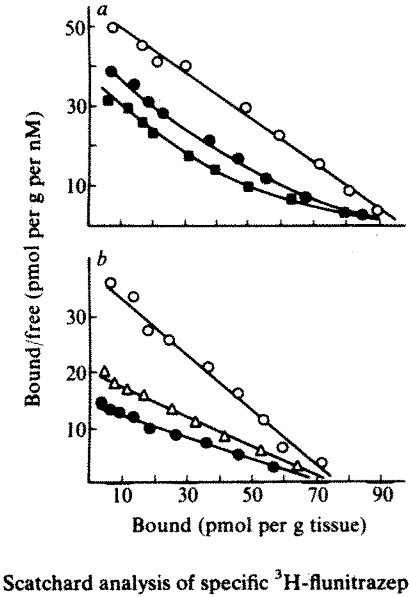

Fig. 2 *a*, Scatchard analysis of specific ^{3}H-flunitrazepam binding in rat hippocampus. Crude membrane fractions (2 mg original tissue per assay) were incubated with ^{3}H-flunitrazepam (0.2–20 nM) in duplicate as described in the text. Blanks contained 3×10^{-6} M diazepam. Control (no addition of inhibitor), ○; addition of ethyl β-carboline-3-carboxylate, ● (0.56 ng ml^{-1}) and ■ (1.1 ng ml^{-1}). The results are from a single experiment which was repeated three times with very similar results. *b*, Scatchard plot of ^{3}H-flunitrazepam binding in rat cerebellum estimated as described in *a*. Control (no addition of inhibitor) ○; addition of ethyl β-carboline-3-carboxylate △ (0.28 ng ml^{-1}) and ● (0.56 ng ml^{-1}). The experiment was repeated three times with similar results.

Adrenal corticoids regulate sensitivity of noradrenaline receptor-coupled adenylate cyclase in brain

Philip L. Mobley & Fridolin Sulser

Psychopharmacology Research Center, Tennessee Neuropsychiatric Institute, 1501 Murfreesboro Road, Nashville, Tennessee 37217

Considerable evidence indicates that alterations in the availability of noradrenaline (NA) at postsynaptic sites can cause compensatory changes in the NA stimulated cyclic AMP generating system in various brain regions. Thus, an increased responsiveness to NA has been reported in the limbic forebrain and cortex following reserpine or 6-hydroxydopamine[1-3]. Conversely, manipulations which increase the availability of NA at receptor sites (monoamine oxidase (MAO) inhibitors, electroconvulsive treatment (ECT), tricyclic antidepressants) cause a decrease in responsiveness[4-6]. This up and down-regulation of central noradrenergic sensitivity is generally linked to changes of the density of β-adrenergic receptors[7-10]. The findings that psychotropic drugs which can either precipitate (reserpine) or alleviate (tricyclic antidepressants, MAO inhibitors and also ECT) depressive states cause opposite changes in the NA receptor-coupled adenylate cyclase system in brain have provided the basis for a revised catecholamine hypothesis of affective disorders[11]. It has also been suggested that the pituitary adrenal axis may have a role in mood disorders[12]. Since manipulation of the levels of corticosterone through bilateral adrenalectomy can alter the sensitivity of catecholamine-sensitive adenylate cyclase systems in preparations from liver[13,14] and adipose tissue[15], we have tried to determine if corticosterone could regulate the NA receptor-coupled adenylate cyclase system in brain tissue. We now report that adrenal corticoids can alter the sensitivity of this system to NA.

Male Sprague–Dawley rats weighing 200–250 g were used for all experiments. Animals were anaesthetized with ether and the adrenal glands removed bilaterally. In sham-operated rats, the glands were located but not removed. All animals were given free access to both tap water and 3% saline as it has been demonstrated that adrenalectomized animals develop a salt taste and are thus able to regulate their own salt intake[16]. Animals had free access to a standard laboratory diet (Purina) and were maintained in standard laboratory conditions (12 h light-dark cycle). Two weeks following surgery, the animals were decapitated, the brains rapidly removed and the frontal cortex dissected. For studies of the NA-sensitive adenylate cyclase system, the cortex was sliced in one plane at 0.3-mm intervals and tissue slices were incubated in Krebs-Ringer bicarbonate buffer (pH 7.4, 37°C) as previously described[17]. The cyclic AMP response to NA was established by exposing the tissue slices to the agonist for 10 min. Following aspiration of the buffer solution, the slices were frozen in liquid nitrogen and homogenized in 0.3 M perchloric acid. Cyclic AMP was isolated by ion exchange chromatography as previously described[17] and measured by the protein binding assay of Gilman[18]. The effect of adrenalectomy on β-adrenergic receptors in the frontal cortex was assessed with ^{3}H-dihydroalprenolol (DHA) based on the method of Bylund and Snyder[19]. Binding curves were determined over a ligand concentration range of 0.3 to 14 nM in a final volume of 1 ml. Nonspecific binding was determined in the presence of 10 μM (±)-propranolol. The dissociation constant (K_d) and maximum binding (B_{max}) values were determined by Scatchard analysis[20]. Protein was assayed by the method of Lowry *et al.*[21]. The significance of the data was evaluated by the 2-tailed Student *t*-test. Drugs were obtained as follows: noradrenaline HCl, isoprenaline HCl, corticosterone, protein kinase from beef heart, cyclic AMP (Sigma) ^{3}H-cyclic AMP and ^{3}H-dihydroalprenolol (both NEN).

Two weeks following bilateral adrenalectomy the NA-induced cyclic AMP accumulation was significantly higher in slices from the rat frontal cortex as compared with the cyclic AMP accumulation in cortical slices from sham-operated rats. Dose–response curves comparing responses in tissue from adrenalectomized and sham-operated animals suggest that this change in sensitivity to NA is due to a shift in the maximum responsiveness of the system (Fig. 1). Significant differences in cyclic AMP accumulation occurred at NA concentrations of 100 and 1,000 μM (68% and 44% respectively). No significant changes in the EC$_{50}$ values were observed. In addition, bilateral adrenalectomy appeared not to have any effects on basal levels of cyclic AMP (Table 1).

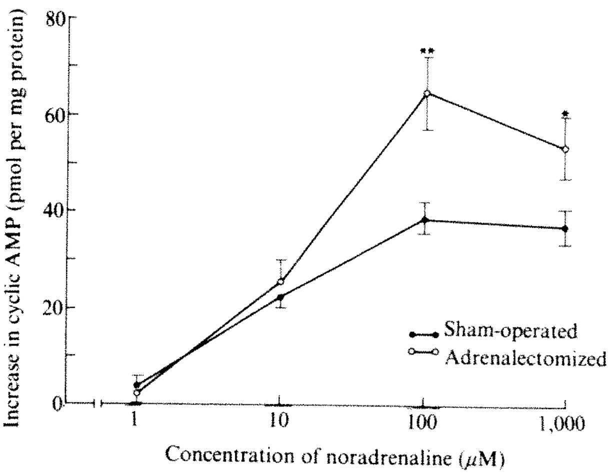

Fig. 1 Effect of adrenalectomy on the noradrenaline-induced increase in cyclic AMP accumulation in slices of rat frontal cortex. Slices of the frontal cortex from either sham-operated or adrenalectomized rats (2 weeks post-operative) were exposed to varying concentrations of noradrenaline for 10 min. The increase in cyclic AMP represents agonist-stimulated cyclic AMP levels minus basal levels (15.5 ± 1.8 and 13.1 ± 1.8 pmol cyclic AMP per mg protein in tissue from sham-operated and adrenalectomized animals respectively). Each point represents the mean of 13 to 16 samples ± s.e.m obtained in four separate experiments. EC$_{50}$ values were calculated to be 7.0 ± 2.2 (n = 4) and 12.0 ± 2.5 (n = 4) μM in tissue from sham-operated and adrenalectomized animals respectively. * $P < 0.05$, ** $P < 0.01$, as compared with sham-operated animals.

Corticosterone (10 mg per kg) administered to adrenalectomized rats for 5 days before death completely abolished the difference in sensitivity to NA (Table 1). Similar treatment elicited only a slight nonsignificant lowering of the accumulation of cyclic AMP in sham-operated rats. Again, no significant changes were observed in basal levels of cyclic AMP with any of these treatments. Also, bilateral demedullation did not produce significant changes in the sensitivity of the system to NA. The results indicate that the observed change in sensitivity to NA after bilateral adrenalectomy is a consequence of the removal of the adrenal corticosteroids.

Although the cyclic AMP accumulation elicited by NA was significantly altered following adrenalectomy, no significant changes were observed in the response to maximally effective concentrations (10 μM) of isoprenaline: 27.6 (s.e.m., 4.2, *n*, 18) and 22.5 (s.e.m., 2.6, *n*, 18) pmol cyclic AMP per mg protein in slices from sham-operated and adrenalectomized animals respectively. Only slight, nonsignificant changes occurred in the B_{max} value for specific ^{3}H-DHA binding. In tissue from sham-

Table 1 Effect of corticosterone on adrenalectomy induced change in sensitivity of the noradrenaline sensitive adenylate cyclase system in frontal cortex

	Cyclic AMP response to noradrenaline (100 μM) (pmol per mg protein ±s.e.m.)	
	Minus corticosterone	Plus corticosterone
Sham-operated	48.8±4.8	40.0±3.2
Adrenalectomized	68.7±4.1*	37.1±1.9†

Corticosterone (10 mg per kg) or vehicle (corn oil) were administered subcutaneously to adrenalectomized and sham-operated rats for 5 days preceding death (injections started 9 days post-operation). The cyclic AMP response to 100 μM noradrenaline equals the agonist-stimulated level minus the basal level. Basal levels in pmol per mg protein ±s.e.m. were as follows: sham-vehicle, 14.5±1.1; sham-corticosterone, 16.6±1.4; adrenalectomy-vehicle, 14.7±1.1, adrenalectomy-corticosterone, 13.2±1.0. Each value represents the mean of 8 samples for basal levels and 12 samples for agonist-stimulated levels.

* $P<0.01$, as compared with sham-operated rats not receiving corticosterone.

† $P<0.001$, as compared with adrenalectomized rats not receiving corticosterone.

operated rats B_{max} was 244 fmol per mg protein (s.e.m., 24; *n*, 6) versus 276 fmol per mg protein (s.e.m., 24; *n*, 6) in tissue from adrenalectomized rats. Also, no significant changes in K_d values were found: 2.59 nM (s.e.m., 0.08; *n*, 6) and 2.83 nM (s.e.m., 0.08; *n*, 6) for sham-operated and adrenalectomized animals respectively.

In the liver, it has been demonstrated that the enhanced cyclic AMP response after adrenalectomy is associated with an increase in the number of β-adrenergic receptors[22]. The results of the present studies suggest that the altered cyclic AMP response to NA in cortical slices following bilateral adrenalectomy is mainly a consequence of changes in a non-β-receptor-mediated portion of the adrenergic cyclic AMP generating system.

Interestingly, it has been reported that chronic stress can decrease the sensitivity of this system[23]. Since chronic stress and antidepressant treatments both produce subsensitivity of the NA receptor-coupled adenylate cyclase system, Stone[24] has proposed subsensitivity to NA as a link between adaptation to stress and antidepressant therapy. Although it can be concluded from the present studies that alterations in the level of adrenal steroids can either directly or indirectly alter the sensitivity of the NA receptor-coupled adenylate cyclase system in brain tissue, both the molecular mechanisms accounting for the observed sensitivity changes and the role of the hypothalamus–pituitary–adrenal axis in affective disorders remain topics for further study.

Suppression of *in vitro* lymphocyte reactivity by cyclosporin A: existence of a population of drug-resistant cytotoxic lymphocytes

T. Horsburgh*, P. Wood & L. Brent

Department of Immunology, St Mary's Hospital Medical School,
London W2 1PG, UK

Cyclosporin A (CS-A) is an unusual endecapeptide isolated from the fungi *Cylindrocarpon lucidum* Booth and *Trichoderma polysporum*[1]. It is a potent immunosuppressive drug that prevents rejection of kidney[2–4] and heart[5,6] allografts whilst having a low myelotoxicity[7]. Its mode of action is still unclear but its main target appears to be the T lymphocyte[8]. The mixed lymphocyte reaction (MLR) and cell-mediated lymphocytoxicity (CML) used here are generally regarded as *in vitro* correlates of allograft rejection[9]. Our data show that CS-A is a powerful inhibitor of MLR reactivity, regardless of whether the cells were obtained from normal or presensitized donors; that the CML of lymph node cells is likewise totally inhibited if the drug is added early during cell culture; and that, by contrast, the cytotoxic response of spleen cells from presensitized but not from normal mice is only partially inhibited, even with a tenfold increase in dose. It is therefore suggested that there exists a population of cytotoxic spleen cells that is relatively resistant to the action of this drug.

Cyclosporin A (CS-A) was added at different times after initiation of MLR between CBA ($H-2^k$) responder cells and irradiated BALB/c ($H-2^d$) or DBA/2 ($H-2^d$) splenic stimulator cells (Fig. 1). The presence of CS-A from the beginning of culture caused almost complete inhibition of ^3H-thymidine (^3H-Tdr) incorporation. Addition of the drug at later times was also effective in inhibiting further proliferative responses. (All experiments were done at least twice, with closely similar results.)

Inhibition of MLR was dose-dependent (Fig. 2). At an initial concentration of either 0.125 or 0.25 $\mu g\ ml^{-1}$, CS-A severely inhibited the primary MLR response whereas lower concentrations, 0.05 and 0.01 $\mu g\ ml^{-1}$ (the latter not shown), were far less effective. MLR cultures of lymph node cells from mice presensitized *in vivo* one month before, by either a skin graft or via allogeneic spleen cells injected intraperitoneally, showed a similar response to the drug. Here the untreated control cells from presensitized donors produced an earlier though lower peak in the MLR. Depression of MLR after *in vivo* presensitization has previously been described by Cooley[10], who suggested that it was brought about by either a redistribution of subpopulations of lymphocytes in the animal or the elimination, during culture, of some of the stimulator cells by preformed cytotoxic cells. In our experiments the presensitized cells gave normal primary MLR responses to third-party spleen cells (C57B1, $H-2^b$) and these cultures were similarly inhibited by the same concentrations of CS-A (not shown).

---

* Present address: Department of Surgery, Leicester General Hospital, Leicester, UK.

0028–0836/80/320609—03$01.00

The same range of CS-A concentrations also impaired the generation of cytotoxic lymphocytes from cultures of both normal and presensitized spleen and lymph node cells (Fig. 3). Thus, cytotoxicity after 5 days of culture was abolished when CS-A was added on day 0. Whereas addition of the drug on day 1, and to a lesser extent on day 2, partially inhibited cytotoxicity, such an effect was no longer demonstrable when the drug was added on day 3. Similar results were obtained when the cells were cultured for 6 rather than 5 days, indicating an early and lasting impairment of the capacity to produce cytotoxic cells. Addition of CS-A at later times affected the cytotoxic response of normal cells more strongly than that of presensitized cells and this probably reflects the more rapid development of cytotoxic cells in the latter[11]. Ethanol, the CS-A solvent, did not affect CML responses at the appropriate concentration; nor was the drug directly cytotoxic as judged by the low background of radioactivity released by ^{51}Cr-labelled target cells when incubated with the drug at 1 μg ml^{-1}. However, when cytotoxic cells were assayed in the presence of 1 μg ml^{-1} CS-A, ^{51}Cr release was reduced from a control value of 68.3% to 34 ± 3%. This suggests that mature cytotoxic lymphocytes are susceptible to the action of CS-A but that they are less vulnerable than MLR and/or CML precursor cells. It is unlikely that CML suppression was due to retention of the drug, because addition of CS-A to control CML cultures on day 5, followed by 30 min incubation and two washes, had no effect on the level of cytotoxicity.

The action of CS-A on the generation of cytotoxic cells, too, was dose-dependent (Fig. 4). CML cultures derived from normal spleen cells incubated with 0.06 μg ml^{-1} or more showed little or no cytotoxicity. Higher doses (0.125 μg ml^{-1}) were required to obtain significant inhibition of cytotoxicity when using cells from presensitized donors, and even a tenfold increase (1 μg ml^{-1}) failed to suppress the response completely, despite the fact that at this higher concentration the response of presensitized lymph node cells had been abolished (see Fig. 3). This, together with the sharp break in the curve for presensitized cells of Fig. 4, strongly suggests that there are at least two subpopulations of cytotoxic lymphocytes, with differing sensitivities to the drug. That preformed cytotoxic cells are less susceptible to CS-A suppression has already been shown above and it is therefore to be assumed that the drug-resistant subpopulation consists of preformed cytotoxic cells present in the spleens of mice sensitized *in vivo*. We have not, however, looked directly for the presence of cytotoxic effector cells in the spleens of *in vivo* sensitized mice, and others[12] have failed to find them 4 weeks after skin graft sensitization, albeit in a different strain combination. It should also be said that while it is reasonable to assume that the cells inhibited at the proliferative stage of MLR are cytotoxic precursors, we cannot exclude the possibility that an entirely different subpopulation of cells, such as T helper lymphocytes, is involved.

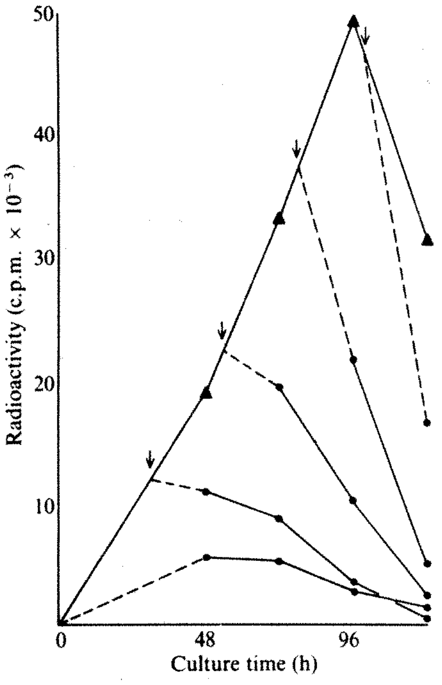

Fig. 1 MLR of mouse spleen cells after addition of CS-A at various times after beginning of culture. MLR's were performed in microtest plates, with each well containing 5×10^5 CBA responder cells and 5×10^5 irradiated (2000R) BALB/c stimulator cells in 0.2 ml RPMI 1640 medium, supplemented with 10% fetal calf serum, 2 mM glutamine, 3×10^{-5} M 2-mercaptoethanol, 24 mM sodium bicarbonate, penicillin (1 iu per ml) and streptomycin (1 μg ml^{-1}). The cells were incubated at 37 °C in a humidified atmosphere of 5% CO_2: 95% air and pulsed with 1 μCi ^{3}H-Tdr at 370 mCi mmol^{-1} 18 h before the cells were collected. CS-A was dissolved in ethanol and added to the cultures at different times (indicated by arrows) to give a final concentration of 1 μg ml^{-1} of CS-A and 0.5% ethanol. The addition of ethanol only did not affect the MLR (data not shown). ▲, Control; ●, experimental curves after addition of CS-A; broken lines, postulate of curves after addition of CS-A.

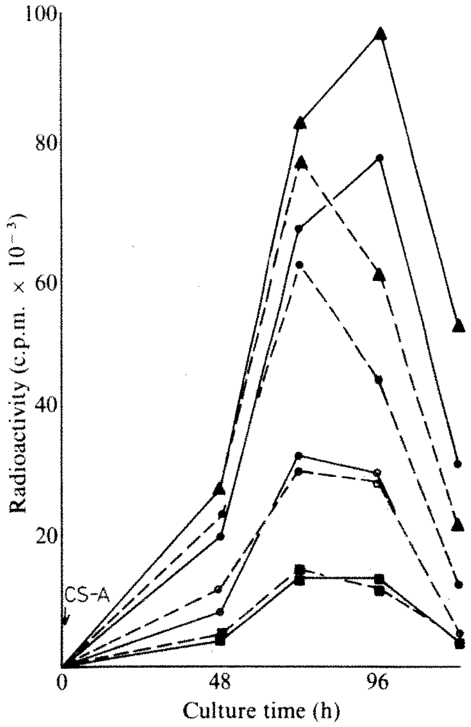

Fig. 2 Addition of different doses of CS-A to cultures of normal or presensitized CBA lymph node cells and DBA/2 stimulator spleen cells. CS-A was added at the beginning of culture. For conditions of culture, see legend to Fig. 1. Solid lines, normal cells; broken lines, presensitized cells; ▲, controls; ●, 0.05 μg ml^{-1}; ○, 0.125 μg ml^{-1}; ■, 0.25 μg ml^{-1}.

These results suggest that higher concentrations of CS-A would be required *in vivo* to suppress T-dependent immune responses in presensitized animals, and preliminary results of skin grafting experiments are consistent with this prediction.

Our MLR data confirm the reports of others[13,14] who have shown that CS-A suppresses the response of lymphocytes to mitogens such as phytohaemagglutinin and to histocompatibility antigens in MLR. We have shown, further, that the drug is a potent inhibitor of CML provided that it is added in the first 48 h of culture. The similarity between the concentration of CS-A required to inhibit CML and MLR suggests that the suppression of CML is brought about, essentially, by inhibition of the proliferative responses required for the generation of cytotoxic cells; it also provides an explanation for the residual cytotoxic activity in presensitized spleen CML's.

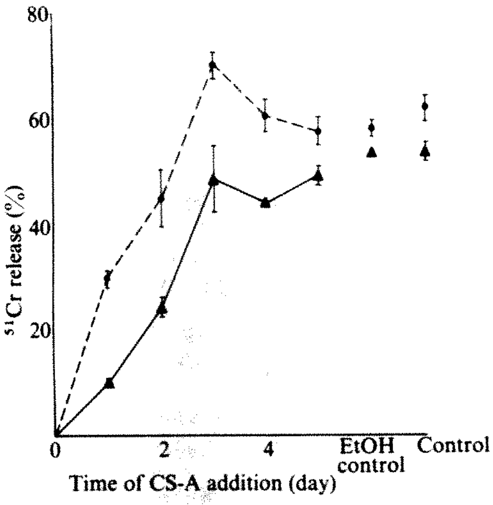

Fig. 3 Addition of CS-A at different times during the course of CML culture between normal or presensitized CBA lymph node cells and DBA/2 stimulator spleen cells: effect on generation of cytotoxicity. CBA responder cells were incubated with irradiated DBA/2 stimulator spleen cells in a ratio of either 1:2 or 2:1 in 10 ml RPMI medium supplemented as described in the legend to Fig. 1, at a total concentration of $3.75\times10^6\,\text{ml}^{-1}$. CS-A was dissolved in ethanol and added either at the beginning of the culture or during the course of the next 5 d, to a final concentration of 1 μg ml^{-1}. The 25 ml flasks were incubated upright at 37°C in a humidified atmosphere of 5% CO_2:95% air. The cells were collected after 5 d and tested for cytotoxicity in a 4 h ^{51}Cr release assay. Equal volumes (100 μl) of effector cells (at $4\times10^6\,\text{ml}^{-1}$) and ^{51}Cr-labelled PY815 mastocytoma target cells (at $10^5\,\text{ml}^{-1}$) were incubated in microtest plates for 4 h at 37 °C. The plates were spun at 200*g* for 5 min, and 100 μl of supernatant from each well was counted. Cytotoxicity (%) was calculated according to the formula:

$$\left(\frac{\text{Test}-\text{background}}{\text{Total release}-\text{background}}\right)\times 100\ \text{(c.p.m.)}$$

Background release of radioactivity from the target cells was never more than 10% and usually less than 5% of the total amount incorporated. ▲, Normal; ●, presensitized. Error bars indicate ±1 s.e.m.

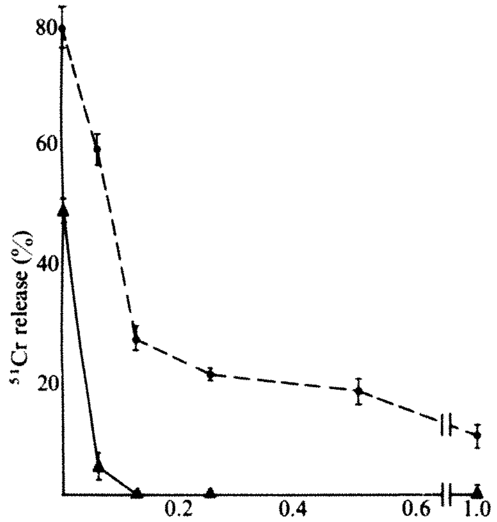

Fig. 4 Addition of different doses of CS-A to CML cultures of either 25×10^6 normal or presensitized CBA spleen cells and 12.5×10^6 DBA/2 stimulator spleen cells: effect on generation of cytotoxicity. CS-A was added at the beginning of culture. For other details, see legend to Fig. 3. Cytoxicity assays were carried out after 5 d of culture. ▲, Normal; ●, presensitized. Error bars indicate ±1 s.e.m.

CS-A may therefore not be an ideal agent for the reversal of rejection crises in clinical transplantation or in the treatment of presensitized graft recipients.

We thank Miss G. Kalsi for technical assistance and J. F. Borel, Sandoz Ltd, Basle for a gift of cyclosporin A. This work was supported by the Medical Research Council.

Endotoxin-induced uveitis in rats as a model for human disease

J. T. Rosenbaum, H. O. McDevitt, R. B. Guss & P. R. Egbert

Department of Medicine, Stanford University School of Medicine,
Stanford University Medical Center, Stanford, California 94305

Acute anterior uveitis is a relatively common disease of uncertain aetiology. Its association with a wide variety of systemic disorders including ankylosing spondylitis, Reiter's syndrome, Behçet's disease, juvenile rheumatoid arthritis, psoriatic arthritis, inflammatory bowel disease and sarcoidosis and the prevalence of the HLA antigen B27 (ref. 1) in cases without associated disease have been noted but not explained. In general, animal models for uveitis have not clarified the mechanism of human disease. Most require direct intravitreal injection[2] or repeated immunizations with retinal or uveal antigens[3]. Uveitis does occur in adjuvant arthritis, a syndrome that can be produced in rats by the systemic injection of peptidoglycan from the cell wall of a variety of Gram-positive bacteria[4]. The disease, which was initially described following the injection of mycobacteria in mineral oil, has many similarities to Reiter's syndrome[5], including the development of eye pathology in as many as 40% of the animals[6]. As Reiter's syndrome is associated with enteric Gram-negative infections such as *Shigella*, *Salmonella* and *Yersinia*, we sought to produce an arthritis in rats by injecting killed Gram-negative bacteria. Although we have not observed clinical arthritis in these animals, careful histological study has shown the near-universal appearance of uveitis. The studies described below indicate that the eye disease is due to a portion of the bacterial cell wall known as endotoxin or lipopolysaccharide (LPS).

The typical eye histology produced is shown in Fig. 1. This response could be produced by 1 mg of *Escherichia coli*, *Klebsiella* or *Shigella* but not by 1 mg of *Staphylococcus* or by 0.1 mg of *E. coli.* The different response following Gram-negative as opposed to Gram-positive bacteria encouraged us to assess the reaction to endotoxin alone.

In Lewis rats, we were able to induce uveitis by intravenous or intraperitoneal (i.p.) injections of LPS as well as LPS by the footpad route (f.p.). Comparable abnormal histology was also noted when the source of LPS was extracted from *Shigella flexneri* or *Shigella sonnei* by the Westphal method. Preliminary studies show that the lipid A portion of LPS as obtained by acid hydrolysis and solubilized by coupling to bovine serum albumin[8] could itself induce uveitis.

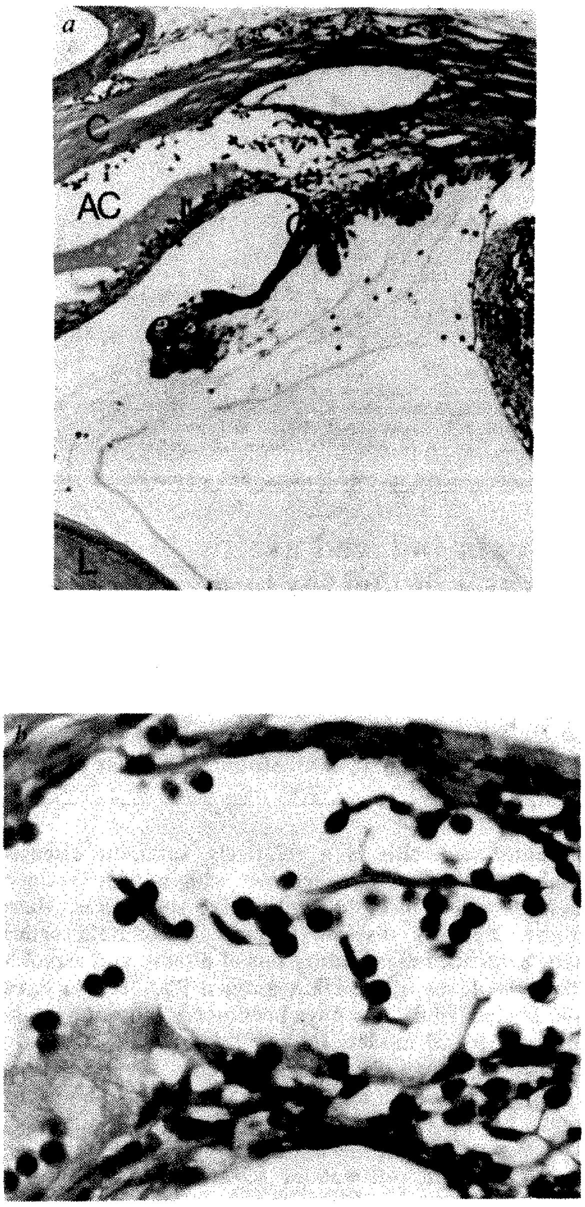

Fig. 1 The top photomicrograph shows many inflammatory cells near the iris (I), anterior chamber (AC) and ciliary body (CB) of a rat eye. A marked proteinaceous exudate is present in the anterior chamber adjacent to the iris. The cornea (C), retina (R) and lens (L) are also labelled for orientation. The photomicrograph below is a higher-power view showing that the infiltrating cells are both polymorphonuclear leukocytes and mononuclear cells. Lewis rats (~250 g), usually 4-6 months old, were used. Bacteria were grown overnight in thioglycollate broth, killed with formalin, washed three times with saline, and lyophilized. Bacteria included *E. coli, Klebsiella, S. sonnei* and *S. aureus*, coagulase positive. Bacteria were injected with 0.1 cm^3 of a mineral oil suspension asceptically into the footpad of a rat that had been lightly anaesthetized with ether. Eyes were obtained 48 h later, after the animal had been killed with ether and exsanguination. Eyes were fixed in 10% neutral buffered formalin and stained with haematoxylin and eosin. Eye pathology was evaluated by two of us (R.G. and P.E.) without knowledge of the treatment received. Eyes were considered to demonstrate uveitis only if a representative cross-section contained five or more inflammatory cells, either polymorphonuclear leukocytes or lymphocytes, in the anterior chamber, posterior chamber or vitreous. In most abnormal eyes a proteinaceous exudate was also apparent. This definition of disease permitted complete concordance by the two observers.

A dose–response curve showed that no detectable changes were present 48 h after 10 μg of *E. coli* LPS injected f.p. but that 50 μg f.p. or 300 μg i.p. produced reactions comparable to that following 100 μg. A dose of LPS sufficient to produce eye disease induced no significant abnormalities in the heart, lung, liver, kidney, spleen, skin, intestine or marrow as judged by light microscopy.

Eyes studied 1 h after an injection of 100 μg LPS f.p. showed no significant abnormality but by 4 h, cells were beginning to accumulate. The disorder was maximal around 48 h, was still present, although declining, 96 h after the injection, and could not be detected 1 week after the injection. When LPS was administered twice over a 3-week period, the disease recurred, but multiple doses of LPS over several weeks tended to abolish or markedly diminish the disease.

In total, bilateral uveitis was seen in all 23 animals 48 h after either 1 mg of lyophilized Gram-negative bacteria or 100 μg LPS given by a variety of routes, in a variety of strains and from a variety of sources (see Table 1). Although a contaminating substance cannot be completely discounted, the reaction seems to be due to endotoxin, in particular the lipid A portion of endotoxin, as argued by its appearance after various Gram-negative bacteria but not after *Staphylococcus aureus* injection and by its occurrence following injection of LPS from different sources.

The absence of cellular abnormalities in other tissues is surprising but it might be predicted from the work of other investigators who have noted that doses of LPS sufficient to cause death (approximately 5 mg in a rat) produce relatively little histological change[9]. The amelioration of disease after repeated injections is reminiscent of the phenomenon of tolerance to endotoxic shock[10].

The concept that bacterial products might induce uveitis is not a novel one. Woods first described 'poisons' from bacteria "which have a definite action upon the uveal tract in the eye" (ref. 11). Others have used live bacteria, primarily streptococcus, and succeeded in producing uveal changes in a minority of rabbits at variable times after injection[12]. For a time, elimination of potential foci of infection such as tonsils or carious teeth was in vogue as a method for treating uveitis[13]. Attention focused specifically on endotoxin when Ayo reported a 'toxic ocular reaction' in rabbits that was ascribed to 'Shwartzman toxins' (ref. 14). This response could include an iridocyclitis but disappeared within 24 h and specifically could not be produced in rats[15]. A change in ocular vascular permeability following intravenous endotoxin had been noted within 1 h in the rabbit[16]. Others have reported that intravenous endotoxin produces an aqueous cellular response in less than 5% of rabbits, although cells in the uvea are common[17].

Endotoxin-induced disease differs markedly from the eye findings in adjuvant arthritis in that the reaction occurs within 24 h of the immunization whereas eye findings in adjuvant disease never occur before 8 days after injection and are maximal at 10–15 days[6]. Eye disease occurs in only a minority of susceptible animals in adjuvant disease[6], but seems to be near universal in rats after LPS injection.

Circumstantial evidence suggests that this model might have relevance for human disease. The most obvious link is with Crohn's disease and ulcerative colitis. In both of these, circulating endotoxaemia may develop with active disease[18].

In Reiter's syndrome a variety of Gram-negative dysenteries may provoke arthritis and uveitis[7]. In Behçet's syndrome, bowel pathology could conceivably account for a source of endotoxaemia. As endotoxin is known to release lysozyme[19], the elevated lysozyme levels seen in Crohn's disease[20], ulcerative colitis[20] and Behçet's disease[21] as well as in sarcoidosis could be related to endotoxin or a stimulus with endotoxin-like activity. Because uveitis in man is closely linked to the HLA antigen B27 (ref. 22), an important advantage of a rat as opposed to a rabbit model, is that the role of the major histocompatibility complex (MHC) can be explored. The variety of strains susceptible to endotoxin-induced uveitis suggests that the effects of LPS are

Table 1 Variety of strains susceptible to endotoxin-induced uveitis

Strain	No. injected with LPS/ no. with uveitis	No. of controls/ no. with uveitis
Lewis	3/3	3/0
Wistar–Lewis	2/2	2/0
Wistar	1/1	
Lea-X	1/1	
BC	1/1	
Fischer	1/1	
Buffalo	2/2	2/0
Sprague–Dawley	2/2	2/0
Long Evans	2/2	2/0
ACI	2/2	1/0
Totals	17/17	12/0

Male rats (200–250 g) were injected in the footpad with *E. coli* LPS 055 (Difco) after light ether anaesthesia. The dose was 100 μg in 0.1 cm^3 of saline. Control rats with the exception of the Lewis rats were given an injection of sterile saline alone. Eyes were removed 48 h after injection. Methods for histology and criteria for uveitis were identical to that used following the injection of whole bacteria. Disease was bilateral in all cases.

not restricted by the MHC. However, if the claimed cross-reaction between *Klebsiella* and HLA-B27 is confirmed[23,24], B27-positive individuals might be predisposed to endotoxaemia through either mimicry or a receptor[25] phenomenon for a *Klebsiella* product. This putative cross-reaction with a Gram-negative bacteria might explain the frequency with which *Klebsiella* is found in the stool of ankylosing spondylitis patients before a flare of uveitis[26].

An alternative explanation for the relationship between the MHC and uveitis is that LPS is only one of several factors responsible for disease in man, with a second factor being determined by an immune response gene within the MHC. For example, intravitreal injection of endotoxin can predispose the eye to immune complex deposition[27] and preliminary evidence in our laboratory suggests that systemic endotoxin might also facilitate immune complex deposition in the eye. Such a dual causality model would account for both the observed MHC association and the lack of strain restriction for the endotoxin effects.

Current work in our laboratory is aimed at establishing the mechanism of disease in the animal model, testing the possible relevance of the animal disease to uveitis in man, and exploring the potential role of endotoxin in the induction of arthritis and immune complex uveitis.

We thank Ms Bonnie Paschal and Ms Priscilla Hendricks for technical assistance, and Dr Jon C. Ross for interpreting slides of organs other than the eye. *Shigella* strains were from Dr John Shively, *E. coli* LPS from Drs Stuart Koretz and Samuel Strober, and Lewis rats from Simonsen Laboratories, Microbiological Associates or the breeding colony of Dr Irving Weissman.

Elution of herpes simplex virus-specific cytotoxic antibodies from squamous cell carcinoma of uterine cervix

Pradeep Seth & N. Balachandran

Department of Microbiology,
All India Institute of Medical Sciences,
Ansari nagar, New Delhi-16, India

There is evidence that carcinoma of the cervix uteri is associated with infection with herpes simplex virus type 2 (HSV-2), and although indirect evidence suggests an aetiological relationship[1–6], this remains controversial[7–9]. One facet of the problem is that complement-dependent cytotoxic antibodies to HSV-2-infected cells have been undetectable or found only in low titre in sera from patients with progressive cervical cancer whereas higher titres have been found where cervical lesions are less advanced[10,11]. Indeed, cytotoxic antibody titres have been found to rise during the follow-up period after successful treatment[11]. Absorption of these antibodies by the tumour cells has been proposed as a possible reason for low HSV-2 cytolytic reactivity in patients with progressing cervical cancer[10]. This explanation assumes the presence of HSV-2-specific antigen(s) on the tumour cells. We now provide support for this assumption with evidence that absorbed HSV-2-specific antibodies can be eluted from cervical cancer tissue.

Elution of bound immunoglobulin from freshly removed tissues from six patients with cervical cancer, stage I (five patients with squamous cell carcinoma, one with adenocarcinoma), one patient with ovarian cancer, two patients with uterine fibroids, three patients with squamous cell carcinoma of the skin and from three normal uterine cervices was achieved by treatment with 15% NaCl (*p*H 7.4) at 37 °C (ref. 12). The protein content of the eluates was estimated[13] and the class of immunoglobulin present was determined by polyacrylamide gel electrophoresis using purified human serum IgM, IgG and IgA as markers. Although the eluates from all tissues contained proteins, IgG was the only detectable immunoglobulin eluted from all squamous cell carcinoma tissues as well as cervical adenocarcinoma tissues (Table 1). Tissues from uterine fibroids and normal cervix failed to yield any immunoglobulin by the technique used. The nature of other protein(s) present in the eluates was not determined.

Complement-dependent cytolytic activity of the eluate was assayed on ^{51}Cr-labelled BHK-21 cells infected 22–24 h previously with HSV-1 or HSV-2, at a multiplicity of infection of 3–5 plaque forming units (PFU) per cell[14]. The eluate (0.1 ml) was diluted 1:5 in Tris-buffered saline, *p*H 7.2, mixed with 5×10^4 cells and incubated at 37 °C for 60 min. Then, 0.2 ml of fresh guinea pig complement diluted 1:10 was added and the mixture was incubated at 37 °C for another 90 min. The cytolysis was stopped by adding 2 ml of cold Tris-diluent to each tube, which was then centrifuged at 600*g* for 3 min at 4 °C. Aliquots (1 ml) of the supernatant were transferred to another tube and counted for radioactivity in a Packard automatic γ spectrometer. Each test included: labelled cells only, which were frozen and thawed in distilled water for maximum ^{51}Cr release, cells with eluate alone to control for eluate toxicity, and cells

Each tissue was minced finely and passed through a 60-wire mesh screen to obtain a cell suspension. It was washed 15 times with 10-ml volumes of phosphate-buffered saline (0.025 M PBS, *p*H 7.4) and the UV absorbance of the supernatant after the 15th wash was checked at 280 nm wavelength in a spectrometer. No further washing was done if *A* was less than 0.025. When it was more, additional washings were given until *A* was less than 0.025. The pellet was then suspended in 5 ml of 15% NaCl (*p*H 7.4) and incubated at 37 °C for 2 h. After that, it was centrifuged at 10,000*g* for 10 min, and the sediment was re-extracted with 15% NaCl. The supernatants of both extractions were pooled and dialysed against 500 ml of PBS for 24 h with two changes of buffer. It was then centrifuged at 36,000*g* for 1 h and the supernatant was collected and concentrated 10-fold by vacuum dialysis. It was centrifuged at 5,000*g* for 30 min and the clear supernatant was taken as eluate for further testing as described in the text. ND, Not done.

* A 1 : 5 dilution of the eluate was tested.

$$‡\ \%\ \text{Specific release} = \frac{\text{test release (c.p.m.)} - \text{spontaneous release (c.p.m.)}}{\text{maximum release (c.p.m.)} - \text{spontaneous release (c.p.m.)}} \times 100.$$

† Values of eluate toxicity controls are always less than spontaneous release control. In cases where the values of the former are greater than the latter, the eluate is too toxic to be tested.

with complement alone as a control for spontaneous ^{51}Cr release. All test systems, including controls, were carried out in duplicate and their c.p.m. were averaged. The cytolytic antibody activity was expressed as the per cent specific release of ^{51}Cr according to the formula[15]

$$\%\ \text{Specific release} = \left(\frac{^{51}\text{Cr release in the presence of eluate and compement} - \text{spontaneous release}}{\text{Maximum release} - \text{spontaneous release}} \right) \times 100$$

The eluates from cervical squamous cell carcinoma produced 8–66% lysis of HSV-1 infected cells and 10–100% lysis of HSV-2-infected cells (see Table 1). The cytolytic pattern of the eluates suggests the presence of antibody activity to cross-reacting antigens of HSV-1 and HSV-2. However, the cytolytic activity was more pronounced against HSV-2-infected cells. Specificity of the antibody activity was established by the failure of the eluates to lyse vaccinia-infected BHK-21 cells[16] or uninfected BHK-21 cells. Moreover, eluates from other tumour tissues as well as normal healthy cervix did not show any cytolytic activity against infected or uninfected BHK-21 cells.

Each tissue was also tested for the presence of virus. A portion of tissue was ground in a homogenizer and 0.1 ml of the homogenate was inoculated onto two stationary cultures of Vero cells grown in Eagle's minimum essential medium (MEM) supplemented with 5% calf serum. The cultures were incubated at 37 °C and observed for 14 days. None of the homogenates produced a cytopathic effect suggestive of HSV. Furthermore, three tissues from squamous cell carcinoma of the cervix, three tissues from squamous cell carcinoma of the skin, one tissue each from adenocarcinoma of the cervix, uterine fibroid and normal cervix were minced separately into 1-mm^3 explants and co-cultivated with monolayers of Vero cells which were then fed with MEM containing 20% fetal calf serum[17]. The cultures were observed for 8 weeks for cytopathic effects before they were discarded. No virus was recovered on co-cultivation.

These data indicate the presence of HSV-specific antigens on the tumour cells of squamous cell carcinoma of the uterine cervix in the absence of apparent infection of these cells by the virus. However, latent or abortive infection of the tumour tissue by HSV cannot be definitely excluded, even though no HSV was isolated from any cervical cancer tissues.

Evidently, HSV-specific cytotoxic antibodies had been absorbed from the blood of the patients with cervical cancer *in vivo* by HSV-specific antigens present on the tumour cells. This absorption seems to be specific for squamous cell carcinoma of the cervix, as HSV-specific immunoglobulins could not be eluted from squamous cell carcinoma of the skin. The absorbed antibody may be either functioning as blocking antibody in tumour enhancement[18] or involved in the cell-mediated destruction of the tumour cells[19]. Furthermore, the absence of HSV-specific antigens in tissues from squamous cell carcinoma of the skin, ovarian carcinoma and uterine fibroids strongly suggests a role of HSV in the aetiology of squamous cell carcinoma of the uterine cervix.

On the basis of the present data, it is difficult to understand how the low titres of HSV-cytolytic antibodies in the sera of patients with progressing cancer of the cervix could arise from absorption of antibodies by the tumour cells[10]. However, the presence of circulating immune complexes in the sera of patients with cervical cancer[20] might interfere with the assay of cytolytic antibodies by the ^{51}Cr-release test, and absorption of antibodies by the tumour cells may account for depletion of only a small portion of cytolytic antibodies from the circulation.

These results, although obtained using only a few patients, are nevertheless striking. As no infective virus could be detected or reactivated, it is tempting to suggest that the virus-specific IgG is adsorbed to virus-specified determinants on the neoplastic cells.

We thank Drs V. L. Bhargava, S. Kumar and D. Ghosh for the clinical material and Drs L. N. Mohapatra, S. Balaya and R. Kumar for their advice.

How many types of erythroleukaemia are induced by retroviruses in mice?

Rita Anand & Richard Steeves*

Albert Einstein College of Medicine, 1300 Morris Park Avenue, Bronx,
New York 10461

Erythroleukaemia, until now defined by morphological criteria, has been observed in mice infected with several distinct virological entities, including the polycythaemia-inducing strains of Friend virus complex (FV-P)[1,2], the anaemia-inducing strains of Friend[3] and Rauscher[4,5] virus complex (FV-A and RV-A, respectively) and various helper-independent virus isolates derived from the FV-A[6] or RV-A[7] complexes. Whereas erythroleukaemia develops rapidly (within 2–3 weeks) in mice infected with any strain of FV or RV, the helper-independent virus alone is pathogenic in mice only if they are infected neonatally[6,7]. We now describe how two biological markers can be used to distinguish among the otherwise confusing array of virus-induced erythroleukaemias in mice. The evidence suggests that there are three different classes of this disease: (1) those (S^+E^+) from which both defective spleen focus-forming virus (SFFV) and erythropoietin-independent, erythroid colony-forming units (CFU-EI) can be recovered, (2) those (S^+E^-) from which only SFFV (but not CFU-EI) can be recovered, and (3) those (S^-E^-) from which neither SFFV nor CFU-EI can be recovered. There is a consistent association between the type of virus used to induce the erythroleukaemia and the class of the disease induced.

Since Friend's isolation of a virus that rapidly induced "a disease having the character of a leukaemia" (ref. 8), there have been many reports on Friend virus, some containing different interpretations of the disease induced by this virus[3,9,10], others describing different host responses to different strains of the virus[11,12], and still others describing different isolations of similar viruses which induce diseases similar to that induced by Friend virus[6,7,13–16]. About a decade ago a defective virus in Friend[17,18] and Rauscher[19] virus preparations was discovered which has the capacity to induce macroscopic spleen foci[20,21] and sometimes polycythaemia[12] in susceptible strains of mice. Clearer knowledge of the virus came from Troxler and colleagues[6,22–24], who analysed single cell clones inoculated with FV-P or with FV-A, and developed from each type of infected clone SFFV-infected non-producer cell lines that were free of detectable helper virus. When they used different helper viruses to rescue infectious pseudotypes of SFFV, they found that the haematocrit response of infected hosts was associated with the origin of SFFV (from FV-P- or FV-A-infected cells) rather than with that of its helper virus[24].

Table 1 Three host response patterns to erythroleukaemia-inducing retroviruses

Virus strain	Recovery of SFFV ($\times 10^3$ FFU ml^{-1})	Recovery of CFU-EI (per 10^5 spleen cells)
FV-P (Lilly)	52.0	620
FV-P (Axelrad)	78.4	371
FV-P (Mirand)	0.2	85
FV-A (Dmochowski)	0.5	0
RV-A (Rauscher)	3.5	0
F-MuLV$_{201}$	0	0
RV-A variant (Fredrickson)	0	0

Abbreviations: CFU-EI, erythropoietin-independent, erythroid colony-forming unit; FV-P, polycythaemia-inducing strain of Friend virus complex; FV-A, anaemia-inducing strain of Friend virus complex; F-MuLV$_{201}$, clone 201 of a helper-independent murine leukaemia virus (MuLV) that was isolated from FV-A[24]; RV-A, anaemia-inducing strain of Rauscher virus complex; RV-A variant, helper-independent MuLV isolated from RV-A that lacks spleen focus-forming virus (SFFV)[7]. Virus complexes (the first five strains) considered to contain SFFV were diluted 10^{-1} from stock (10% w/v spleen homogenates) and injected intravenously into young adult BALB/c mice. Two weeks later their spleens were collected and assayed for SFFV by the spleen focus assay[20] and for CFU-EI according to the method of Liao and Axelrad[27]. Helper-independent MuLVs (the last two strains) considered to lack SFFV were not diluted from stock, but were injected intraperitoneally into suckling BALB/c mice within 48 h of birth. Three to four weeks later their spleens were collected and assayed as described above.

However, the pathology of erythroid leukaemias and dyscrasias in mice has not been well defined, and there has been little agreement among the morphological descriptions of virus-induced diseases of this sort. For example some investigators have described the diseases induced by the same viruses as erythroblastosis[9,10,25,26] or simply erythrocytopoietic disease[13]. In a search for non-morphological criteria that could be used to define erythroid leukaemias, we compared several different virus strains according to their capacity to initiate SFFV replication and/or the production of CFU-EI[27] in BALB/c mice. The results of this comparison, summarized in Table 1, show that by 3 weeks after infection the diseases induced could be divided into three categories on the basis of the recovery from splenic tissues of: both SFFV and CFU-EI (S^+E^+); SFFV but not CFU-EI (S^+E^-); neither SFFV nor CFU-EI (S^-E^-).

Let us now correlate these classes of erythroid leukaemia with the viruses used to induce them. Because of previous reports[12,27] it was not surprising that all strains of FV-P would induce S^+E^+ leukaemias. (On the basis of this clear association we would predict that the recently discovered, cloned, murine sarcoma virus[28] that induces an S^+E^+ erythroid cell proliferation might also induce polycythaemia.) The presence of SFFV in FV-A-infected mice was also not surprising, for earlier conflicting reports on this finding[12,29] were recently settled by the elegant cloning experiments of Troxler *et al.*[24]. However, the absence of CFU-EI among SFFV-positive leukaemia cells of FV-A-infected mice was significant.

Could the lack of CFU-EI in FV-A-infected mice be attributed to the lower titres of SFFV usually encountered in FV-A stocks[30]? Probably not, as the recovery of SFFV from mice infected with a low dose of FV-P (Mirand) was 10-fold lower than that of FV-A-infected mice (Table 1), although CFU-EI were only recovered from the former. Also, Steinheider *et al.*[31] failed to recover CFU-EI from FV-A-infected DBA/2 mice given an amount of SFFV 'comparable' to that given to CFU-EI-positive, FV-P-infected mice, although the actual dose of SFFV in the infecting inoculum was not stated. In the present study (data not shown) CFU-EI were readily detected in mice after infection with FV-P diluted almost to the end point for SFFV. Therefore, it seems that CFU-EI are not an expression of SFFV infection *per se*, but of erythropoietin-independent erythroid precursors destined to contribute to the development of polycythaemia. Their apparent absence after FV-A infection is in keeping with the failure of infected hosts to develop polycythaemia; this provides another qualitative distinction (in addition to the haematocrit response) between FV-A and FV-P.

The last (S^-E^-) class of leukaemias, like the first two classes, is distinctly erythroid in nature[22,32], and disease can be induced almost as rapidly (within 3–4 weeks of infection). Unlike the first two classes, the S^-E^- leukaemias develop only if the recipient mice have been inoculated with virus neonatally, probably due to the lack of immunodepressive SFFV in the viral inocula. This absence of SFFV was clearly shown for F-MuLV clone 201 by transfection experiments with molecularly cloned viral DNA[33]. Even though mice infected neonatally with F-MuLV$_{201}$ or with the Fredrickson variant of RV-A[7] did not yield SFFV or CFU-EI (Table 1), they did develop erythroid leukaemia, as tested by cytological examination of blood smears or splenic imprints.

Other candidate viral agents that might induce S^-E^- leukaemias are Dawson's F-MuLV variant[16] and Kirsten's MuLV[14]. Unfortunately, the former was not available to us, and samples of the latter failed to induce disease in our mice. There are other examples of murine viruses, apparently lacking SFFV, with the capacity to induce leukaemia[34]. These agents should all be examined and compared with the prototype strain, F-MuLV$_{201}$, by both biological and biochemical means.

It is curious that F-MuLV$_{201}$, isolated from FV-A and regularly collected from the spleens of infected mice only 3 weeks post-infection, should induce erythroid leukaemia, whereas F-MuLV originally isolated from the Friend or Rauscher virus complexes induced lymphoid leukaemias[35–37]. The latter viruses were obtained from lymphomatous lymph nodes and spleen 3–4 months post-infection, so it is possible that differences in the passage histories of these viruses altered their tissue tropism. Alternatively, there may be a genetic difference between erythrotropic and lymphotropic forms of F-MuLV in Friend and Rauscher virus stocks. One way to test the latter possibility might be to compare the pathogenic properties of erythrotropic and lymphotropic MuLV pseudotypes of polycythaemia-inducing and anaemia-inducing strains of SFFV. Such a study, recently made by Troxler *et al.*[24] with erythrotropic F-MuLV$_{201}$ and lymphotropic Moloney MuLV, failed to show any effect of the pseudotyping helper virus on the haematocrit response of mice to either polycythaemia-inducing SFFV or anaemia-inducing SFFV. More studies are needed to clarify the pathogenic roles of helper virus and defective virus in the induction of erythroleukaemia.

We thank Dr Frank Lilly for helpful discussions and Mrs Ida Shapiro and Mr Vernon Grant for secretarial and technical assistance, respectively. This investigation was supported by NCI grant CA-19873.

New regulators of melanin biosynthesis and the autodestruction of melanoma cells

John Pawelek*, Ann Körner, Alan Bergstrom & Jean Bologna

Department of Dermatology, Yale University School of Medicine,
New Haven, Connecticut 06510

The hues of mammalian skin and hair vary from white to jet black. Silvers has recently catalogued over 130 different coat colour mutations at more than 50 genetic loci in the house mouse (*Mus musculus*), a useful model for study[1]. Some of these loci govern differentiation of melanocytes and their migration from the neural crest region during embryogenesis[2]. Others, however, involve expression of genes for melanin synthesis within the pigment cell, such as *c*-locus mutations, where animals are phenotypically albino. *c*-locus albinism is presumably due to a deficiency of active tyrosinase, the enzyme catalysing the initial steps in the melanin synthetic pathway. It has generally been assumed that the only regulated steps in this pathway are those governed by tyrosinase, since *in vitro*, melanin is spontaneously formed from dopa quinone (Fig. 1). However, Logan and Weatherhead have provided evidence for post-tyrosinase inhibition of melanogenesis by melatonin in hair follicles of Siberian hamsters[5], as do our studies with various mutants of Cloudman mouse melanoma cells, suggesting the involvement of a second regulatory site. We describe here three new factors which control melanin synthesis that we have partially purified from Cloudman cells: (1) dopachrome conversion factor (DCF), which accelerates the conversion of dopachrome to 5,6-dihydroxyindole (see ref. 6 for detailed description); (2) 5,6-dihydroxindole conversion factor, which catalyses the conversion of 5,6-dihydroxyindole to melanin and is active only when cells are exposed to melanotropin (MSH), and (3) 5,6-dihydroxyindole blocking factor, which restricts melanogenesis at 5,6-dihydroxyindole. This third factor appears to protect cells from the cytotoxic effects of melanin precursors, and it is removed when the cells are exposed to MSH. Discovery of the factors indicates that regulation of the melanin biosynthetic pathway is more complex than previously supposed.

DCF has recently been described[6]. In brief, it was first discovered by the observation that extracts of amelanotic melanoma cells rapidly converted dopachrome to a colourless compound. A factor was subsequently isolated that catalysed the conversion of dopachrome to 5,6-dihydroxyindole-2-carboxylic acid followed by a spontaneous decarboxylation to 5,6-dihydroxyindole. DCF reacts specifically with dopachrome, having no effect on tyrosine or dopa. DCF was found in two different mouse melanomas (B16 and Cloudman S91), the hamster melanoma of Greene[7], and mushrooms. It was absent from Friend erythroleukaemia cells, neuroblastoma cells, myeloma cells, and L-cell fibroblasts. Serial dilutions of melanoma cell extracts showed that equal amounts of DCF were present in cells whether or not they had been exposed to MSH. All three factors were observed in experiments described below. Extracts of control cells or MSH-treated cells were mixed with dopachrome. In each case there was a rapid decrease in absorbance at 475 nm due to DCF activity compared with the slow, spontaneous decrease in the buffer blank (Fig. 2*a*). (Note that this figure shows the DCF reaction in extracts of control cells. The extent and magnitude of the reactions were the same in extracts of MSH-treated cells.) Following the DCF reaction, the samples containing extracts of control cells remained colourless for at least 24 h. However, samples containing extracts of MSH-treated cells turned dark rapidly as melanochrome (absorbing at 540 nm) and then melanin were formed (Fig. 2*b*). Melanin production in reactions with extracts of MSH-treated cells was faster than that occurring spontaneously in the reactions containing only buffer and dopachrome.

These experiments were extended using 5,6-dihydroxyindole rather than dopachrome as a substrate. Extracts of control or MSH-treated cells were mixed with 5,6-dihydroxyindole for 3 h at 30°C. The following points were evident: (1) there was a slow, spontaneous conversion of 5,6-dihydroxyindole to melanin in tubes containing buffer only; (2) melanin production was prevented by extracts of control cells; and (3) melanin production was accelerated by extracts of MSH-treated cells. After 24 h the tube containing buffer had turned black due to spontaneous melanin formation while the tubes containing extract of control cells remained colourless (data not shown).

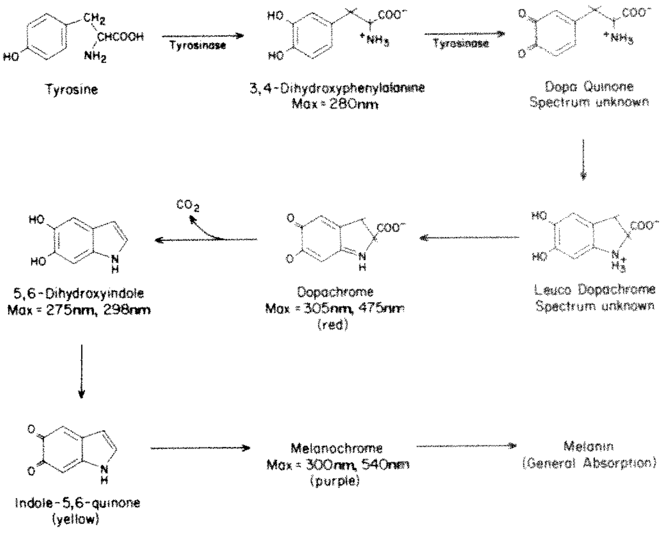

Fig. 1 Stages in the oxidation of tyrosine to melanin, modified slightly from the scheme of Mason and Raper[3]. Note that while this scheme depicts melanin biosynthesis as a polymerization of indole-5,6-quinone alone, it has been shown that mammalian melanins are heteropolymers, containing many different combinations of the precursors shown[4].

Samples were removed from the tubes and analysed for 5,6-dihydroxyindole content by HPLC (Fig. 3). The 5,6-dihydroxyindole peaks (arrows) were integrated and the results are as follows. Panel *a* shows the 5,6-dihydroxyindole content of a mixture of buffer and indole that was kept on ice for 3 h. Panel *b* shows 5,6-dihydroxyindole from the same mixture that was incubated for 3 h at 30 °C (89% of the sample in *a*). Panel *c* shows the 5,6-dihydroxyindole content of an incubated mixture

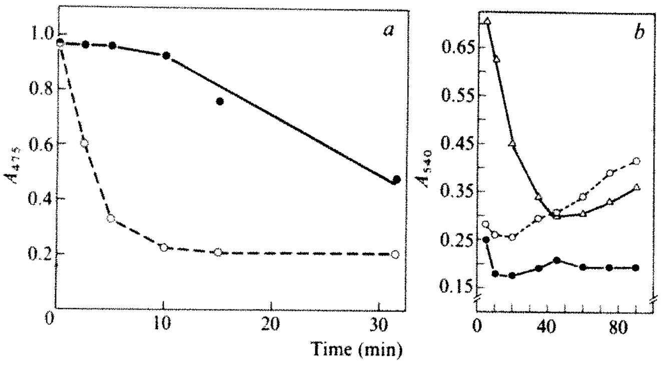

Fig. 2 Effects of cell extracts on dopachrome. Extracts were prepared from an MSH-responsive cell line (PSI-mel-1 (ref. 8)) by the following procedure. Cells were collected with EDTA (1 mM) in isotonic saline, spun for 10 min at 2,000*g*, and lysed with 5 vol ice-cold Triton X-100 (0.5%) in sodium phosphate buffer (50 mM, *p*H6.8). The lysate was then centrifuged (30,000*g*, 15 min) and the pellet containing melanin and cellular debris was discarded. Protein content of the supernatant fraction was determined by the method of Bradford[9]. Such extracts were prepared from control cells and cells that had been exposed to MSH (2×10^{-7} M) for 3 days (isobutylmethyl xanthine was not used in this experiment). The extracts (0.1 ml, 0.4 mg protein) were mixed with 0.2 ml dopachrome which had been diluted for absorbance measurements. Panel *a* shows a decrease in absorbance due to dopachrome at 475 nm after different incubation periods at room temperature with extracts from control cells (solid line: buffer; dotted line: cell extract). The disappearance in absorbance with time was due to the action of DCF which was present in equal amounts in extracts of both control and MSH-treated cells[6]. Panel *b* shows the changes in absorbance at 540 nm with time. The initial decreases were due to DCF activity since dopachrome shows some absorbance at 540 nm. Increases in absorbance at 540 nm were due to melanin synthesis which could be readily detected by the eye. Dopachrome solution was prepared by mixing a solution of dopa with Ag_2O and filtering[10]. ●, Control cell extract; ○, MSH-treated cell extract; △, buffer blank.

of indole and control cell extract (98% of the sample in *a*). Panel *d* shows the 5,6-dihydroxyindole content in the incubated mixture of indole and MSH-treated cell extract (5.7% of the sample in *a*). Thus direct measurements of the 5,6-dihydroxyindole content of the tubes confirmed what was visually apparent: melanin synthesis from 5,6-dihydroxyindole was prevented by control cell extracts and accelerated by MSH-treated cell extracts. These experiments demonstrate the existence of both a 5,6-dihydroxyindole conversion factor and a blocking factor. MSH treatment removes the blocking factor and allows for expression of the conversion factor.

It has been known for some time that melanin precursors can be cytotoxic[12–15]. Because MSH increases tyrosinase levels one would predict that, in the presence of MSH, the rate of production of melanin precursors is also increased. This has been shown to be the case in culture as cells exposed to MSH are much more susceptible to the toxic effects of tyrosine and dopa than control cells[14].

If it were true that only tyrosinase activity were affected by MSH, then the toxicity of melanin precursors distal to dopa quinone should not be influenced by the presence or absence of MSH. We show below that this is not the case. We have found that the toxic effects of dopachrome are markedly increased when the target cells have been treated with MSH (Fig. 4). (Note in Fig. 4 legend that 3-methylisobutylxanthine was used to potentiate the MSH effect.) The effects were quite striking when observed with the phase microscope. After only 1 h exposure to dopachrome (10^{-4}M), cells preincubated with MSH began to lyse. In contrast, cells exposed during this same time to either control culture medium, or medium containing MSH, dopa plus MSH, or dopachrome alone still appeared healthy. About fivefold less dopachrome was sufficient for 50% killing when the cells were exposed to MSH compared to when they were not exposed to the hormone. Addition of dibutyryl-cyclic-AMP (10^{-3} M) also increased the sensitivity to dopachrome, indicating that the cellular response was likely to be cyclic-AMP mediated (data not shown). The dose–response studies shown in Fig. 4 were done in parallel with an amelanotic variant cell line[8] that showed a very weak response to MSH in terms of pigment production. The 'non-responsive' line was only slightly sensitized by MSH to the toxicity of dopachrome. Extracts of the amelanotic line contained 5,6-dihydroxyindole blocking factor and no 5,6-dihydroxyindole conversion factor activity whether or not the cells were exposed to MSH (data not shown). We feel that the most likely explanation for the increased sensitivity of MSH-activated cells to dopachrome is the removal of the 5,6-dihydroxyindole blocking factor and the expression of active 5,6-dihydroxyindole conversion factor. We realize, however, that our evidence is only circumstantial and that more experiments are necessary to prove these points.

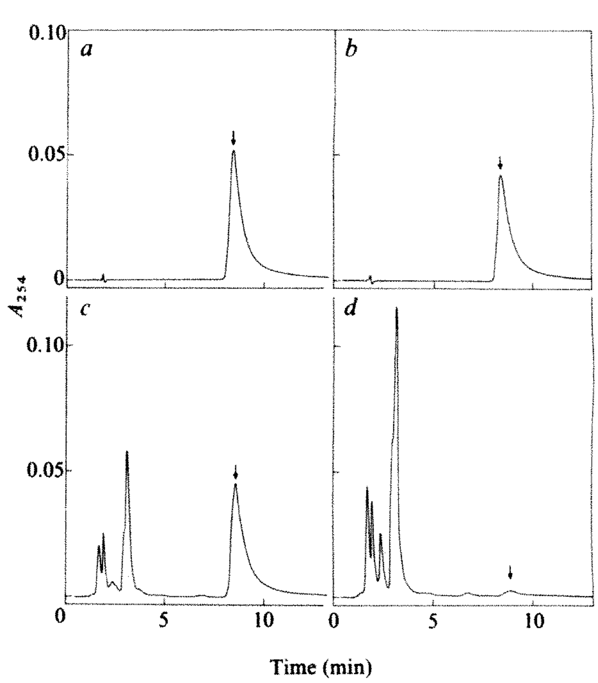

Fig. 3 Effects of extracts prepared from control- and MSH-treated cells on 5,6-dihydroxyindole as analysed by HPLC. Experimental design is outlined in the legend to Fig. 2. 5,6-dihydroxyindole (3.5×10^{-4} M) was used instead of dopachrome. Protein concentrations in the undiluted cell extracts were 7 mg ml^{-1}. The reaction mixes were adjusted to 100 µl with sodium phosphate (0.05 M, *p*H6.8), incubated in a shaking water bath at 30 °C for 3 h and aliquots (20 µl) from the tubes were analysed for 5,6-dihydroxyindole content. An Altex Molel 330 Isocractic liquid chromatograph equipped with a Model 110A pump and a 20-µl sample loop was used. Absorbance of the eluent was monitored at 254 nm with an 8-µl Analytical Optical Unit. Experiments were performed with an Ultrasil ODS Column (Altex Instruments, Inc.), 0.46 cm internal diameter × 25 cm. The column was packed with octadecyl-silica particles of 10 µm average diameter. The mobile phase was methanol/sodium phosphate (50 mM, *p*H 6.5) 1:9. Flow rate was maintained at 1.8 ml min^{-1}. 5,6-dihydroxyindole eluted at about 8.4 min (arrows). The indole was synthesized as described by Axelrod and Lerner[11] and stored in crystalline form in N_2 at −20 °C. Before each experiment, appropriate amounts of 5,6-dihydroxyindole were dissolved in degassed buffer (sodium phosphate, 0.05M, *p*H6.5). *a*, Indole plus buffer, 3 h in ice; *b*, indole plus buffer, 3 h at 30 °C; *c*, indole plus control cell extract (50 µl), 3 h at 30 °C; *d*, indole plus extract (50 µl) of MSH-treated cells, 3 h at 30 °C. Material that eluted between 1 and 4 min was from the cell extracts alone and did not change during the 3-h incubation period.

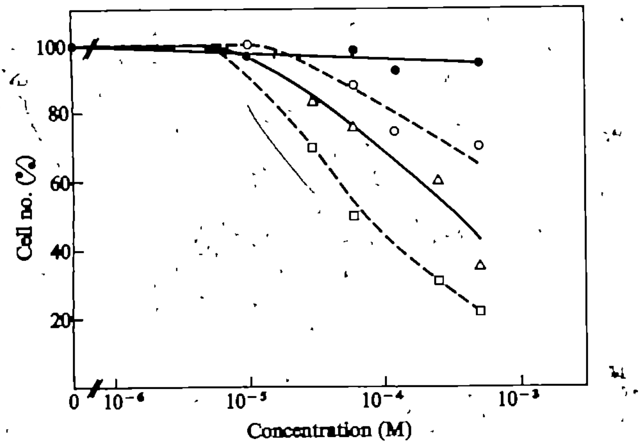

Fig. 4 Effects of MSH on the toxicity of dopa and dopachrome against Cloudman S91 mouse melanoma cells. Cells (10^5) from an MSH-responsive line (PSI-mel-1 (ref. 8)) were cultured in monolayer for two days either in plain culture medium or in medium supplemented with MSH (2×10^{-7} M) and methylisobutylxanthine (MIX 5×10^{-5} M). Two days later the cells were given fresh medium containing dopa or dopachrome as indicated. After 2.5 h, the dopa and dopachrome were removed and the cells were given fresh medium. The next day the cells were collected with EDTA (1 mM) in isotonic saline, and counted in a Coulter counter. Dopachrome was prepared as above by oxidizing dopa with Ag_2O. Control cultures received either buffer that had been mixed with Ag_2O and filtered, or buffer only (sodium phosphate, 0.05 M pH 6.8). The control cell numbers were similar in each case. Values represent the averages from quadruplicate cultures and the variation was less than ±10%. The experiments were repeated several times with similar results. MIX, a phosphodiesterase inhibitor, was used to potentiate the MSH effect. At the concentration used (5×10^{-5} M) MIX had no effect by itself. ●, Dopa; ○, dopa+MSH; △, dopachrome; □, dopachrome+MSH.

The relevance of the three factors to mammalian melanogenesis remains to be demonstrated. There are, however, numerous reports of skin and coat colour regulation which might be explained by the actions of one or more of these factors. Three examples are tyrosinase-positive albinism in humans[16], the annual pelage colour cycle in the Siberian hamster[5], and in general the wide variation in mammalian coat colours[1]. Also, the MSH-mediated sensitization of melanoma cells to dopachrome shown in Fig. 4 is likely to be explained by the factors we have described and is of relevance to the establishment of a rational therapy for human melanoma. The first step towards a full understanding of the physiological role of these factors is the elucidation of their molecular structures, a goal that we are now pursuing.

We thank Karen Vane and Marilyn Murray for providing cells, Dr Aaron B. Lerner for 5,6-dihydroxyindole, and Drs Saul Lande and Gisela Moellmann for helpful discussions. Supported by grants from the USPHS and The American Cancer Society.

Transformation-specific secreted phosphoproteins

Donald R. Senger*, Dyann F. Wirth† & Richard O. Hynes

Department of Biology and Center for Cancer Research,
Massachusetts Institute of Technology, Cambridge,
Massachusetts 02139

We have previously shown that transformed mammalian cells secrete two classes of transformation-specific proteins of molecular weight (MW) about 60,000 (ref. 1). Secretion of both classes of proteins occurs regardless of the transforming agent and is temperature-sensitive in a cell line which is temperature-sensitive for the transformed phenotype (ts B77 Rat 1; see ref. 1). One of the classes consists of non-phosphorylated polypeptides. The proteins of this class, derived from transformed mouse, rat and hamster lines, are all antigenically related to one another. The second class of transformation-specific secreted proteins is antigenically distinct from the first class, that is, it is not precipitated by antiserum which recognizes the non-phosphorylated class. This second class comprises major phosphoproteins also in the 60,000 MW range[1]. These major phosphoproteins were found to be secreted by transformed hamster, rat, mouse and rabbit cells. We now report that these transformation-specific phosphoproteins are all antigenically related, regardless of the transforming agent. The phosphoproteins are synthesized by the cells, phosphorylated intracellularly and subsequently released into the culture medium. These transformed cells also secrete protein kinase activities capable of phosphorylating the transformation-specific phosphoproteins *in vitro*. The major sites of *in vivo* and *in vitro* phosphorylation seem to be identical.

Antiserum was raised to the purified phosphoproteins secreted by B77 Rat 1 cells. $^{32}PO_4$-labelled conditioned media from several cell lines were immunoprecipitated with this antiserum. Figure 1 shows that the transformation-dependent phosphoproteins derived from the various species are, in fact, all antigenically related. The size and degree of heterogeneity of the phosphoproteins vary (Fig. 1) and seem to be dependent on the species from which the transformed cell line was derived rather than on the transforming agent[1]. There are several possible explanations for the apparent size differences and heterogeneity. The various phosphoproteins may have identical amino acid sequences but differ in degree of phosphorylation or proteolytic processing. Alternatively, the phosphoproteins may have similar but not identical primary structure. In any event, all show transformation sensitivity, and rat phosphoprotein antigens are present among the phosphoproteins of the other species.

In order to establish that the transformation-specific phosphoproteins are synthesized by the cells and do not arise by phosphorylation of serum proteins, the antiserum raised against the ts B77 Rat 1 (34 °C) phosphoproteins was preabsorbed with fetal calf serum (in which cells were cultured). This preabsorption did not alter the extent or specificity of the immunoprecipitation of the phosphoproteins of MW 62,000 (62K) (not shown). In addition, when the ts B77 Rat 1 cells (34 °C) were cultured and labelled with $^{32}PO_4$ in the absence of serum, the same amounts of 62K phosphoproteins were found in the conditioned medium (not shown). These results indicate that the 62 K phosphoproteins

---

Present addresses: *Department of Pathology, Beth Israel Hospital, Boston, Massachusetts 02215 †Biological Laboratories, Harvard University, Cambridge, Massachusetts 02138 are not fetal calf serum proteins that are simply phosphorylated by the cells.

To obtain further evidence that the phosphoproteins are synthesized by the cell, ts B77 Rat 1 cells (34 °C, transformed phenotype) were preincubated in the presence and absence of cycloheximide and then labelled with $^{32}PO_4$ in the continued presence or absence of the drug. As shown in Fig. 2, cycloheximide treatment abolishes secretion of the 62K phosphoproteins, indicating that protein synthesis is required for their phosphorylation and release from the cells.

The cell-associated forms of the B77 Rat 1 phosphoproteins were identified by immune precipitation of ^{32}P-labelled cellular lysates. Figure 3 shows the results of such an experiment, which also shows the specificity of the antiserum. From among the very large number of phosphoproteins present in cell lysates (Fig. 3, track *g*) the antiserum bound only three proteins, all of MW about 62,000 (Fig. 3, track *d*). These intracellular 62K proteins have mobilities identical with those found in the conditioned medium after a chase (Fig. 3, track *f*). We were unable to chase completely the radioactivity in the 62K proteins from cell lysates, presumably because of the difficulty encountered in chasing phosphate pools[2]. However, proportional amounts of pulse lysate and chase medium were found to contain identical quantities of 62K proteins (compare Fig. 3, tracks *d* and *f*), suggesting efficient secretion of the phosphoproteins synthesized during the pulse. Furthermore, the ratios of the different phosphate-labelled bands are the same in the pulse-labelled cells and the chase medium. These results indicate that all the 62K phosphoproteins are phosphorylated intracellularly and subsequently secreted into the culture medium in parallel.

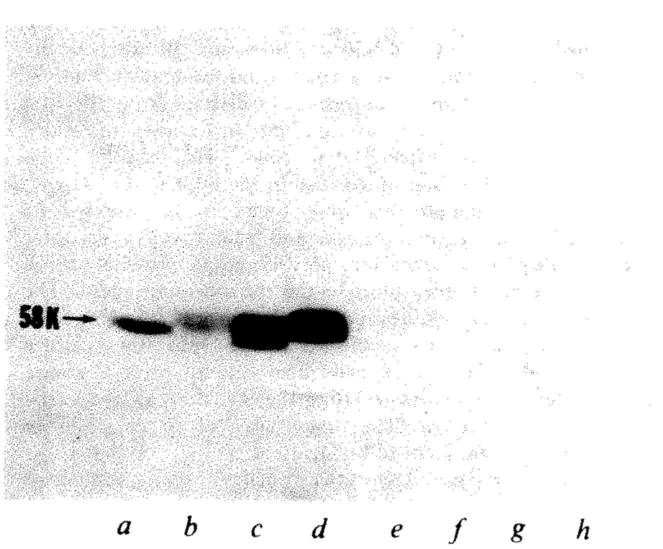

Fig. 1 ^{32}P-labelled conditioned media from various transformed cell lines were immunoprecipitated with antibody to the 62K transformation-specific secreted proteins from B77 Rat 1 cells. Cells and culture conditions, metabolic labelling with ^{32}P-orthophosphate, immunoprecipitation, SDS-polyacrylamide (7.5%) gel electrophoresis and autoradiography were as previously described[1]. Antiserum was prepared as follows. ts B77 Rat cells were grown to confluence at 34 C in roller bottles, washed three times with serum-free medium and incubated overnight with serum-free medium (200 ml per roller bottle). Conditioned medium (1,800 ml) was spun at 10,000 r.p.m. for 10 min and passed over a water-washed DE-11 cellulose (Whatman) column (100 ml). The DE-11 cellulose had been pre-swollen in acid and base as recommended by Whatman and washed extensively with distilled water before loading. Virtually 100% of the transformation-dependent 62K phosphoprotein in the conditioned medium bound to the column (there actually seem to be several transformation-dependent phosphoproteins all with similar mobility corresponding to a MW of 62,000; see track *d* above and track *f* of Fig. 3). The loaded column was then washed with 1,000 ml of 0.25 M NaCl; this step removed contaminants without eluting the 62K phosphoproteins. The 62K phosphoproteins were eluted from the column with 0.5 M NaCl and concentrated by vacuum dialysis against phosphate-buffered saline. This antigen preparation was analysed by SDS-polyacrylamide gel electrophoresis, and it was determined that 90% of the protein had mobility identical to that of the 62K phosphoproteins. The remainder consisted of several other species in very low concentration. The 58K–62K transformation-dependent, non-phosphorylated proteins, which we have described previously[1], were not present in the antigen preparation because they do not bind to DE-11 at the ionic strength used here (our unpublished data). The rabbit was injected the first time (at eight dorsal sites) with 1 mg of 62K phosphoprotein in complete Freund's adjuvant. Three weeks later the injections were repeated with 1 mg protein and incomplete Freund's adjuvant. Antibody was present in serum 2 weeks later. The specificity of the antiserum is indicated in Fig 3. *a*, Immune serum, NIL.8-HSV (hamster); *b*, immune serum, py3T3 (mouse); *c*, immune serum, Moloney MSV-MuLV SIRC (rabbit); *d*, immune serum, ts B77 Rat 1 (34 °C) (rat); *e*–*h*, preimmune serum, media as in *a*–*d*.

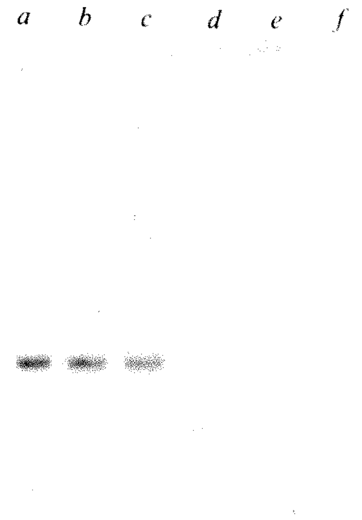

Fig. 2 Protein synthesis is required for secretion of the transformation-specific 62K phosphoproteins by ts B77 Rat 1 (34 C) cells. *a*–*c*, Media from control cells labelled for 1 h with ^{32}P-orthophosphate; *d*–*f*, media from cells preincubated with cycloheximide (20 μg ml^{-1}) for 1 h before labelling for 1 h. The prominent band in tracks *a*–*c* corresponds to a MW of 62,000.

The phosphoproteins secreted specifically by transformed cells can be phosphorylated *in vitro* by incubating the conditioned media with [γ-^{32}P]ATP. The *in vitro* labelled phosphoproteins are precipitable with the antiserum which recognizes the *in vivo* labelled form (not shown). Furthermore,

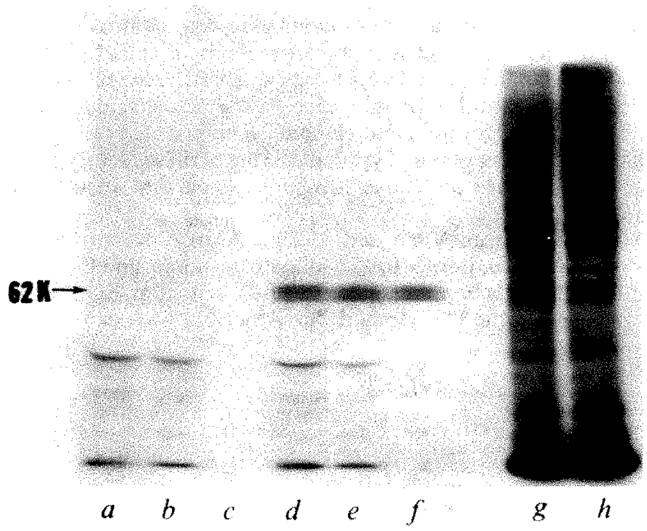

Fig. 3 ^{32}P-orthophosphate-labelled ts B77 Rat 1 (34 C, transformed phenotype) cell lysates and chase medium were immunoprecipitated with antibody to the 62K transformation-specific phosphoproteins. *a*, Preimmune serum, cell lysate, 45 min label; *b*, preimmune serum, cell lysate, 45 min label, 45 min chase; *c*, preimmune serum, equivalent amount of chase medium; *d*, immune serum, cell lysate, 45 min label; *e*, immune serum, cell lysate, 45 min label, 45 min chase; *f*, immune serum, equivalent amount of chase medium; *g*, total cell lysate, 45 min label, 1/10th the volume used in *d*; *h*, total cell lysate, 45 min label, 45 min chase, 1/10th the volume used in *e*.

a comparison of the phosphopeptides generated by partial proteolysis of the *in vitro* and *in vivo* labelled 62K phosphoproteins indicates that the major *in vitro* and *in vivo* sites of phosphorylation are likely to be identical (see Fig. 4).

Identical levels of *in vitro* phosphorylation of the 62K phosphoproteins (ts B77 Rat 1, 34 °C) were observed in serum-free conditioned medium and in conditioned medium containing 5% fetal calf serum (not shown). This result indicates that the protein kinase activity is secreted by the cells and is not a serum protein. We also found that conditioned medium from ts B77 Rat 1 cells (34 °C) can phosphorylate histones in the presence of ^{32}P-ATP, whereas unconditioned medium does not have this phosphorylating activity, again indicating secretion of protein kinase by the cells (data not shown). We have found that the phosphorylating activity secreted by B77 Rat 1 cells and ts B77 Rat 1 cells can be equally inactivated by preincubation at 41 °C. This suggests that the phosphorylating activity does not contain the lesion responsible for the temperature-sensitive phenotype of the ts B77 Rat 1 cells.

Experiments with serum from tumour-bearing animals[3,4] have suggested that the transformation-specific phosphoproteins described here are antigenically distinct from pp60^{src}, the 60,000-MW phosphoprotein encoded by the *src* gene of avian sarcoma virus. Serum active against the endogenous *sarc* gene protein of both avian and mammalian cells[5] also failed to precipitate the secreted phosphoproteins.

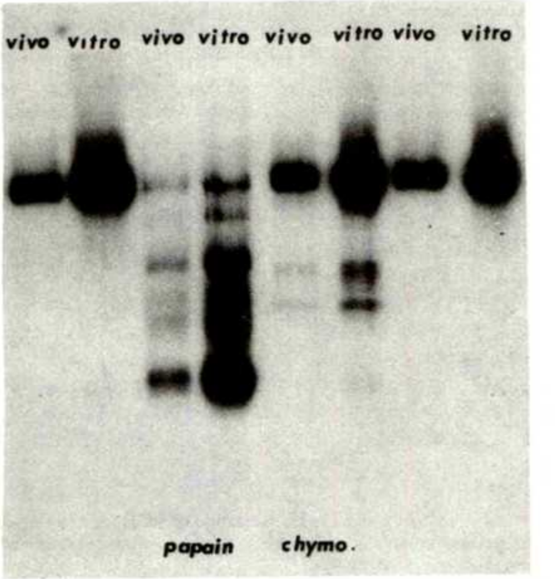

Fig. 4 Partial proteolysis of the 62K phosphoproteins from ts B77 Rat 1 (34 °C) cells labelled *in vivo* with ^{32}P-orthophosphate or *in vitro* with [γ-^{32}P]ATP. Total labelled conditioned medium, labelled *in vivo* or *in vitro* as previously described[1], was electrophoresed on a 7.5% preparative slab gel. The 62K phosphoprotein band containing all the 62K species was cut from the dried preparative gel, rehydrated in Laemmli stacking gel buffer[8] and electrophoresed on a 12.5% Laemmli gel with 250 μg papain or 50 μg chymotrypsin (chymo.), or no additions. 'vivo' 62K ^{32}P-labelled proteins from the media of cells labelled *in vivo* with $^{32}PO_4$; 'vitro', 62K proteins from the media of unlabelled cells, 62K proteins subsequently labelled *in vitro* with [γ-^{32}P]ATP.

In addition, the transformation-specific phosphoproteins are unable to phosphorylate IgG in immune precipitates, an activity which is characteristic of pp60^{src} and pp60^{sarc} (refs 4–7). However, incubations of [γ-^{32}P]ATP and washed 62K phosphoprotein immunoprecipitates did result in ^{32}P labelling of the 62K phosphoprotein itself. Whether this represents autophosphorylation or phosphorylation by a separate kinase activity in the immunoprecipitate is not known.

To summarize, the phosphoproteins described here are closely correlated with the transformed phenotype. In cells which are temperature-sensitive for transformation, secretion of the phosphoproteins is temperature-dependent. The phosphoproteins are synthesized by the cells and are not derived by phosphorylation of serum proteins. These transformation-dependent phosphoproteins are common to all mammals for which we have so far obtained transformed cell lines—hamster, rat, mouse and rabbit. Because of their antigenic relatedness, it seems likely that the transformation-specific phosphoproteins secreted by the various cell lines have a common function. Their close correlation with transformation suggests that they may be involved in the maintenance of some aspect of the transformed state.

We thank Carl Bryant and Antonia Destree for technical assistance, Naomi Foster for photography, Dr P. W. Robbins for his interest and helpful suggestions, and all those who provided the cells and antisera used in these studies. Evidence that a developmentally regulated glycoprotein is target of adhesion-blocking Fab in reaggregating *Dictyostelium*

Claudia Steinemann & Roger W. Parish

Department of Cytology, Plant Biology Institute, University of Zürich,
Zollikerstrasse 107, CH 8008 Zürich, Switzerland

The target site of adhesion-blocking Fab in aggregating *Dictyostelium discoideum* cells is a plasma membrane glycoprotein of approximate molecular weight 82,000 (refs 1–3), which is no longer synthesized after aggregation, and disappears from the plasma membrane[4,5]. However, since cell adhesion remains important during later stages of differentiation[6–8], presumably another protein(s) takes over its function. One candidate is a glycoprotein (molecular weight 95,000) whose synthesis commences at the tip stage and continues until the completion of development[5,8]. Both proteins are strongly antigenic[4]. When pseudoplasmodia ('slugs', a late developmental stage) are disaggregated and replated, the cells recapitulate the previous sequence of morphological changes much more quickly than before[6–8], although the glycoprotein of molecular weight 82,000 is not resynthesized during reaggregation[4,8]. We report here that monovalent antibody (Fab) directed against slug plasma membranes inhibits reaggregation by binding to the glycoprotein of molecular weight 95,000 which thus seems to be involved in cell adhesion.

Antisera against slug plasma membranes contained antibodies specific for a number of proteins (Fig. 1*a*). Apart from actin, the major antigen in the membrane was a glycoprotein of molecular weight 95,000 (ref. 4, Fig. 1*a*). This antigen could be extracted from the plasma membrane with butanol and was the major antigen in the butanol extract (Fig. 1*b*). Radioactive

0028–0836/80/320621—03$01.00

acetate and glucosamine were incorporated into this glycoprotein from the tip stage until late culmination[5] (Fig. 1*c*, *d*). The glycoprotein was not present in the plasma membrane of amoebae or aggregating cells[4,5].

When slug cells were disaggregated and the single cells shaken in buffer, aggregates had already formed after 45 min (Fig. 2*a*). Reaggregation was inhibited when Fab directed against slug plasma membrane was present (Fig. 2*b*). Fab directed against plasma membranes from vegetative or early aggregation cells had no effect on reaggregation (Fig. 2*d*). When a butanol extract from slug plasma membrane was incubated with the anti-slug Fab, reaggregation was no longer inhibited (Fig. 2*c*). Hence, antigens in the butanol extract were evidently competing with cells for adhesion-blocking Fab.

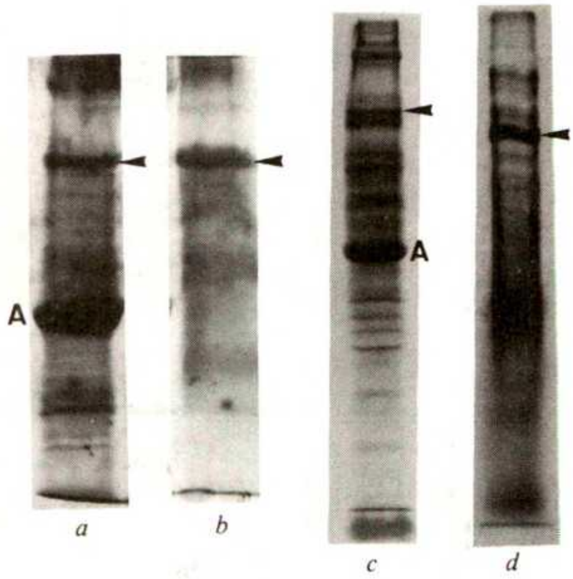

Fig. 1 The plasma membrane of slug cells: antigens and proteins incorporating L-[1 − ^{14}C]fucose and [1 − ^{14}C]acetate. Growth of *D. discoideum* NC-4 (wild type) cells, labelling of cultures with isotopes, plasma membrane isolation, SDS-polyacrylamide gel electrophoresis, autoradiography, preparation of antisera and detection of antigens on gels were performed as described previously[4,5,9]. Plasma membranes were injected into rabbits in Freunds Complete Adjuvant; injection in saline resulted in a low titre of antibody directed against the antigen of molecular weight 95,000, (indicated by the arrow). *a*, Antigens in total slug plasma membrane; SDS-polyacrylamide gels were incubated with antisera raised against slug plasma membranes. (A = actin; molecular weight 42,000.) *b*, Antigens in the butanol extract of slug plasma membranes; SDS-polyacrylamide gels incubated with antisera as in *a*. *c*, Autoradiograph of SDS-polyacrylamide gel of slug plasma membrane after labelling from the tip stage with [1 − ^{14}C]acetate. *d*, Autoradiograph of plasma membrane from early slug stage after labelling from mid-aggregation with L-[1 − ^{14}C]fucose.

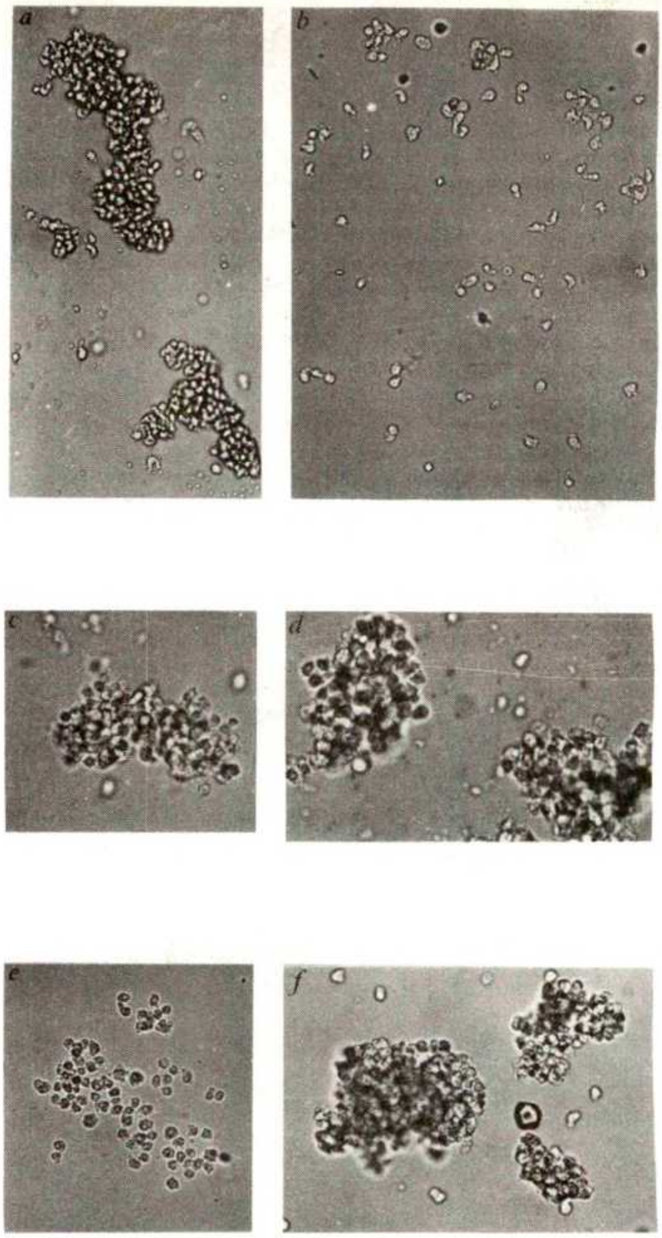

Fig. 2 The effects of Fab on the reaggregation of disaggregated slug cells. Fab was purified as described previously[9]. Reaggregation was assayed by incubating disaggregated slug cells[8] (2×10^7 cells ml^{-1}) in a roller culture (40 r.p.m., Multipurpose Rotator, Scientific Industries) in 20 mM KCl, 24 mM $MgCl_2$ and 10 mM EDTA in 0.05 M Sørensens phosphate buffer (*p*H 6.5). Fab was added to give a final concentration of 1 mg protein ml^{-1}. Removal of Fab specific for the antigen of molecular weight 95,000 was accomplished in the following way. Plasma membranes were isolated from vegetative cells (3.6×10^9) and extracted with butanol. The extract (1.1 mg protein in 370 µl) was electrophoresed on SDS slab gels (18 lanes). The region corresponding to the antigen of molecular weight 95,000 was cut out and SDS removed by shaking the gel pieces in 25% isopropanol/10% acetic acid solution for 20 h, changing the solution once. The gel pieces were then washed with 15 mM Na phosphate buffer (*p*H 6.8) for 3 h with one change of buffer. The slices were shaken for 6 h with 200 µg Fab in 2.0 ml PDF solution (20 mM KCl, 25 mM $MgCl_2$ in 0.05 M Sørensens phosphate buffer, *p*H 6.5). The PDF solution containing Fab which had not bound to the antigen in the gel was removed and the gel shaken overnight in 2.0 ml PDF solution to further remove any non-specifically bound Fab. The two PDF solutions were combined (4.0 ml) and concentrated by vacuum dialysis (final volume 0.20 ml). Hence, a Fab fraction was obtained from which the Fab binding to the antigen of molecular weight 95,000 had been at least partially removed. As controls, Fab was incubated with other regions of the gel. Cells were photographed after 45 min in the roller culture. *a*, Control; *b*, anti-slug Fab; *c*, anti-slug Fab plus proteins extracted from slug plasma membranes using butanol; *d*, Fab (against aggregation competent cells); *e*, anti-slug Fab remaining after incubation with a gel slice from the region of the gel corresponding to molecular weights 80,000–90,000; *f*, anti-slug Fab after removal of Fab specifically binding to the antigen of molecular weight 95,000.

We determined whether the antigen of molecular weight 95,000 was involved in cell adhesion by cutting the antigen from SDS gels and using the gel slices to remove the specific Fab from the total Fab[9]. The remaining Fab (more than 98% of total Fab) was subsequently unable to inhibit reaggregation (Fig. 2*f*). Preincubation of anti-slug Fab with another region of the gel (such as the region representing molecular weights 80,000–90,000) did not prevent Fab inhibiting reaggregation (Fig. 2*e*).

Anti-slug Fab was also incubated with aggregation-competent cells to remove any Fab directed against contact sites for the protein of molecular weight 82,000 that might be present. The remaining Fab still inhibited reaggregation of disaggregated slug cells. Hence the results were not due to contamination with Fab against this antigen. The anti-slug Fab did not block the EDTA-resistant adhesion of aggregation-competent cells or the EDTA-sensitive adhesion of vegetative cells. (Fab against aggregation-competent cells did, however, block the adhesion of these cells.)

Recently, Geltosky *et al.*[10] described a glycoprotein of molecular weight 150,000, present on the surface of vegetative *D. discoideum* cells, whose concentration increased during the first 10 h of development. Fab directed against this protein blocked the ability of aggregation-competent cells to reaggregate. However, the synthesis of such a glycoprotein was not detected in labelling experiments[5]. (A glycoprotein of molecular weight 155,000 was synthesized later, between early aggregation and culmination[5].) One explanation for this discrepancy would be that the glycoprotein described by Geltosky *et al.*[10] is stored in the cytoplasm of vegetative cells and transported to the cell surface during early development. It may bind to one of the glycoproteins of molecular weights 82,000 or 95,000 on adjacent cells. In our plasma membrane preparations no proteins with molecular weights of approximately 150,000 were markedly antigenic. Hence, our Fab contained few, if any, molecules directed against the glycoprotein of Geltosky *et al.*[10]. When the region of the gel corresponding to a molecular weight of 150,000 was preincubated with anti-slug Fab, the remaining Fab still inhibited aggregation.

Our results suggest that the antigen of molecular weight 95,000 is involved in cell adhesion, although we cannot be absolutely sure that it is not another protein running at around that region on gels that is responsible. However, we consider this unlikely as butanol extracts contained no other detectable proteins which ran so near to this antigen as to be included in the gel slice. The possibility that binding of Fab to the antigen of molecular weight 95,000 indirectly inhibits reaggregation by selective steric impairment of another set of molecules cannot be excluded.

The plasma membrane glycoproteins involved in cell adhesion during the early developmental stages of both *D. discoideum* (molecular weight 82,000)[2] and *Polysphondylium pallidum*[11] (molecular weight 71,000)[9] are no longer synthesized when aggregation is complete and are subsequently lost from the cells[4,5,8,9]. This may be related to the sorting out of pre-spore and pre-stalk cells that occurs during the post-aggregation phase[12–16]. The glycoprotein of molecular weight 95,000 of *D. discoideum*, for example, may be restricted to one cell type or occur at different concentrations on the two types. We are using immunofluorescence to check these possiblities. The glycoprotein of molecular weight 150,000 apparently does not disappear from the plasma membrane during differentiation[10]. However, it may be part of a second type of adhesion which is not involved in sorting out. Alternatively, a change in only one component of an adhesion system may be sufficient to induce sorting out.

We thank Dr C. R. Parish for providing the antisera. This work was supported by the Schweizerische Nationalfonds zur Förderung der wissenschaftlichen Forschung (grant no. 3.421–0.78).

Phosphorylation of membrane components is thought to be an important process in membrane function[1]. Phosphorylated proteins[2] and a special class of phospholipids, the (poly)phosphoinositides (poly PI)[3], are implicated in the regulation of membrane permeability and synaptic transmission in neurones. For many years, protein phosphorylation and poly PI metabolism have been studied in parallel without knowledge of their possible interaction. We report here that the ACTH-sensitive protein kinase/B-50 protein complex which we recently isolated in soluble form from rat brain synaptosomal plasma membranes[4,5] has lipid phosphorylating activity. Exogenously added phosphatidylinositol 4-phosphate (DPI) is phosphorylated to phosphatidylinositol 4,5-diphosphate (TPI), and this DPI-kinase activity is dependent on the state of phosphorylation of the protein kinase/B-50 protein complex. The results imply that phosphorylation of protein may affect the metabolism of (poly)PI in brain cell membranes.

Effects of peptide hormones on phosphatidylinositol (PI) metabolism in cell membranes of peripheral tissues have been obtained[6–8]. Similarly, corticotropin (ACTH) is known to affect (poly)PI metabolism in membrane fractions from rat brain[9]. An enhanced metabolism of TPI was also found in response to cholinergic and noradrenergic receptor stimulation[10] and after the influx of Ca^{2+} into the cell[11]. With respect to the phosphorylation of proteins, we found that ACTH exerts a dose- and structure-dependent inhibitory effect on the *in vitro* phosphorylation of specific proteins in synaptosomal plasma membranes[4]. The ACTH-sensitive protein kinase (molecular weight 71,000; isoelectric point 5.5) and one of its substrate proteins (B-50; molecular weight 48,000; isoelectric point 4.5) were isolated and the phosphorylation of the B-50 protein was found to be Ca^{2+}-dependent[5].

The protein kinase/B-50 complex used in the present study was obtained from a Triton–KCl solubilized synaptosomal plasma membrane fraction and subjected to further purification by DEAE-cellulose chromatography and ammonium sulphate precipitation (ASP) as described before (see legend to Fig. 1). The ASP fraction has been characterized by SDS–polyacrylamide slab gel electrophoresis: the position of B-50 and its protein kinase are indicated in Fig. 1*a*. Upon incubation of this ASP fraction with [γ-^{32}P]ATP only the B-50 protein became labelled (Fig. 1*b*). Interestingly, addition of DPI to the ASP fraction in the phosphorylation medium produced [^{32}P]TPI as shown by autoradiography after thin layer chromatography of the lipid extract (Fig. 1*c*).

When the eluate of the DEAE–cellulose column was assayed for B-50 protein and DPI-kinase activity, it was found that the two activities cochromatographed, suggesting a possible relationship (J.J. *et al.*, in preparation). Confirming previous results[6], incubation of the ASP fraction in the presence of $ACTH_{1-24}$ resulted in a dose-dependent inhibition of B-50 phosphorylation (Table 1). Concomitantly, the phosphorylation

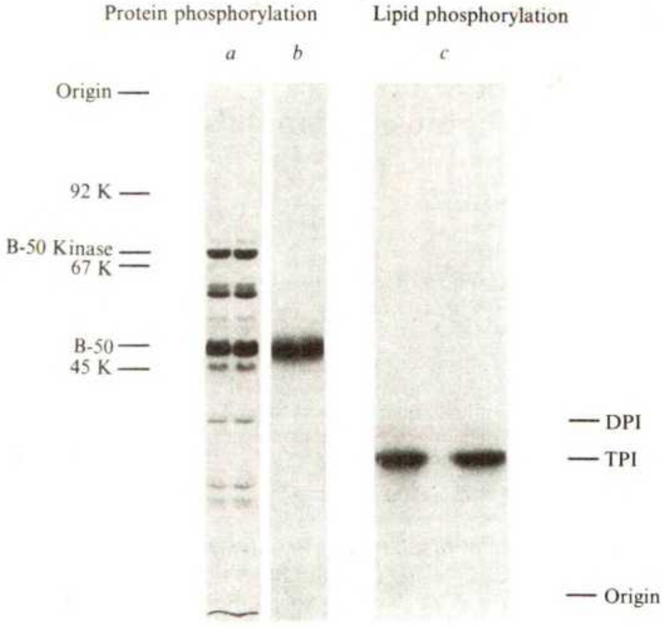

Fig. 1 *a*, Gel staining pattern showing the position of the protein bands, and *b*, autoradiogram showing the endogenous phosphorylation profile of the $ASP_{55-80\%}$ fraction. Each track contains 6 μg of total ASP protein. The position of molecular weight marker proteins, and of B-50 and B-50 kinase is indicated. *c*, Autoradiogram after extraction and thin layer chromatography of ASP fraction incubated with exogenous DPI. The position of DPI and TPI is indicated. Each lane shows the results of duplicate determinations. The ACTH-sensitive protein kinase and its protein substrate, the B-50 protein, were isolated as described by Zwiers *et al.*[5,6]. Briefly, a crude synaptosomal plasma membrane fraction was prepared from rat brain. The membrane-bound B-50 protein kinase activity was solubilized with 0.5% Triton X-100 with 75 mM KCl in 6 mM Tris, 0.1 mM dithiothreitol (*p*H 8.1) and the solubilized proteins separated by DEAE-cellulose chromatography. The proteins were eluted with a salt gradient in 10 mM Tris, 1 mM $CaCl_2$, 0.1 mM dithiothreitol, *p*H 7.4 (buffer A). The eluate fractions containing the peak of B-50 protein and B-50 phosphorylating activity were pooled and subjected to 55% ammonium sulphate saturation. After separation of the precipitated proteins by centrifugation the supernatant was saturated to 80% with ammonium sulphate and the precipitate collected by centrifugation. This $ASP_{55-80\%}$ fraction was dissolved in 400 μl buffer A and dialysed overnight against 1 l of buffer A. The phosphorylation assay was performed in the following conditions: 50 mM Na acetate, 10 mM Mg acetate, 1 mM Ca acetate (*p*H 6.5), 7.5 μM ATP, 2 μCi [γ-^{32}P]ATP (~3,000 Ci $mmol^{-1}$, Amersham), 7.5 μl ASP fraction, 40 μM DPI (disodium salt, Sigma) in a final volume of 25 μl. The enzyme fraction was routinely preincubated for 5 min before the incubation was started by the addition of DPI and ATP. Buffer with or without $ACTH_{1-24}$ was added 15 s before the ATP and incubation continued for 15 min unless indicated otherwise. Protein phosphorylation and lipid phosphorylation assays were always run in parallel. The protein phosphorylation reaction was terminated by the addition of a denaturating solution and the proteins were separated by SDS–polyacrylamide gel electrophoresis. After staining with Fast Green FCF and autoradiography the labelled protein bands were cut from the gel and measured for radioactivity by liquid scintillation counting[4,5]. The lipid phosphorylation reaction was terminated by the addition of ice-cold chloroform/methanol/13 N HCl solution (200 : 100 : 0.75 v/v). Carrier poly PI were added and an acid extraction was carried out. The lipid extract was separated by one-dimensional high performance thin layer chromatography (HPTLC) on precoated HPTLC plates (Merck) impregnated with 1% K oxalate. After lipid staining and autoradiography the labelled lipids were scraped from the plate and counted for radioactivity in a liquid scintillation counter[8,12]. All experiments were performed at least three times.

of exogenously added DPI to TPI was stimulated (+35% and +149% at 10 μM and 100 μM ACTH respectively). Because similar ACTH effects have been obtained with brain synaptosomal membrane fractions[4,12], it seems very probable that the enzymes responsive to the peptide in synaptosomal plasma membranes are present in the ASP fraction. The correlation between inhibited B-50 phosphorylation and stimulated TPI formation suggests that the state of B-50 phosphorylation may affect the DPI kinase activity (see ref. 13 for a recent review on the regulation of enzymatic activity by phosphorylation). To test this hypothesis the ASP fraction was preincubated with [γ-^{32}P]ATP for various periods of time, and DPI kinase activity was measured after this B-50 prephosphorylation period. As Fig. 2*a* shows, the extent of B-50 protein phosphorylation increased with time up to 40 min but DPI kinase activity diminished with increasing B-50 phosphorylation, providing additional evidence for a direct relationship between B-50 protein and DPI phosphorylation. It appears that the formation of TPI is especially affected by the final 30% of the protein phosphorylation; more insight into the exact molecular mechanisms involved is needed to appreciate the significance of this finding more fully. To eliminate the possibility that the decreased formation of TPI is due to enzyme breakdown during the phosphorylation period,

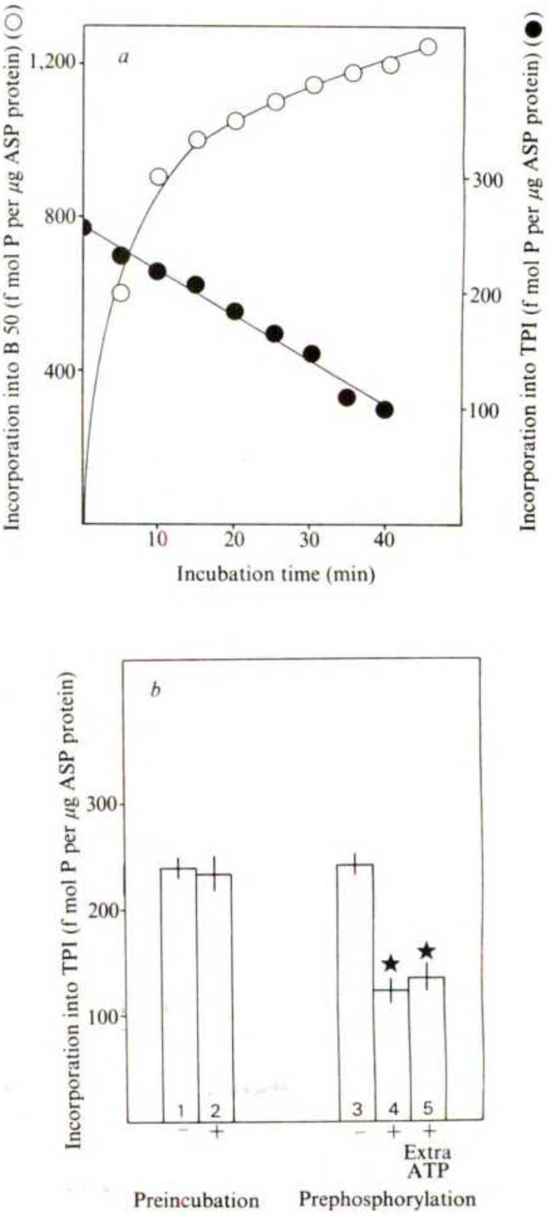

Fig. 2 *a*, The effect of B-50 prephosphorylation on TPI formation. Incubations were performed as described in the legend to Fig. 1, with the following modifications: ASP fractions were incubated in the absence of DPI for 5–45 min (○). Exogenous DPI was added to the ASP fraction after the various prephosphorylation time periods (0–40 min) and incubation continued for another 5 min. The amount of TPI formation in these 5 min periods (0–5, 5–10 min etc.) was measured (●). *b*, The effect of B-50 prephosphorylation on TPI formation: influence of preincubation and ATP. ASP fractions were incubated for 15 min in the presence of ATP and DPI as indicated in the legend to Fig. 1 (group 1 and 3). Group 2 was preincubated for 30 min before addition of DPI and ATP. Group 4 was preincubated for 30 min in the presence of ATP before DPI was added and the incubation continued for another 15 min. Group 5 was treated like group 4 but extra ATP containing 2 μCi [γ-^{32}P]ATP was added together with the DPI to give a final concentration of 15 μM ATP.

TPI formation was measured with and without 30 min preincubation in the absence of ATP. As Fig. 2*b* shows, preincubation had no effect. Furthermore, the decreased TPI formation seemed not to be related to exhaustion of ATP during the prephosphorylation, as the amount of labelled lipid was significantly depressed even after the addition of extra ATP (Fig. 2b). These results are in line with those obtained with ACTH (Table 1 and refs 4, 5, 12): there seems to be an inverse relationship between B-50 phosphorylation and TPI formation. Therefore, and in view of the studies on enzyme phosphorylation[13], we propose that the effect of ACTH on TPI production is secondary to the effect on protein phosphorylation: the peptide inhibits the B-50 kinase[4], and the B-50 substrate protein in its non-phosphorylated form, stimulates TPI formation. It awaits further experimentation to determine whether the B-50 protein is a regulatory factor of the DPI-kinase or the kinase itself.

Table 1 The effect of $ACTH_{1-24}$ on B-50 phosphorylation and TPI formation

Treatment	Incorporation (f mol P per µg ASP protein) B-50	Increase (%)	TPI	Increase (%)
No addition	994.9±8.0		180.0±9.1	
$ACTH_{1-24}$ (10 µM)	517.3±21.2	−48†	242.2±16.2	+35*
$ACTH_{1-24}$ (100 µM)	308.4±25.4	−69†	448.4±30.0	+149†

Incubations were performed as described in the legend to Fig. 1. Values represent mean ± s.e.m. ($n = 5$). Differences were tested with Student's t-test.

* $P < 0.01$.

† $P < 0.001$.

Interestingly, Takai *et al.*[14,15] recently demonstrated that the activity of a Ca^{2+}-dependent protein kinase is linked to PI and its breakdown product 1,2-diacylglycerol, suggesting that a functional relation exists between protein phosphorylation and phosphatidylinositol metabolism. DPI and especially TPI are very potent chelators of Ca^{2+} and Mg^{2+} (refs 3, 16); they interact strongly with proteins and, due to their very negative headgroup which contains three (DPI) or five (TPI) negative charges, these lipids may carry the negative potential of the membrane[17,18]. Thus a change in the relative amounts of the phosphoinositides PI/DPI/TPI in the membrane may affect the conformation of membrane proteins and change the amount of Ca^{2+} and Mg^{2+} bound to the membrane. Both protein phosphorylation[1,2] and (poly)PI metabolism[3] are implicated in the regulation of membrane permeability and synaptic transmission in neurones. The results obtained in the present study suggest that the phosphorylation of a quantitatively minor membrane protein (B-50 protein), may bring about profound changes in membrane characteristics by changing the content of poly PIs. The demonstration that ACTH influences this process may suggest new avenues for investigating the biochemical mechanisms underlying agonist–effector cell membrane interactions.

Chemically induced myotonia in amphibia

A. H. Bretag, S. R. Dawe & A. G. Moskwa

South Australian Institute of Technology, North Terrace, Adelaide, South Australia, Australia

Frogs and toads treated with high doses of anthracene-9-carboxylic acid (A-9-C) develop prolonged muscular contractions and 'divebomber' electromyograms characteristic of myotonia. Hitherto, myotonia has been considered peculiar to homeotherms where it is associated with several hereditable diseases and can be induced by specific treatments, most of which seem to act by decreasing membrane chloride conductance[1]. Our work indicates that myotonia can be induced in amphibia by similar means. We offer possible reasons why others have missed seeing myotonia in amphibia.

Toads, *Bufo marinus,* weighing about 120 g and frogs, *Littoria aurea,* of 30–60 g were kept at room temperatures of 20–25 °C and injected subcutaneously with A-9-C (167 mg per kg as a 10 mg ml^{-1} solution neutralized with NaOH). Myotonic behaviour could then be observed in the toads within half an hour. In the frogs it took a number of hours to develop. If jumping was provoked it resulted in one or a few normal jumps followed by jumps with severe extensor spasm on landing. This often caused the animal to freeze in a bizarre attitude for some seconds (Fig. 1), before slowly relaxing and then resuming a normal squatting position. Continued provocation to jump eventually resulted in a return to normal. After rest for half an hour, however, the whole cycle could be repeated. This kind of response could be obtained for 2 or 3 days following the injection of A-9-C after which jumping behaviour gradually returned to normal over the next few days.

Library
SCIENCE COLLEGE,
Upper Circular Road
CALCUTTA.

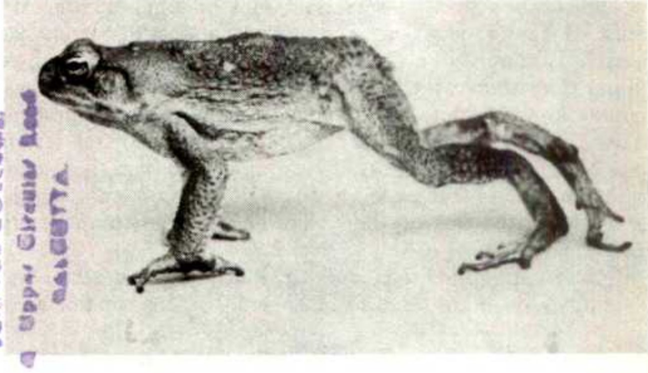

Fig. 1 An A-9-C treated toad, still immobile and stiff-legged, ~3s after landing from a jump. We have occasionally seen these animals overbalance on landing to become supported on their forelegs and snout with their hind legs extended above them. By contrast, untreated toads jump, land and resume their normal squatting position within half a second.

While animals were displaying myotonic behaviour, audio electromyograms could be recorded from leg muscles with frequent 'divebomber' bursts of activity in response to slight movements of the concentric recording needle. After exercise 'warm up', divebomber sounds were virtually eliminated.

Sartorius muscles, *in vitro,* could also be made to produce myotonic contractions (Fig. 2*a*) in response to A-9-C at concentrations comparable to those expected to pertain in the *in vivo* experiments. Similar results could be obtained using 4,

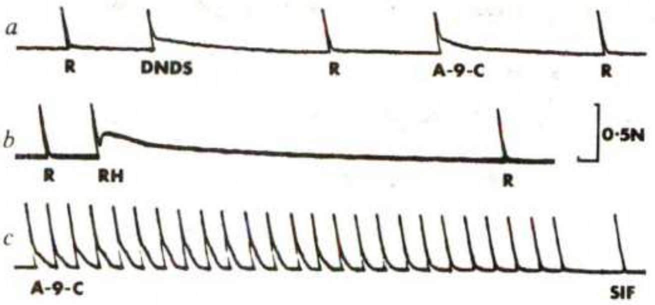

Fig. 2 Isometric tension records from isolated frog and toad sartorius muscles bathed at room temperature (20 °C) in Ringer solution[2] (R) and synthetic interstitial fluid[3] (SIF), respectively. Muscles were allowed to equilibrate in particular solutions for 10 min before stimulation with a train of three, just supramaximal, 1 ms pulses[4] at 225 Hz. *a*, Frog sartorius muscle in control solution (R) and with the addition of DNDS (2mmol l^{-1}) and A-9-C (2.25 mmol l^{-1}) showing that normal relaxation is interrupted and prolonged by these agents. Time scale, 1 s. *b*, Frog sartorius muscle. Response in control solution (R) compared with response in a chloride-free solution (RH) made by substituting appropriate quantities of sodium 3,5-diacetamido-2,4,6-triiodobenzoate (Hypaque, Winthrop) for sodium chloride, and potassium and calcium sulphate for their chlorides. Cationic activities were maintained constant[5]. Time scale, 1 s. *c*, Toad sartorius muscle. Record of contractions resulting from stimulation at 5 s intervals in the presence of A-9-C (2.25 mmol l^{-1}). After about 20 such stimuli the prolonged relaxation returns to normal, as illustrated in the final contraction of the record which was initiated 10 min after washout of the A-9-C with SIF. Time scale, 5 s.

4'-dinitro-2, 2'stilbenedisulphonic acid (DNDS, Fig. 2*a*), furosemide (not shown) or a chloride-free bathing solution (Fig. 2*b*). Muscles were stimulated only once every 10 min as 'warm up' was rapidly produced by more frequent stimuli (Fig. 2*c*). Typical myotonic after-discharges of action potentials could be found in A-9-C treated toad sartorius muscle fibres following constant current stimulation (Fig. 3). An increase in input resistance was observed in these A-9-C treated fibres.

The effects we have observed in amphibian muscle suggest a reduced membrane leakage conductance and, as in mammalian muscle[1], are most likely to be low chloride-conductance myotonia. Consistent with this interpretation, A-9-C is the most potent known chloride conductance blocker in mammalian muscle[6] while DNDS and furosemide are similarly potent blockers of anion transport in red blood cells[7] and the kidney respectively[8]. In our experiments their action cannot be distinguished from that of a low chloride solution (compare Fig. 2*a*, *b*).

Induced myotonia has not previously been described in amphibia and there seem to be several reasons for this apart from the possibility of species differences. First, the doses of A-9-C that we have used are considerably higher than those used by others[9] and the long delay before significant behavioural effects appear in frogs may have caused slight myotonia to be overlooked. Second, since exercise quickly produces 'warm up', myotonia is best seen if the animals are closely confined for half an hour before testing.

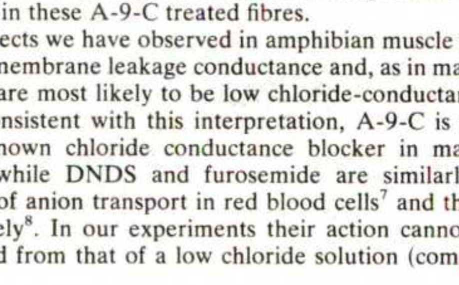

Fig. 3 Intracellular 3M KCl microelectrode recording of a myotonic after-discharge of action potentials in a single fibre of toad sartorius muscle bathed in SIF containing A-9-C (2.25 mmol l^{-1}) at 20 °C. The fibre was stimulated by the constant current pulse shown in the upper trace delivered through a second microelectrode (2M K citrate) inserted close to the voltage recording electrode.

We thank the Muscular Dystrophy Association of S.A. and the Research Committee of the South Australian Institute of Technology for support.

Control of tension development in scallop muscle fibres with foreign regulatory light chains

R. M. Simmons & A. G. Szent-Györgyi

Department of Physiology, University College London, Gower Street,

We have shown previously that chemically skinned fibre bundles from scallop muscle can be desensitized to the action of calcium by the removal of the regulatory light chains of myosin and that sensitivity can be restored by the re-addition of scallop light chains[1]. We have now confirmed these results and extended our observations to fibre bundles from which one or both of the regulatory light chains per myosin have been removed (by treatment with EDTA at 7 and 25 °C, respectively) and replaced by the corresponding light chains from other species. In the case of a double substitution—where both light chains were replaced—sensitivity was restored completely by light chains from other molluscs and from gizzard muscle; for a single substitution there was restoration of sensitivity by all the light chains tested.

The tension response of a chemically skinned fibre bundle to an activation–relaxation sequence is shown in Fig. 1*a*. There was no tension development in relaxing solution ($[Ca^{2+}] < 10^{-10}$ M) and maximal development in activating solution ($[Ca^{2+}] = 10^{-4.8}$ M). Treatment with EDTA at 25 °C removed both regulatory light chains, as shown in other preparations by urea gel electrophoresis, and tension development was maximal in relaxing solution as well as in activating solution (Fig. 1*b*). Thus, the fibre bundle was no longer sensitive to calcium, in the sense that regulatory control had been completely lost.

Fully desensitized fibre bundles were exposed to light chains from the same and other species, tested for their sensitivity to calcium and analysed for light chain content by urea (and in some cases SDS) gel electrophoresis. The results are summarized in Table 1. In most cases, two light chains per myosin were successfully combined. Preparations treated with light chains from the scallop and other molluscan species (spisula, mercenaria and loligo) showed a complete restoration of sensitivity towards calcium (Fig. 1*c*). Sensitivity was also restored by the combination of chicken gizzard light chains (Fig. 1*d*), but rabbit skeletal, bovine cardiac and lobster tail muscle light chains had little or no effect (Fig. 1*e*). Some fibre bundles which

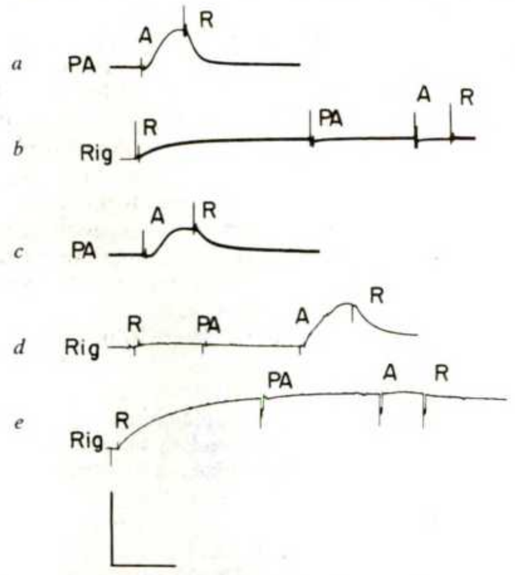

Fig. 1 Double-substitution experiments. Tension responses of skinned fibre bundles to activation–relaxation sequences; effects of complete removal of scallop regulatory light chains and of replacement by light chains from the scallop and other species. *a–c*, Same fibre bundle; *a*, before EDTA treatment; *b*, desensitized by treatment with EDTA at 25 °C (control); *c*, resensitized with scallop light chains; *d*, complete substitution of scallop light chains by gizzard light chains; *e*, complete substitution by lobster light chains. Fibre bundles were from the striated adductor muscle of *Placopecten magellanicus*. Removal and addition of light chains were as described in Table 1 legend. Symbols for solutions: PA, pre-activating (a relaxing solution with low [EGTA] to increase rate of tension development in activating solution); A, activating; R, relaxing; Rig, rigor. Solutions[6] (concentrations in mM unless stated): PA; EGTA 0.1, HDTA 29.9, $[Ca^{2+}] \sim 10^{-8}$ M. A; CaEGTA 30, $[Ca^{2+}] = 10^{-4.8}$M. R, Rig; EGTA 30, $[Ca^{2+}] < 10^{-10}$ M. PA, R, A; phosphocreatine 19, [MgATP] = 5, creatine kinase 1–2 mg ml^{-1}. All solutions; $[Mg^{2+}] = 1$, trimethylamino ethanesulphonic acid 100, *p*H 7.0, I 0.2 M, 20 °C. Scales: *a–c*, tension 100 mg, time 1 min; *d*, *e*, tension 84 mg, time 41 s. Tension was close to zero at the start of the records.

had been treated with cardiac and rabbit skeletal light chains produced less tension than normal both in the presence and absence of calcium. This inhibition was particularly pronounced after long incubations with light chains and no inhibition was observed when the same fibre bundle was tested before and after the addition of light chains, when full combination was achieved after incubation for 1 h.

Although it was comparatively simple to remove both scallop light chains per myosin, it proved difficult to remove exactly one light chain per myosin (by treatment with EDTA at 7 °C, which is successful with myofibrillar preparations[2–4]). Different preparations and slightly different procedures resulted in from 0.7 to 0.9 light chains remaining. These fibre bundles did not show a complete loss of sensitivity towards calcium, that is, the tension developed in activating solution was greater than that in relaxing solution (control fibre bundles in Fig. 2*a* and Table 2). This result is difficult to interpret quantitatively because light chain removal may not have been homogeneous throughout a bundle, so that some myosin molecules may have remained with both light chains intact. The addition of non-molluscan light chains to such fibre bundles resulted in the combination on average of more than one foreign light chain per myosin and there was a considerable variation in the amount combined (range 1.26–1.60 light chains per myosin). All the light chains tested gave a considerable restoration of sensitivity towards calcium (Fig. 2*b* and Table 2) and it is likely that the restoration was mainly due to the combination of foreign light chains to myosin molecules with a single remaining scallop light chain. The degree of restoration of sensitivity for rabbit skeletal and cardiac light chains is surprisingly high; the gel results show that a substantial number of myosin molecules must have become doubly substituted, and these molecules would have remained desensitized (Table 1). It is possible that the inhibition of tension development observed for double substitutions by these light chains reduced their contribution, resulting in an overestimate of sensitivity. Double substitution by lobster light chains had no inhibitory effect and it is noticeable that the degree of restoration of sensitivity in the single substitution experiments with lobster light chains was less than for cardiac or rabbit skeletal light chains. The full restoration of sensitivity by gizzard light chains was to be expected as these light chains confer sensitivity on their own (Table 1).

These results confirm ATPase measurements in scallop myofibrils; when both scallop light chains have been removed, sensitivity can be wholly restored by the combination of light chains from molluscan species and from vertebrate smooth muscle, but not with light chains from vertebrate skeletal, cardiac or lobster muscle[5]. They also confirm that sensitivity is restored in the case of a single remaining scallop light chain following the combination of light chains that do not themselves confer sensitivity towards calcium[3,4].

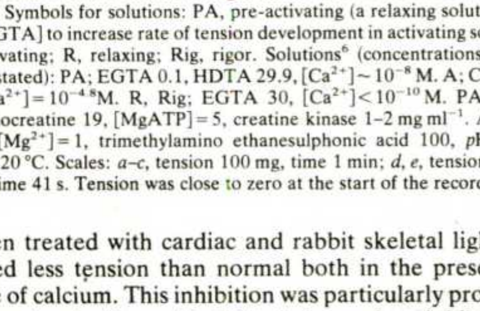

Fig. 2 Single-substitution experiments. Effect on tension development of removal of a single scallop regulatory light chain and replacement by a non-molluscan light chain. *a*, Single remaining scallop light chain (control); *b*, single substitution by cardiac light chains. Solutions as described in Fig. 1 legend. Scales: *a*, tension 50 mg, time 1 min; *b*, tension 50 mg, time 43 s.

Table 1 Regulatory light chain content and calcium dependence of tension development in double-substitution experiments

Source of added regulatory light chain	No. of fibre bundles	% Sensitivity (mean±s.d.)	Regulatory light chains per myosin (mean ± s.d.)
Control	15	0	0
Scallop striated	7	89 ± 18	1.66 ± 0.35
Spisula	2	100	1.76
Loligo syphon retractor	2	98	2.14
Mercenaria	3	95 ± 3	1.77 ± 0.10
Bovine cardiac	4	14 ± 28*	1.74 ± 0.12
Rabbit striated	9	5 ± 6	1.84 ± 0.45
Lobster tail	4	3 ± 2	1.65 ± 0.46
Chicken gizzard	6	92 ± 5	2.05 ± 0.30

Sensitivity of tension development (second column) was obtained from the ratio of the extra tension developed in activating solution (compared with the tension in relaxing solution) to the total tension developed in activating solution and expressed as a percentage. Fibre bundles were chemically skinned with 1% Brij 35 in 50 mM KCl, 5 mM EGTA, 5 mM $MgCl_2$, 5 mM ATP and 20 mM imidazole-HCl, *p*H 7.0, usually at 18–20 °C for 0.5–1 h. Light chains were removed by a 0.5–3-h incubation at 25–27 °C with 10 mM EDTA in 40 mM KCl and 20 mM imidazole-HCl, *p*H 7.0. Fibre bundles were combined with light chains by a 1–3-h incubation with 0.5 ml 0.1% light chain in 50 mM KCl, 5 mM $MgCl_2$, 5 mM EGTA and 20 mM imidazole-HCl, *p*H 7.0, in the presence of 1 mM freshly prepared dithiothreitol. Incubation at 4 °C gave the most reproducible results for tension measurements. Light chains were prepared as described previously[4]. Scallop, mercenaria and spisula light chain contents were determined by urea–acrylamide gel electrophoresis; lobster, loligo, rabbit skeletal, cardiac and gizzard light chain contents were obtained from 14–15% SDS-acrylamide gel electrophoresis in phosphate. Fibre bundles were rinsed with water and freeze-dried. Sample buffer (70 µl) was added to the dried fibre bundles and incubated for 3 min in boiling water (SDS gels) or for 2 h at 37 °C (urea gels). Although the fibre bundles did not dissolve completely in the sample buffer, the light chains dissociated fully and repeated incubation with new sample buffer did not extract additional light chains. Aliquots (50 µl) of the samples were applied on tube gels. Gels were stained with acid fast green and analysed densitometrically. Densities obtained with light chains were corrected for molecular weights and stain uptake. Regulatory light chain content per myosin was obtained from the density ratios of the regulatory and essential light chain bands. The two essential light chains of myosin are not removed by EDTA treatment[2], so a ratio of 1 corresponds to 2 regulatory light chains per myosin.

* Three of the fibre bundles gave low tensions.

Table 2 Regulatory light chain content and calcium dependence of tension development in single-substitution experiments

Source of added regulatory light chain	No. of fibre bundles	% Sensitivity (mean ± s.d.)	Scallop regulatory light chains per myosin (mean ± s.d.)	Foreign light chains per myosin (mean ± s.d.)
Control	7	43 ± 21	0.78 ± 0.07	
Bovine cardiac	6	96 ± 3		1.35 ± 0.08
Rabbit striated	6	88 ± 8		1.47 ± 0.11
Lobster tail	6	73 ± 17		1.33 ± 0.09
Chicken gizzard	6	98 ± 3		1.52 ± 0.12

Methods used were similar to those given in Table 1 legend except that incubation in EDTA solution was at 7 °C.

These experiments were performed at the Marine Biological Laboratory, Woods Hole and at University College London. The work was supported by PHS grant AM 15963 and a Muscular Dystrophy Association grant to A.G.S.-G. and a Programme Grant from the MRC to R.M.S. We thank the Wellcome Trust for a travel grant to R.M.S.

Formation of helical filaments by copolymerization of two types of 'straight' flagellins

Ritsu Kamiya & Sho Asakura

Institute of Molecular Biology, School of Science, Nagoya University, Nagoya 464, Japan

Shigeru Yamaguchi

Department of Biology, School of Education, Waseda University, Tokyo 160, Japan

Bacterial flagella undergo transition between several discrete types of left-handed and right-handed helical structures when exposed to acidic[1] or alkaline *p*H[2], or to mechanical force[3]. Calladine[4] and ourselves[5] have presented models to explain such polymorphism, assuming that protein subunits (flagellin) in a flagellum can be transformed into two conformations (L- and R-states) depending on the species of flagellin and on the environmental conditions. An obvious prediction from these 'two-state' models is that there should be two types of straight flagella (L- and R-types) that are made up exclusively of flagellins in either the L-state or the R-state. We have shown that straight flagella from two species of mutants, *Salmonella* SJ814 (ref. 6) and *Escherichia coli* hag 177 (ref. 7), are closely similar to the predicted R- and L-types, respectively[5]. Recently we have isolated 10 strains of straight-flagellar mutants of *Salmonella*. We show here that their flagella can also be classified into the L- and the R-types, and that copolymerization of flagellins from two heterologous types (L and R) makes discrete types of helical filaments, whereas that of homologous pairs of flagellins (L and L, or R and R) makes only straight filaments.

Ten mutant strains with a straight-flagellar phenotype (SJW 1655–SJW1664) were isolated from SJW1103, which produces normal flagella with the antigenicity of i in phase 1 and is nonflagellate in phase 2 (S.Y., in preparation). All of them are spontaneous mutants selected on semi-solid agar plates. Flagella from these mutants were examined by electron microscopy and optical diffraction, after they had been detached from the cell body and partially purified by differential centrifugation. It was found that the diffraction pattern of the SJW1655 flagella was significantly different from those of the other nine species. Most notably, the *z*-coordinate of the near-equatorial layer-line (the reflection from 11 near-longitudinal rows of subunits[6]) was as large as 1/400 $Å^{-1}$ in SJW1655, whereas it was about threefold smaller in the rest of the mutants (Fig. 1). As the diffraction pattern of the SJW1655 flagella was closely similar to that of *Salmonella* SJ814 flagella[6], we considered these two types of flagella to be homologous forms. The twisting of the near-longitudinal rows of subunits in the SJW1655 flagella, obtained from 34 measurements, was 7.8 ± 0.8° at the surface of the flagellum. This value was in good agreement with the twisting predicted for the R-type straight flagella[5]. On the other hand, the diffraction patterns of the other nine kinds of straight flagella were similar to that of *E. coli* hag177 flagella[7], which have been considered to be L-type[5], in that the spacing of the near-equatorial layer-line was about 1,500 Å. Measurements of this spacing in 31 diffraction patterns of SJW1660 flagella indicated that the near-longitudinal rows of subunits in this kind of flagella were inclined at an angle of 3.4 ± 1.0° with respect to the filament axis. Also, the other species of flagella (about 10 measurements for each) had mean values of twisting of between 2.0° and 3.4°, agreeing with the value predicted for the L-type[5]. From these results, we considered that flagella from strains SJW1656 to SJW1664 belonged to the L-type.

Flagellins from two R-type mutants (SJ814 and SJW1655) and two L-type mutants (SJW1658 and SJW1660) were mixed pairwise in all possible combinations at various protein ratios, and polymerized by the addition of fragmented flagella[8]. It was

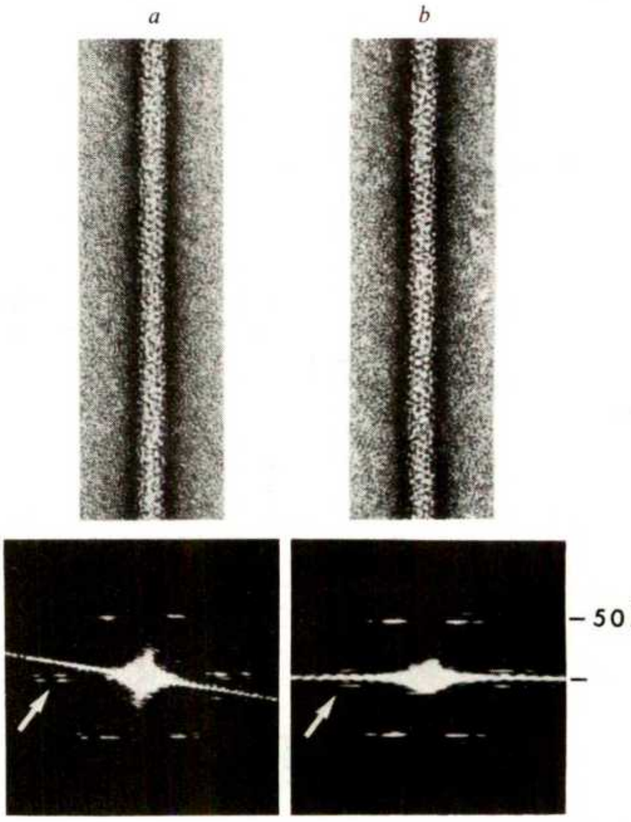

Fig. 1 Electron micrographs and optical diffraction patterns of the two types of straight flagella. *a*, The L-type from SJW1660; *b*, the R-type from SJW1655. Flagellar specimens were negatively stained with 1% uranylacetate. The diameter of the flagellum is about 200 Å. In the diffraction pattern, the near-equatorial layer-line is arrowed. Other mutants (SJW1656–SJW1659, SJW1661–SJW1664) gave diffraction patterns closely similar to that of *a*.

0028-0836/80/320628—03$01.00

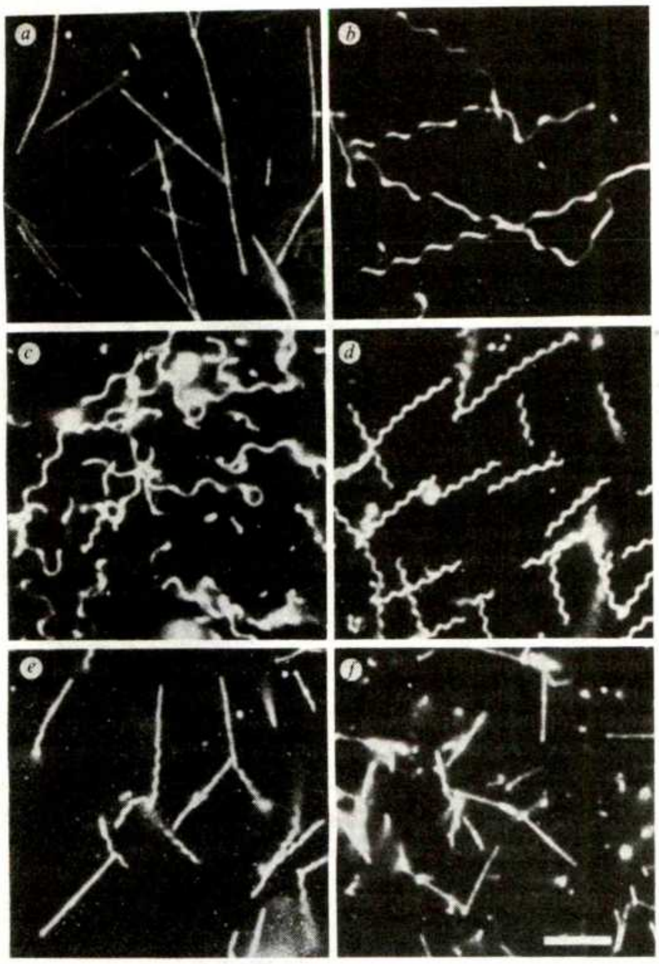

Fig. 2 The products of copolymerization of flagellins from SJW1660 (L-type) and SJW1655 (R-type) at various mixing ratios. The protein ratio of the R-type flagellin to the total monomers was: *a*, 0%; *b*, 10%; *c*, 25%; *d*, 50%; *e*, 90%; *f*, 100%. The two kinds of monomeric flagellins were prepared by the method of S.A. and Iino[8] to give a concentration of 5.0 mg protein ml^{-1} in 0.15 M NaCl. After they had been mixed at various ratios, 1/20 to 1/8 volume of fragmented flagella from SJW1655 (5.0 mg ml^{-1}) was added to each mixture as nuclei for polymerization. It took about 2 days for almost all the flagellin monomers to be polymerized. Essentially the same results were obtained when fragmented flagella from SJW1660 were used as the polymerization nuclei. The SJW1665 flagellin polymerized much more slowly than the SJW1660 flagellin, and for unknown reasons, it was difficult to obtain long polymers of the SJW1655 flagellin. All the photographs were taken with a dark-field microscope with an intense light source[1] after the specimens had been diluted to about 0.03 mg ml^{-1} with 10 mM sodium phosphate buffer (*p*H 7.0). Scale bar, 5 μm.

found that when homologous pairs of flagellins (L and L, or R and R) were mixed, the products were always straight filaments, irrespective of the mixing ratio. However, when heterologous combinations of flagellins (L and R) were mixed, the products assumed various helical forms (Fig. 2). As in the previous experiments of copolymerization using flagellins from SJ814 and from a wild-type strain[8], helical shapes assumed by the products were discrete. It was the frequency of appearance of a helical form that depended on the mixing ratio of the two kinds of flagellins. The frequency of a helical form depended also on the species of the two types of flagellins used. When the ratio of the R-type flagellin was less than 25% of the total monomers, in the copolymerization of the SJW1660 and the SJW1655 flagellins, the products were mostly left-handed helices, including a form resembling the wild-type flagella (normal form). As the ratio of the R-type flagellin was increased, several types of right-handed helices appeared, including the so-called curly type. We have observed seven types of helical forms in these copolymerization experiments besides the two types of straight flagella. Morphological analyses of these helices will be reported elsewhere.

As the antigenicity of the SJ814 flagellin (1, 2) was different from that of the other kinds of flagellins used (i), we could prove that the polymers formed in the mixture of the SJ814 and one of the other species of flagellins were actually copolymers, by showing that all of them could be labelled with either anti-1, 2 or anti-i antibody (Fig. 3). The distribution of the antibodies along a filament showed a strong gradient, corresponding to the different rate of polymerization of the two kinds of flagellins. Such a gradient has frequently been observed in previous studies of copolymerization[8,9], and may explain the simultaneous occurrence of several types of helices in a single copolymer. We are now examining the distribution of the antibodies at a substructural level in heterologous copolymers such as shown in Fig. 3*a*, to see whether or not the two types of flagellin molecules are arranged with regularity. Although we have not come to a definite conclusion due to the limited resolution of electron micrographs, our impression has been that the substructural distribution is rather random. If this is found to be the case, we should assume that the flagellin molecules from either the L- or the R-type of straight flagella can be transformed into both L- and R-forms once they are incorporated into a copolymer, and that a flagellar filament has an inherent ability to organize itself into a uniform helix. At any rate, our demonstration that two types of flagellins from straight flagella copolymerize into helical

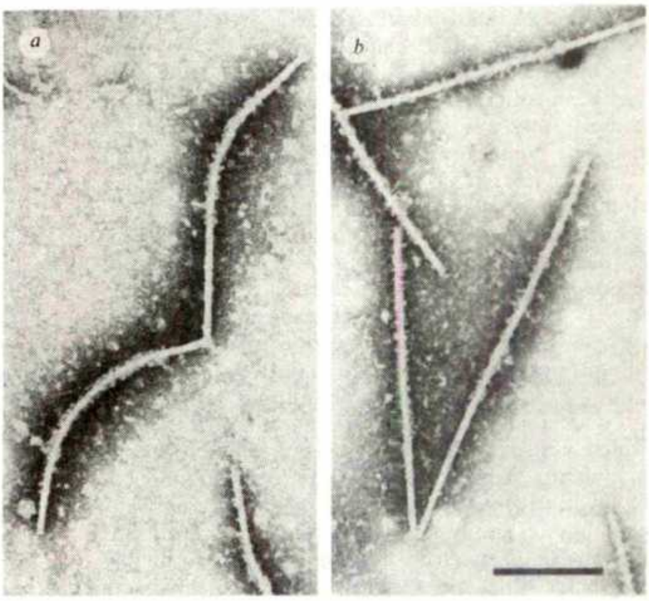

Fig. 3 Antibody staining of copolymers. Flagellins used are: *a*, SJ814 (R-type, antigenicity 1, 2) and SJW1660 (L-type, antigenicity i); *b*, SJ814 and SJW1655 (R-type, antigenicity i). Note that the filaments are curved in *a*, whereas they are straight in *b*. In each case, 1 : 1 mixture of the two kinds of flagellins (5.0 mg ml^{-1}) was polymerized by the addition of 1/2 volume of fragmented flagella from SJ814 (5.0 mg ml^{-1}). After being adsorbed onto electron microscope grids, the specimens were treated with anti-i antibody and negatively stained with 0.5% phosphotungstate (*p*H 7.0). In both of the photographs, the V-shaped portions with no antibodies attached correspond to the fragments of the SJ814 flagella used as the nuclei of polymerization. In *a*, the density of antibodies rapidly decreases along the length towards the tip, indicating that the SJW1660 flagellin was incorporated much faster than the SJ814 flagellin. When these specimens were reacted with anti-1, 2 antibody instead of anti-i, whole lengths of filaments were labelled, with density distributions complementary to these photographs (data not shown). Scale bar, 0.2 μm.

filaments should provide strong support for the idea that flagellar polymorphism arises as the consequence of dimorphic transition of the flagellin molecules.

A conformational isomer of bovine pancreatic trypsin inhibitor protein produced by refolding

D. J. States, C. M. Dobson, M. Karplus & T. E. Creighton*

Department of Chemistry, Harvard University, 12 Oxford Street,
Cambridge, Massachusetts 02138

Hills Road, Cambridge CB2 2QH, UK

Refolding of the bovine pancreatic trypsin inhibitor protein (BPTI) after reduction of its three cysteine disulphide linkages can occur when the reduced protein is placed in a suitable oxidizing medium (ref. 1 and refs therein). The refolding process has been studied by trapping chemically intermediates which contain only one or two disulphide bonds (ref. 1 and refs therein). We report here that during structural studies of these intermediates by NMR, we have found that complete re-oxidation of the protein results in substantial quantities of a metastable folded species which is identical to native BPTI in its covalent bonding (including the disulphide bonds) but possesses a somewhat different conformation. The existence of such a species is supported by circular dichroism measurements on refolded BPTI[2]. This novel form of BPTI is of considerable interest because it can be used to provide information about the folding mechanism and conformational stability of the protein.

Figure 1 shows ^{1}H NMR spectra of native BPTI and of BPTI which was reduced and re-oxidized fully as described in detail elsewhere[3]. The overall appearance of the spectrum of the re-oxidized material is similar to that of the native protein, but examination shows that two species are present. One of these has an NMR spectrum indistinguishable from that of native BPTI; the other has a slightly different spectrum and is a new species formed in the refolding process. Samples of BPTI were reduced and refolded in various conditions (using oxidized dithiothreitol rather than glutathione as the oxidizing agent and varying the *p*H, ionic composition and temperature of the refolding environment). In every case a mixture of two products was obtained and the novel species had the same NMR spectrum. It seems, therefore, that a conformational isomer exists which has a structure independent of the specific folding conditions, although the amount of the isomer produced does depend on them. In particular, more isomer was observed when refolding was carried out with slower rates of disulphide formation and at lower temperatures; the ratio of the isomer to native BPTI varied from 2.3 at 5 °C to 0.7 at 35 °C in the conditions described in Fig. 1 legend.

The NMR spectra of samples of the refolded material remained essentially constant when samples were left in solution for days at room temperature. Warming the solution to 37 °C for several minutes resulted in the disappearance of the resonances

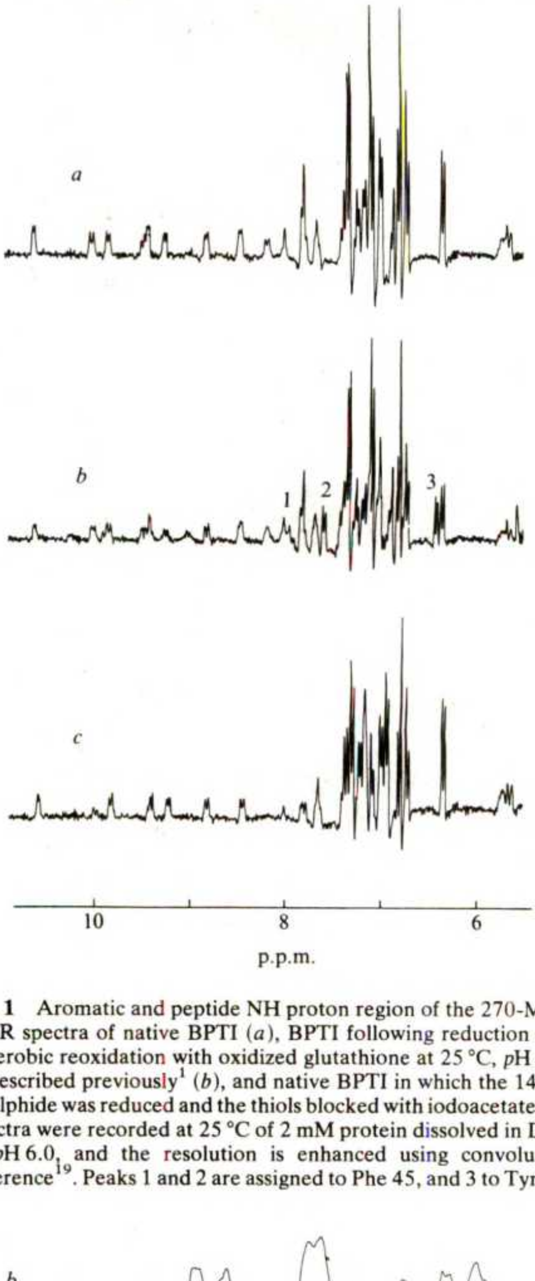

Fig. 1 Aromatic and peptide NH proton region of the 270-MHz NMR spectra of native BPTI (*a*), BPTI following reduction and anaerobic reoxidation with oxidized glutathione at 25 °C, *p*H 8.7, as described previously[1] (*b*), and native BPTI in which the 14–38 disulphide was reduced and the thiols blocked with iodoacetate (*c*). Spectra were recorded at 25 °C of 2 mM protein dissolved in D_2O at *p*H 6.0, and the resolution is enhanced using convolution difference[19]. Peaks 1 and 2 are assigned to Phe 45, and 3 to Tyr 23.

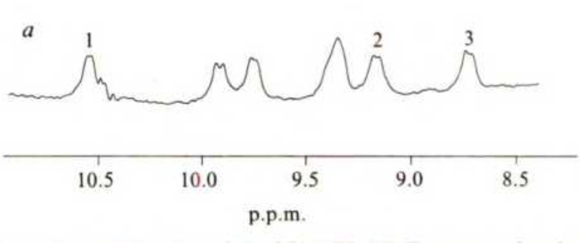

Fig. 2 Low field region of the 270-MHz NMR spectra of native BPTI (*a*) and BPTI refolded (*b*) as described in Fig. 1 legend. Spectrum *c* is a difference spectrum in which a fraction of *a* was subtracted from *b* to reveal the spectrum of isomeric BPTI. Peaks 1, 2 and 3 are from the peptide NH protons of Tyr 23, Tyr 21 and Gln 31, respectively[9].

0028–0836/80/320630—03$01.00

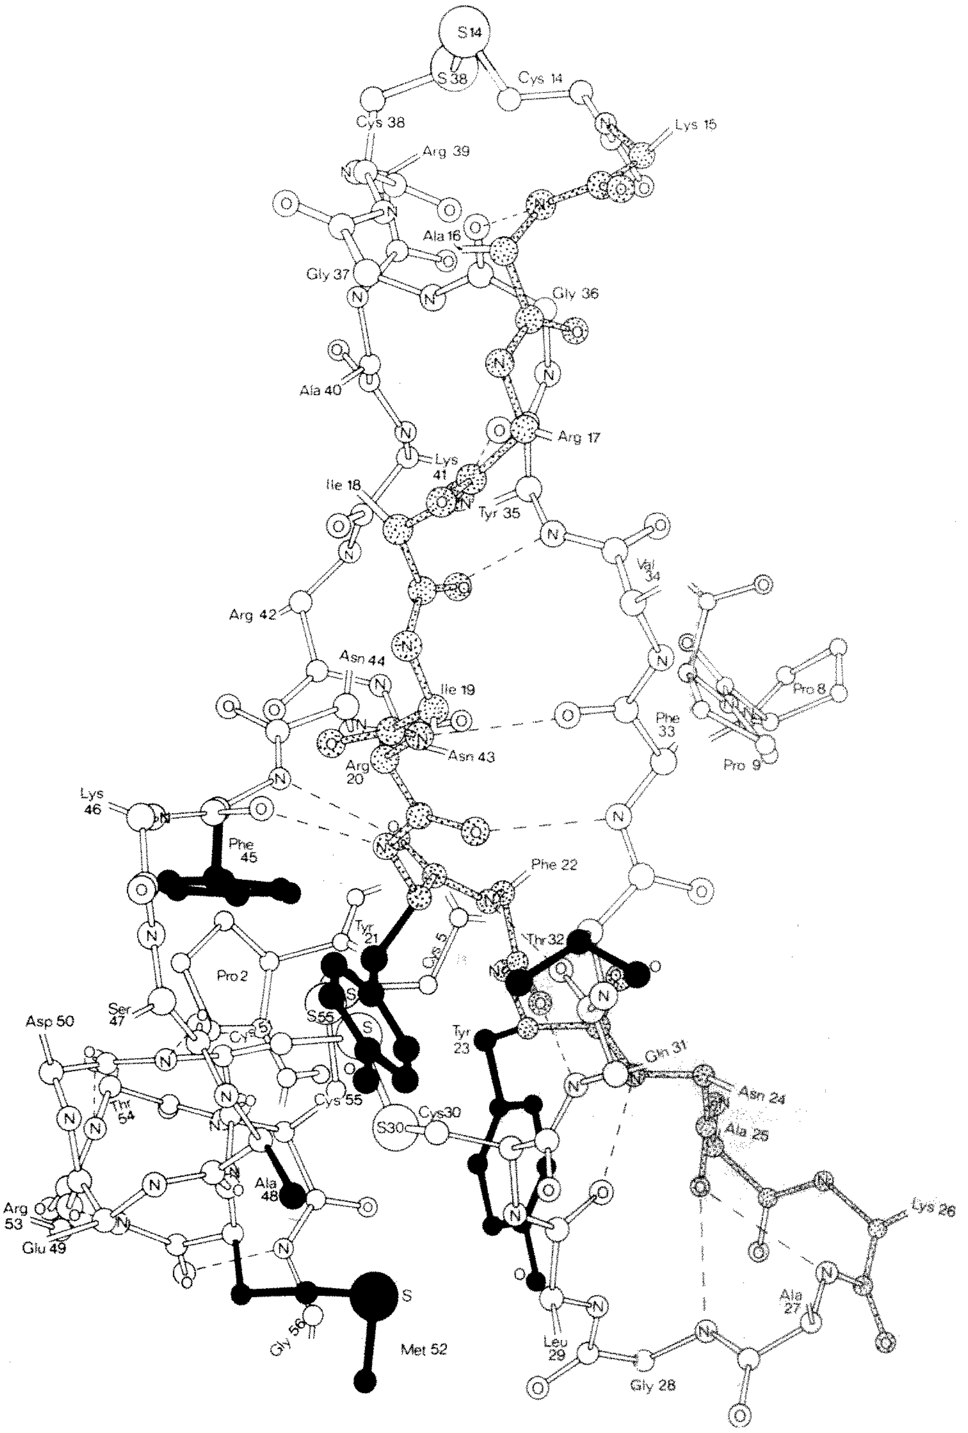

Fig. 3 Part of the crystal structure[12] of native BPTI showing the region of the protein where conformational differences exist in the metastable form. Side chains of residues whose resonances have been observed to have the largest chemical shift differences between the native and isomeric BPTI are shown in dark shading. The lightly stippled backbone is that portion which is threaded through the loop generated by the 30–51 disulphide bond.

of the isomer and an increase in the intensity of the resonances of the native protein. By following the intensities of resonances of the two species, the conversion of the isomer to the native species was found to proceed at a rate of $(3.5\pm0.7)\times10^{-5}\,s^{-1}$ at 37 °C and *p*H 6.0. Measurement of the temperature dependence of the rate gave an activation energy of 55 ± 10 kcal mol^{-1}.

It is clear from these data that the refolding of BPTI results in a significant and sometimes dominant amount of a metastable species with a different NMR spectrum, and therefore a different conformation, from native BPTI. That the conversion of the metastable species to the native species takes place in conditions in which rearrangement of disulphide bonds cannot occur shows that the same disulphide bonds are present as in the native species, as had also been shown by peptide analysis[4]. Comparison of the two NMR spectra shows further that the basic structural arrangement of the native BPTI is not lost in the new species. Of particular importance is a comparison of the proton resonances of the aromatic and methyl groups, which have all been assigned in the spectrum of native BPTI[5–7]. Most of these resonances have the same positions (to ±0.02 p.p.m.) in the two spectra, indicating that much of the protein conformation is essentially the same in the two species. Significant differences (shifts up to ±0.1 p.p.m.) are found for the resonances of Tyr 21, Tyr 23 and Phe 45 in the aromatic region and of Thr 32, Ala 48 and Met 52 in the methyl region. Further information comes from the resonances of the peptide NH hydrogens which exchange slowly with solvent. In the spectrum of isomeric BPTI there are resonances within 0.05 p.p.m. of resonances in the spectrum of native BPTI for 7 out of the 10 protons whose exchange rates[9,11] are less than $10^{-3}\,min^{-1}$ at 22 °C and *p*H 6.5. Three peaks, assigned to Tyr 21, Tyr 23 and Gln 31, have chemical shift values which differ in the two spectra by more than 0.1 p.p.m. (Fig. 2). The distinctive chemical shifts and long exchange rates of these protons have been attributed to their role in internal hydrogen bonding[10,11]; most of the resonances arise from the β-sheet secondary structure, which passes through the entire molecule (see Fig. 3). The conservation in number and near conservation of chemical shifts of these NH resonances in the two spectra indicate, therefore, that the hydrogen bonding network of native BPTI is intact in the isomeric species. In particular, it has been established[12] in native BPTI that the polypeptide chain passes through a loop produced by the existence of the 30–51 disulphide bond (Fig. 3), and the NMR data exclude the possibility that the protein chain is incorrectly 'threaded' in the isomer.

All the residues whose resonances are perturbed are rather close together, in the portion of the molecule (native structure) surrounding the 30–51 and 5–55 disulphide bonds, which are near to each other (Fig. 3). The major conformational differences between native and metastable BPTI therefore lie in this part of the structure.

It is useful to compare this conclusion with the results[5] from studies of a derivative of BPTI with one of the disulphide bonds, 14–38, reduced. The spectrum of this species is shown in Fig. 1*c*. There are no large shifts in any of the resonances and those with small shifts arise from residues in the part of the molecule near to the broken 14–38 bond, notably Thr 11 and Tyr 35. There are negligible shifts in the resonances perturbed in the isomeric BPTI, indicating that the conformations of the isomeric BPTI and the 14–38 reduced species are altered in different regions of the structure.

The simplest explanation for the existence of the isomer would be that it is a normal intermediate in the final step of the refolding process; that is, when the last disulphide bond (14–38) is formed, the isomeric conformation is produced which then goes on to generate slowly the native conformation. This possibility is unlikely because a significant proportion of BPTI in the native conformation is formed when refolding (which takes only minutes) is carried out at temperatures so low (<25 °C) that the metastable isomeric species converts to the native species only over a period of days. Thus, it is more likely that the two forms of folded BPTI arise from alternative parallel pathways. Further, it has been found that re-oxidation of the 14–38 reduced species results in BPTI with a spectrum identical to that of the native species, so that it is unlikely that the conformational differences between the isomers arise in the formation of the 14–38 bond.

To investigate possible origins of the alternative pathway in earlier parts of the refolding reaction, the one- and two-disulphide bond intermediates have been examined. The conformations of these, other than the one with only the 14–38 bond in the reduced state, are significantly different from that of native BPTI, with a much less well defined globular structure, particularly in the one-disulphide species. This is in essential agreement with conclusions from immunochemical analysis of these intermediates[13]. It seems possible, therefore, that the conformational isomer arises from the same disulphide bond formation sequence as native BPTI but has a difference in structure which arises because of the stability of this difference in an early intermediate. This could be due to the existence of a *cis* rather than the *trans* conformer found for all four proline residues in native BPTI (Pro 2 is close to the region of the observed structural changes)[14,15], a different conformation around the 30–51 or 5–55 disulphide bond, or some other difference in a main-chain or side-chain dihedral angle. The formation of the 14–38 bond, or some earlier step, could then 'lock in' the conformational difference. Alternatively, the two different folded species could result from pathways in which the sequences of disulphide bond formation are different. For example, in the initial stages of folding several pathways are known to exist and to result in the formation of different two-disulphide species, which then rearrange to the 30–51, 5–55 species before complete refolding. It is interesting in view of the results reported here that the relative stabilities of different two-disulphide species have been found to be temperature dependent (T.E.C., unpublished results).

The present results are of significance for an understanding of the mechanism of protein folding and for the analysis of the determinants of protein conformation. Of primary interest is the demonstration that two similar globular structures can exist; even in a protein as small as BPTI a specific structure can be formed during folding that is not at the free energy minimum[16,17]. Further, the activation energy for the transition from the metastable to the native species is high; it is of the order of the highest activation energies measured for exchange of the backbone amide hydrogens of native BPTI[10]. This suggests that, although the conformational difference between the two species is localized, the transition involves a significant disruption of the structure. If the specific element that distinguishes the two structures is a dihedral angle rotation, conformational constraints would have to be the source of the high activation energy. This is analogous to the tyrosine and phenylalanine ring 'flips' for which the observed activation energies of up to 25 kcal mol^{-1} are much larger than the internal rotation barrier[7,18].

It will be of considerable interest to use the existence of this conformational isomer to elucidate the structural and dynamic aspects of folding transitions in proteins.

We thank Bayer AG for a gift of BPTI (Trasylol). The NMR experiments were carried out at the NMR Facility for Biomolecular Research, Francis Bitter National Magnet Laboratory, Massachusetts Institute of Technology. The NMR Facility is supported by grant RR0995 from the Division of Research Resources of the NIH, and by the NSF under contract C-670. This work is also supported in part by grants GM26272 and EY00062 from the NIH.

A diffusion–collision–adhesion model for the kinetics of myoglobin refolding

F. E. Cohen*, M. J. E. Sternberg & D. C. Phillips

There are two distinct experimental and theoretical problems of protein folding: the thermodynamic issue of characterizing the folded state, and the kinetic question of the path between the unfolded and native states[1]. Here we consider the second question and present a diffusion–collision–adhesion model for the folding of the α-helical protein myoglobin. In particular, we consider the fast refolding species of the unfolded state and ignore the slow transition between unfolded states that has been attributed to proline isomerization[2].

---

* Present address: Department of Pharmaceutical Chemistry, School of Pharmacy, University of California, San Francisco, California.

Baldwin[3] and Karplus and Weaver[4,5] have considered the experimental and theoretical evidence as to the probable rate-limiting step during (fast) folding. They agree that the formation of a local structure by a random search is unlikely to act as a nucleus for subsequent rapid folding. Instead, they opt for intermediate control in which the relative stabilities of the intermediates determine the pathway(s) and the rate of folding. Local structures (for example, α-helices) of transient stability diffuse together, collide and then adhere (pair) together. There is no requirement for an obligatory intermediate and folding may proceed along several paths. The intermediates for myoglobin are assemblies of α-helices as suggested by Ptitsyn and Rashin[6].

Rate constants for the steps are derived from the model of Karplus and Weaver[4,5]: collision, not adhesion, is the rate-limiting step. Detailed stereochemical information about helix packing in myoglobin is taken from the work of Richards and co-workers[7,8]. The folding follows intermediate control, shows the cooperative behaviour that has been observed experimentally[9,10], and we find several paths linking the unfolded and native states. A second calculation considers N-terminal folding that may occur during biosynthesis[11,12]. In our model, apomyoglobin is considered as six fluctuating α-helices (ABEFGH). Initially, pairs of α-helices collide to form a cluster. Each cluster can grow by docking either with one other α-helix or with another cluster that contains two or more α-helices. We allow only the five strongest helix/helix interactions (AH, BE, BG, GH, FH)[7] that are observed in the folded myoglobin. This implies that the interactions that are dominant in the final structure are important in the folding pathway and that incorrect helix pairings do not significantly interfere with the rate of formation of native intermediates.

In the model of Karplus and Weaver[4,5], the time required for the interaction of two helices is

$$\tau = \frac{1}{\beta}\left(\frac{l\Delta V}{DA}\right) \tag{1}$$

where l is the characteristic length, ΔV is the volume of finite diffusion space, D is a diffusion coefficient ($\sim 1\times10^{10}$ Å^2 s^{-1}), A is the area of the target surface and β is the fraction of time that both segments are helical when they collide.

To calculate rate constants for the condensation of two helices, we assume that ΔV is the space between two concentric spheres. The outer radius is determined by

$$r_{ij}^{\mathrm{ext}} = 1.5H + 3.3C \tag{2}$$

where i and j are the residues central to the helix–helix interaction[7], and H and C are the number of residues between i and j in helical and coiled conformations, respectively. The inner radius, r_{ij}^{pack}, is taken as the length of the segment which is mutually perpendicular to the axes of the interacting helices[7,8].

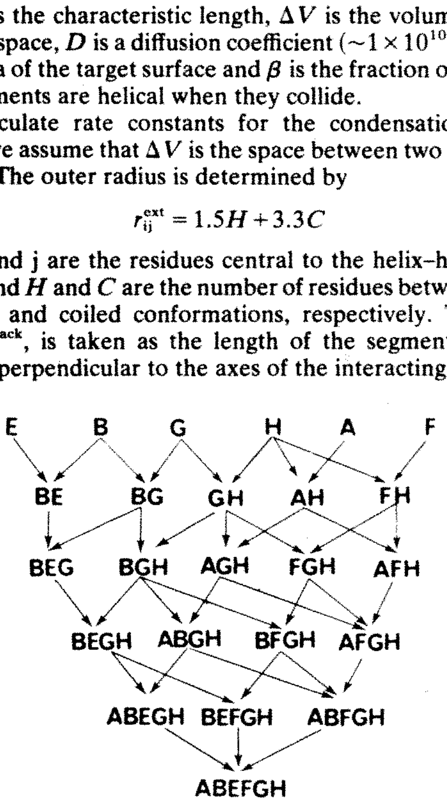

Fig. 1 Possible folding paths for myoglobin. Only the addition of single helices to preformed clusters is depicted. Condensations between preformed clusters, for example, BE + GH → BEGH, are omitted for the sake of clarity.

Table 1 Parameters for the diffusion–collision equation

Interaction	Average potential contact area loss on association* $A = (A_i + A_j)/2$(Å^2)	r_{ij}^{pack} (Å)	r_{uj}^{ext} (Å)
G111-H135	185	10.5	25.05 (17.55‡, 19.05§, 17.55‖)
A10-H134	170	8.5	189.3 (95.3†, 26.0§, 118.2‖, 142.05¶, 15.2§¶)
B25-E65	145	7.5	50.70 (43.20§, 24.00§‖¶)
F90-H142	125	8.5	66.90 (54.15‡, 12.90¶)
B28-G110	155	8.5	120.00 (45.45†, 112.50¶, 12.9‡¶ 89.40‖¶)

* From Richmond and Richards[7].

‡ AH formed; † BE formed; § BG formed; ‖ FH formed; ¶ GH formed.

If the target area for the interaction is the average of the potential accessible areas lost when the two helices pack (A_i and A_j)[7], then equation (1) becomes

$$\tau = \frac{\frac{1}{2}(r_{ij}^{\mathrm{ext}} + r_{ij}^{\mathrm{pack}}) \times \frac{4}{3}\pi((r_{ij}^{\mathrm{ext}})^3 - (r_{ij}^{\mathrm{pack}})^3)}{\beta 10^{10} \frac{1}{2}(A_i + A_j)} \tag{3}$$

Clearly, r_{ij}^{ext} is a function of the degree and nature of the condensation of the molecule. For example, the volume of diffusion space available for the FH interaction is decreased if GH has been formed (see Table 1).

In our model, α-helices that have correctly paired do not dissociate. Clearly, proteins denature and so a helix–helix pair can dissociate. However, in conditions where the folded structure is stable, dissociation will be slower than association. If the stability of the native structure is indicative of the stability of various intermediates, dissociation is probably negligible. Moreover, the rate of dissociation is a complex function of the solvent and temperature that remains undefined.

The only adjustable constant in this anlysis is ρ, the probability that a potential helical segment will be helical when it interacts. For a pair of fluctuating helices, $\beta = \rho^2$; for one fluctuating helix packing against a solid cluster, $\beta = \rho$; and for two solid clusters packing, $\beta = 1$. In the two simulations that follow, $\rho = 0.002$. Smaller values of ρ decrease the cooperativity of the folding transition and larger values decrease the lag time for renaturation. Changes in ρ had little effect on which intermediates were observed, although the half lives of these species were affected.

In our model of myoglobin, there are 24 states (see Fig. 1). There exists a matrix of 24 × 24 second order rate constants which define a system of simultaneous second order differential equations. As a closed form solution to this problem does not exist in general, the rate equations are solved iteratively with time steps of 25 μs. Figure 2*a* shows the exponential behaviour of the concentration of the final state. The concentration begins to level off after 2 ms and slowly goes to completion. Two intermediate states are significantly (>5%) populated: FGH and ABFGH. The lag phase, although noticeable, is small. This is undoubtedly because the initial steps in this simulation overwhelmingly favour products. In the refolding of ribonuclease A in 50% methanol at temperatures less than −20 °C, a lag in the absorbance change due to the burial of tyrosine residues is observed. The lag lasts approximately 100 s at *p*H 6.0, −25 °C (A. L. Fink and B. Lustig, personal communication).

In an attempt to simulate biosynthesis, the initial concentrations of the isolated helices were repeated. Thus, the concentration of H was 0.0 until the concentration of G reached 1.0. The rate of synthesis was such that a myoglobin chain was made in 1.2 s. BE is the first intermediate to appear, followed by the production of BEG, BEGH and then the native state (see Fig. 2*b*).

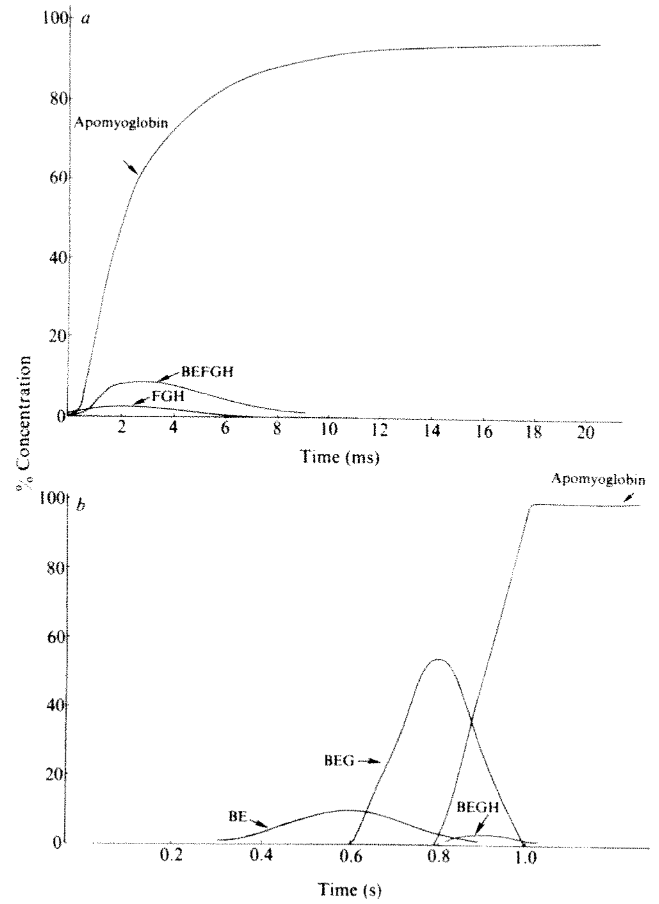

Fig. 2 *a*, Simulated renaturation kinetics of apomyoglobin as a function of time. The concentrations of intermediates which are significant are also plotted. *b*, Simulated folding kinetics of apomyoglobin during biosynthesis. The time taken to synthesize a helical segment is 0.2 s.

In these two simulations, two distinct sets of intermediates were significantly populated. Thus, we suggest that folding can occur through many alternative pathways which ultimately converge to the native structure. Cooperativity results from the decrease in the volume of diffusion space as a function of molecular organization. In principle, the intermediates of renaturation could be trapped and identified in a stop-flow experiment. Alternatively, the sites of helix–helix interaction could be chemically blocked to inhibit the completion of the folding and the intermediates created could then be characterized. Studies by Zabin and co-workers suggest that intermediates in biosynthesis could be characterized by immunological probes[12].

This model assumes that no mismatched pairs of hydrophobic patches on the surface of the α-helices are stabilized. A more realistic assumption would be that mismatched helix–helix pairs could tautomerize to a correct pairing. These tautomerizations would have low activation barriers, as the individual helical conformations have been stabilized and the volume of diffusion space is reduced. This tautomerization mechanism might explain Creighton's finding[1] that there is an obligatory mismatched disulphide bridge on the pathway joining the unfolded and native states of pancreatic trypsin inhibitor.

Rescue of a splicing defective mutant by insertion of an heterologous intron

Peter Gruss & George Khoury

Laboratory of Molecular Virology, National Cancer Institute,
National Institutes of Health, Bethesda, Maryland 20205

It is now widely accepted that the primary transcripts of many eukaryotic genes contain intervening sequences (introns)[1-3]. These introns, which vary considerably in length, have been found in both coding and noncoding regions[4-15]. They are removed from the primary transcript in one or more steps by a process called RNA splicing[16]. The role of RNA splicing, the size and position of introns and the signals which modulate the splicing process are under intense investigation. These studies have been greatly facilitated by the use of viral mutants or viral–eukaryotic recombinant molecules. The SV40 system has been of particular value in elucidating certain genetic elements which are critically involved in the splicing process[17-21]. Further insight into the biological significance of the splicing process has come from a mutant from which precisely one intron has been removed (intron-minus mutant, d1-2350). This deletion mutant has the potential to circumvent the need for splicing. However, the inability of d1-2350 to accumulate late viral transcripts indicates that splicing is a requirement for the biogenesis of stable mRNA[22]. This finding is supported by studies using the mouse β^{maj} globin gene inserted into SV40. The inserted portions contained either the complete globin gene[23] or a segment encompassing the intron plus the entire 3′ end of the gene[24]. As polyadenylation is known to precede splicing[2,3], the possibility exists that every transcript possesses sequences near the 3′ end that are directly involved in the splicing process. We report here that, to test this possibility as well as to pursue the question of whether the splicing event and/or defined sequences in the intron are required for the biogenesis of mRNAs, we inserted an isolated intron lacking its own genomic 5′ and 3′ ends into the intron-minus mutant previously described. The experimental protocol provided for obtaining both possible orientations of the insert relative to the late genomic region. Investigation of the transcriptional products indicated that stable mRNA was produced only by the mutant containing the intron in the sense orientation.

There are, however, a few reported examples of abundant unspliced cytoplasmic mRNA. These include the histone mRNAs[38] (which also differ from most other eukaryotic transcripts in having an abbreviated or absent 3′-polyadenylation signal) and the messenger for adenovirus polypeptide IX[39]. Whether these examples are fundamentally different from the majority of eukaryotic genes studied thus far, or if there is a special category of unspliced stable transcripts remains to be determined.

The *in vitro* construction of the recombinants is outlined in Fig. 1. An *Eco*RI fragment containing the entire chromosomal portion of the mouse β^{maj} globin gene[15,25] was cloned at the *Eco*RI site in pBR322. This DNA was cleaved with *Hin*dII and a fragment 573 nucleotides long was isolated by gel electrophoresis. This fragment represents the small intron (intron *1*) of mouse β^{maj} globin chromosomal DNA plus some flanking sequences, but lacks the 5′- and 3′-terminal sequences of the β^{maj} globin gene. An enzyme which conveniently cuts at a single site present in the late region of the intron-minus mutant (d1-2350) is *Hpa*II. This recipient site is located in the leader region of d1-2350, 221 nucleotides upstream from the donor splice junction[22,26], for the SV40 16S mRNA. The cleavage of d1-2350 DNA with *Hpa*II thus results in a linearized DNA containing 'sticky' *Hpa*II ends. To obtain efficient ligation of the globin intron fragment harbouring 'blunt' *Hin*dII termini to the linearized DNA, the *Hin*dII ends were converted to *Hpa*II ends by the addition of synthetic oligonucleotides (linkers)[27]. Liga-

0028-0836/80/320634—04$01.00

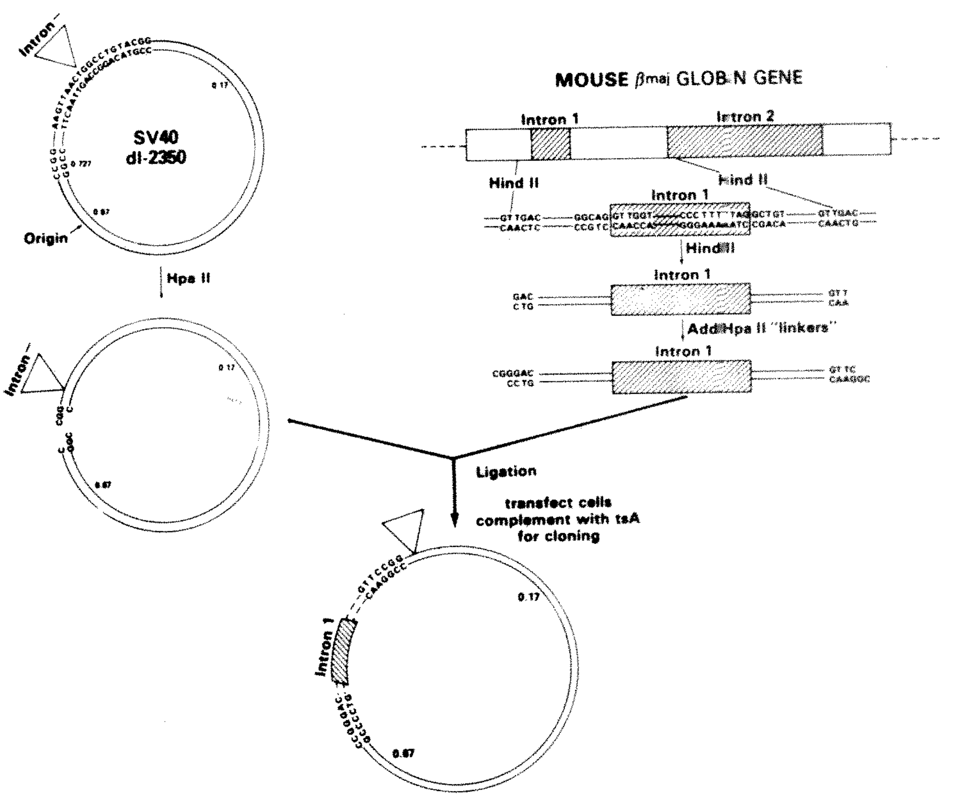

Fig. 1 Insertion of mouse $\beta^{\rm maj}$ globin intron *1* into SV40 d1-2350. Plasmid DNA (pBR322) containing the active mouse $\beta^{\rm maj}$ globin gene[15,25] insert was cleaved with *Hin*dII and a fragment of 573 nucleotides representing the entire intron *1* plus some flanking sequences was purified. This DNA (10 μg) was blunt-end ligated to 2.5 μg of *Hpa*II decamer linkers (CCGGATCCGG from Collaborative Research) in conditions exactly as described by Maniatis *et al.*[27]. The DNA containing *Hpa*II linkers was purified away from unligated linkers by gel electrophoresis and subsequently cleaved with *Hpa*II. A second electrophoresis step was used to purify the DNA containing sticky *Hpa*II ends. In parallel, SV40 d1-2350 DNA (4.5 μg) was reacted with *Hpa*II, extracted with phenol and dialysed. The globin fragment containing *Hpa*II ends (1.2 μg) was ligated to d1-2350 DNA (4.5 μg) in a total volume of 100 μl in a buffer (50 mM Tris-HCl *p*H 7.8, 10 mM $MgCl_2$, 20 mM dithiothreitol, 60 μM ATP) using 2 units T4 DNA ligase (Biolabs). The reaction mix was incubated for 1 h at 15 °C, then further reacted for 16 h at 4 °C. The ligated recombinants were separated from unligated material by agarose gel electrophoresis. Purified recombinant DNA was used in an infectious centre assay[40] and complemented with SV40 tsA. Many plaques were picked and used to grow viral stocks in secondary African green monkey kidney cells[40].

tion was subsequently carried out using a twofold molar excess of globin DNA over the d1-2350 recipient DNA. As *Hpa*II termini were present on every end, the insertion of the globin intron can occur in both possible orientations relative to the late transcription unit. The ligated DNA products were transfected into secondary AGMK cells using the facilitating agent DEAE-dextran[28,29]. We used tsA, a helper virus defective in early gene function at non-permissive temperature (40 °C)[30], to complement the ligated DNA product by providing the missing gene functions for the late viral structural proteins VP2, VP3 and VP1. The decision to use tsA rather than tsB (which is temperature sensitive for VP1) was based on three critical points: (1) As tsA provides an intact late region, it non-selectively complements all mutants defective in late function(s). The tsA mutant should be capable of complementing our ligated recombinant molecules, even if no stable mRNA or protein is produced after insertion of an intact intron. (2) Regardless of the orientation of the inserted globin intron relative to the late transcription unit, tsA should complement the recombinant molecule. (3) The chromosomal $\beta^{\rm maj}$ globin DNA fragment providing the intron also contains some flanking sequences from the globin gene. Close inspection of these sequences[24] reveals the presence of six ATG triplets. Should these triplets serve at the RNA level as translation initiation codons, they would produce proteins which differ from VP1, and would not complement tsB.

With the help of tsA, many clones were obtained and screened for the presence of globin DNA sequences (see Fig. 2). A plasmid carrying the entire mouse $\beta^{\rm maj}$ globin gene was cleaved with *Sac*I and the two resulting fragments were separated on an agarose gel and subsequently transferred to nitrocellulose filter paper[31]. The filter was cut into small (3 mm) strips and hybridized to ^{32}P-labelled DNA from cloned recombinants. As an example (Fig. 2*a*, *c*, *d*), three mutant clones hybridize exclusively to the small (1.15 kilobase) fragment representing intron *1* and the 5′ region of the $\beta^{\rm maj}$ globin gene. One cloned mutant (Fig. 2*b*) seems not to contain a globin-specific insert.

The entire DNA sequence of SV40[32,33] and mouse $\beta^{\rm maj}$ globin is known. Thus, our physical characterization of cloned recombinant DNA could be limited to a few restriction endonucleases so as to determine the orientation of the insert. A combination of cleavage by *endo R Ava*II and *endo R Bam*HI, and subsequent size determinations of the fragments by polyacrylamide gel electrophoresis, allows an identification of the orientation of the inserted globin intron relative to the late transcription unit (data not shown). Two classes of recombinants were obtained and are schematically outlined in Fig. 3. In the case of the recombinant d1-2350-I, the globin intron is inserted in the sense direction, whereas in d1-2350-II the intron is orientated in the antisense direction.

The structure of the recombinant molecules suggests that even after the removal of the intron by a potential splicing reaction, a stable transcript should retain a total of 456 nucleotides (intron flanking sequences) derived from the mouse $\beta^{\rm maj}$ globin gene. Thus, an mRNA from the recombinant template is expected to increase in size by this amount relative to 16S mRNA transcribed from the tsA helper template. Should unspliced recombinant mRNA be present, the size increase would be 456 + 116 = 572 nucleotides. To identify such a hybrid mRNA and to distinguish between spliced and unspliced transcripts, cytoplasmic polyadenylated RNA was prepared from AGMK cells infected with the recombinants containing the

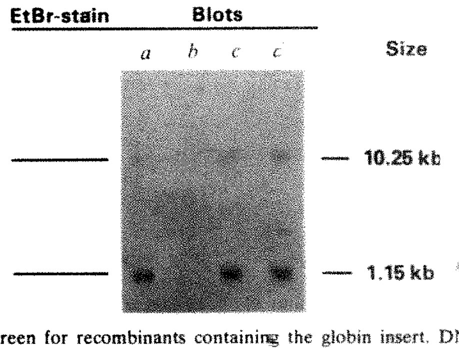

Fig. 2 Screen for recombinants containing the globin insert. DNA was prepared from a plasmid containing the entire mouse $\beta^{\rm maj}$ globin gene. This DNA was cleaved with *Sac*I, an enzyme generating two fragments. The smaller fragment (1.15 kilobases (kb)) represents the 5′-end portion (including intron *1*) of the gene, the larger fragment (10.25 kilobases) contains the sequences of the 3′ end. This cleaved DNA (20 μg) was electrophoresed into an 1.4% agarose gel (in 0.04 M Tris *p*H 7.8, 0.005 M sodium acetate, 0.001 M EDTA) and subsequently blotted on to a nitrocellulose filter paper[31]. The filter paper was cut into strips 3 mm wide. Each strip was hybridized to a ^{32}P-labelled DNA preparation obtained from cells infected with the different mutant stocks[35]. Mutants *a*, *c* and *d* contain the globin-specific insert, whereas mutant *b* does not have any detectable globin-specific sequences. EtBr, Ethidium bromide.

intron in either the sense or the antisense direction. Aliquots of both RNA preparations were electrophoresed in duplicate through an agarose gel containing methyl mercury hydroxide and subsequently transferred to diazotized benzyloxymethyl (DBM) paper[34]. One track of each preparation was hybridized to ^{32}P-labelled SV40 DNA; the second track was hybridized to ^{32}P-labelled mouse β^{maj} globin DNA. Figure 4 presents the results. In the right-hand panel of the gel, RNA from the two recombinants (d1-2350-I and d1-2350-II) was hybridized to ^{32}P-labelled SV40 DNA. In both tracks two bands appear in similar positions. These positions are identical to those for the 16S and 19S mRNAs of the SV40 control (not shown). Thus, these classes apparently represent RNA derived from the tsA helper genome. In the track containing RNA from the recombinant which has the globin intron in the sense direction, an additional band (2,050 nucleotides) appears. This class of mRNA is 450 nucleotides larger than 16S mRNA. In addition to SV40 homologous sequences, this class of RNA alone also has sequences which are homologous to mouse β^{maj} globin DNA (Fig. 4, left panel). These observations indicate that the insertion of an intron in the sense direction is sufficient for activation of a late spliced SV40-containing mRNA. It seems that mouse β^{maj} globin intron *1* and its flanking nucleotides are functional as a splice signal in heterologous genes even in the absence of its original 5′- and 3′-genomic end.

Split genes, containing introns which are not represented in their terminally processed RNA, are unique to eukaryotes. The precise removal of the intron takes place at the RNA level[1–3]. It has been suggested that the splicing mechanism is required not only for the removal of the intron but also for stabilization of the RNA[17,18,22,23]. In the present study we have examined directly the role of an isolated globin gene intron and its flanking nucleotides inserted into a previously constructed SV40 mutant lacking precisely the intervening sequence of 16S mRNA (intron-minus mutant d1-2350)[22]. A principal experimental difference between this study and previous reports[23] is the rescue of stable SV40 RNA from the splicing defective mutant d1-2350 by insertion of an intron derived from a heterologous gene. As an intron source we selected a restriction enzyme fragment from the mouse β^{maj} globin gene[15,25], representing the entire intron *1* plus some flanking sequences. However, the 5′- and 3′-terminal sequences of the globin gene are not retained. Construction of the mutant involves insertion of globin gene intron *1* into the late region (0.72 map unit) of d1-2350. The site of insertion is 221 nucleotides upstream from the original splice junction for 16S mRNA. Thus, the location of the inserted intron differs from the original position of the intron for 16S RNA. Although the experimental protocol for the insertion allowed ligation in both possible orientations relative to the late transcription unit, only the presence of an intron in the sense direction rescued stable mRNA. This confirms the earlier observation by Hamer and Leder that the polarity of a genomic fragment consisting of the 3′ end and large β^{maj} globin intron, relative to the SV40 transcription unit, was critical to the splicing of the hybrid mRNAs[23]. A correctly orientated intron can be removed in a splicing process, as indicated by the size of the resultant chimaeric RNA. It should be emphasized, however, that some mouse flanking sequences for globin intron *1* are preserved in these recombinant molecules and may be required for efficient splicing. Recent studies have suggested that small nuclear RNA (snRNA) molecules may serve as a 'guide' or strut in aligning pre-mRNA sites for splicing[35,36].

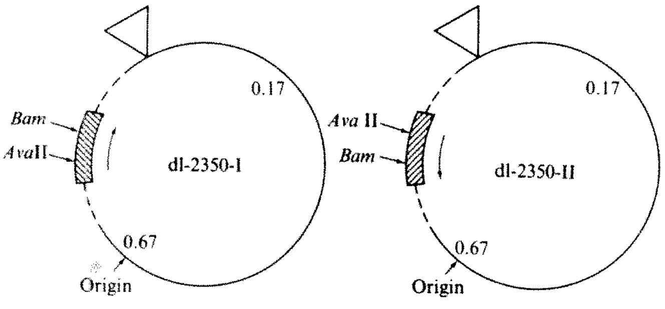

Fig. 3 Physical map of the recombinant DNA. For the establishment of a physical map, we concentrated on a determination of the orientation of the insert relative to the late transcription unit. A combination of *Ava*II and *Bam*HI endonucleases enabled us to determine the orientation by sizing the fragments. Both possible classes of recombinant give rise to six specific fragments, using these particular enzymes. Four out of those six fragments were expected to be identical (1,580, 1,006, 519 and 185 base pairs). The size of the remaining two fragments in the case of d1-2350-I (sense direction) was 867 and 710 base pairs, whereas the insert in the antisense direction (d1-2350-II) yielded two fragments of 987 and 590 base pairs. The analysis was carried out using 4% polyacrylamide gels (acrylamide = bis, 20 : 1) for electrophoresis in a 0.04 M Tris *p*H 7.8, 0.02 M sodium acetate, 0.001 M EDTA buffer.

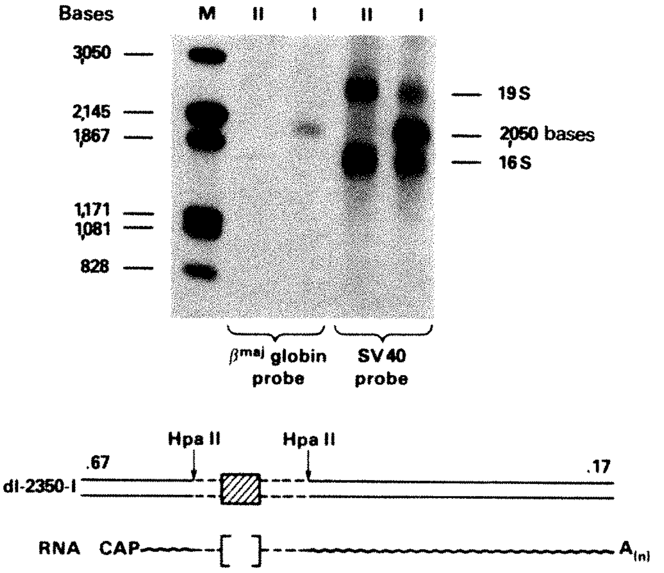

Fig. 4 RNA analysis. Cytoplasmic RNA from the recombinants was prepared 48 h after infection of secondary AGMK cells with 10 plaque-forming units per cell. Cells were treated with 0.5% NP40, 0.14 M NaCl, 0.01 M Tris *p*H 7.5 and 0.0015 M $MgCl_2$ (ref. 41). Poly(A)-containing RNA was selected by chromatography on an oligo(dT)–cellulose column. Aliquots of the RNA preparations from d1-2350-I (sense insert) and d1-2350-II (antisense insert) were electrophoresed in a 1.2% agarose gel containing methyl mercury hydroxide. Electrophoresis and subsequent transfer of the RNA to DBM paper were as described by Alwine *et al.*[34]. The resulting imprints were preincubated and hybridized with 200,000 c.p.m. of either a ^{32}P-labelled SV40 DNA or a ^{32}P-labelled plasmid DNA containing the entire mouse β^{maj} globin gene. Both probes were made by nick translation and had a specific activity of 10^8 c.p.m. per μg DNA. As a size marker, ^{32}P-labelled restriction enzyme fragments of the indicated sizes were electrophoresed in a parallel track. The bottom portion of the figure outlines an interpretation of the data (the transcript deriving from the recombinant d1-2350-I, sense insert).

The globin sequences flanking the inserted intron contain six ATG triplets, which are potential candidates for translational initiation in each reading frame. All precede the actual AUG triplet for initiation of VP1 translation. Attempts to clone these recombinant molecules using tsB in parallel experiments did not result in any plaques containing the recombinants. This observation confirms the data of others[37] suggesting that the first available AUG is in most cases preferentially used as the initiation signal for translation. Therefore, VP1 cannot be produced in amounts sufficient to complement SV40-tsB.

The flanking sequences which are preserved do not contain either the 5′ or 3′ end of the globin gene. Thus, it seems unlikely that either end specific to a particular mRNA is directly involved in splicing. Furthermore, the lack of obvious homology between SV40 and globin 5′ or 3′ ends suggests that no similar sequence is likely to be provided by SV40. The comparison of SV40 late introns with globin intron *1* did not show extensive homology, with the exception of consensus sequences at the splice junctions. Nevertheless, the insertion of the globin intron resulted in the reconstitution of stable RNA. This experimental result provides strong support for the idea that the splicing event is coupled to the stability of the RNA. Accordingly, defined intron sequences seem less likely to be involved in a positive transcriptional regulation event. Thus, while the polarity of the intron is critical to its function, the species of origin and the relative position in the mRNA are not. These observations suggest that introns represent functional elements in the generation of certain stable mRNAs.

We thank P. Leder for providing the cloned mouse β^{mai} globin gene, M. König and J. Duvall for technical assistance, and C.-J. Lai, J. Alwine, R. Dhar, S. Segal and B. Dunn for helpful discussions. P. G. is a recipient of a grant of Deutsche Forschungsgemeinschaft.

Theoretical analysis of transitions between B- and Z-conformations in torsionally stressed DNA

Craig J. Benham

Department of Mathematics, University of Kentucky, Lexington, Kentucky 40506

Recently, a new structure called Z-DNA has been proposed for alternating poly(dG-dC)·poly(dG-dC) sequences based on crystallographic analysis of the hexanucleotide[1]. The Z-form is a left-handed double helix containing 12 base pairs per turn. In contrast, the Watson–Crick B-form helix is thought to have 10.4 pairs per turn of right-handed helix[2,3,8]. A cooperative, salt-induced conformational transition has been observed in poly(dG-dC)·poly(dG-dC)[4], which has been interpreted as being between the B-form (low salt) and the Z-form (high salt)[1]. We now analyse the possibility that such transitions could occur in susceptible sequences in physiological conditions as a consequence of the torsional stresses imposed by superhelicity. As *in vivo* DNA commonly occurs in a negatively supercoiled, hence underwound, state, these transitions could serve important biological functions. Both thermodynamic and statistical mechanical theories of stress-induced two-state transitions have been developed previously[5,6]. Here we apply these theories to transitions between the B-form and the Z-form in regions of appropriate base sequence. Assuming that the unstressed duplex is entirely B-form, we show that when the molecule is constrained to be underwound, susceptible regions may transform to the Z-form, thereby absorbing most of the torsional deformation. Interestingly, this transition is relatively independent of temperature.

Consider a linear segment containing N base pairs, of which N_Z sequential pairs may undergo the B–Z transition. Let this segment be twisted by q turns away from its unstressed (hence totally B-form) shape. This torsional deformation will be partitioned between local transitions to the Z-form and smooth twisting in both the B- and Z-form regions so as to minimize the total conformational free energy involved. Denote the number of base pairs per helix repeat in the unstressed B-form by $A_B = 10.4$ and in the Z-form by $A_Z = -12$ (the negative sign deriving from the presumed opposite handedness of the two forms). Let τ_B (and τ_Z) denote the twist rate at which the B-form (and Z-form) regions are deformed away from their unstressed shape. If n bases occur in the Z-form, then

$$\tau_B = 2\pi[q + (n/A) - (n\tau_Z/2\pi)]/(N - n) \qquad (1)$$

where $1/A = 1/A_B - 1/A_Z$. The conformational free energy associated to this torsionally deformed structure is given by

$$F(n, \tau_Z) = a + bn + \frac{nC_Z\tau_Z^2}{2} + \frac{C_B}{2(N-n)}\left[2\pi\left(q + \frac{n}{A}\right) - n\tau_Z\right]^2 \qquad (2)$$

Here, C_Z and C_B are the torsional stiffnesses of the Z- and the B-form structures, b is the free energy required to change one base pair from B to Z and a is the extra free energy needed to initiate the transition in a region. Although C_Z is not known, it is reasonable to assume that $C_Z \simeq C_B$. Stable conformations occur at those values of n and τ_Z which minimize the free energy of equation (2)[5]. It follows that the segment must be underwound

Fig. 1 The probability of being in the B-form is computed for a sequence of $N = 80$ base pairs, of which $N_Z = 8$ consecutive pairs are susceptible to transition to the Z-form. For clarity, the transition profiles of a sequence of 40 base pairs containing the susceptible region are plotted at various values of the torsional deformation q. First, when $q = 0$ all base pairs are in the B-form with probability 1. The other four curves are for $q = -0.38m$, $m = 1, 4$. As the amount of negative torsional deformation increases, so does the probability of susceptible pairs transforming to Z-form. The parameters used in this calculation are $T = 298$ K, $\sigma = 1.36 \times 10^{-6}$, $s = 3.86$. For intermediate values of q (before the transition is complete) the statistical mechanical calculation gives $\tau_B = \tau_Z = -0.4$ deg per base pair. The transition profiles calculated at $T = 353$ K are virtually identical to those shown here. These results agree well with those from the thermodynamic analysis.

0028–0836/80/320637—02$01.00

by $q < -bNA/4\pi^2 C_B$ before stable regions of Z-structure occur. When q satisfies this condition, unique non-zero values of n and τ_Z exist which minimize the conformational free energy[5]. These are

$$n = -qA - (bNA^2/4\pi^2 C_B) \tag{3}$$

$$\tau_B = \tau_Z = -bA/2\pi C_B \tag{4}$$

where $0 < n < N_Z$. (If the segment is sufficiently underwound that $n = N_Z$, then $\tau_z = \tau_B$ is found from equation (1). To illustrate these results we use values $C_B = 8.5 \times 10^{-12}$ erg base pair rad^{-2} and $b = 0.8$ kcal mol^{-1} from the literature[4,7]. Then a segment must be underwound by 0.33 deg per base pair before the onset of transition to structures containing stable Z-form regions. When deformed beyond this threshold, enough susceptible base pairs switch to Z-structure for the twist rates to be maintained at $\tau_B = \tau_Z = -0.33$ deg per base pair. Only when the segment is so underwound that all susceptible sequences are in the Z-form do τ_B and τ_Z decrease below -0.33 deg per base pair.

To augment the above treatment we apply the statistical mechanical theory of two state transitions in torsionally stressed DNA[6] to the present problem. This renders computable the transition probability profiles of specific base sequences, which more accurately reflect the fluctuational character of these transitions.

The partition function for this transition is[6]

$$Z = \sum_{n=0}^{N_Z} \left[I_n \sum_{r_n} (s^n \sigma^\gamma) \right] \tag{5}$$

where r_n enumerates all states containing n Z-form base pairs, s is the equilibrium constant for a susceptible base pair, σ is the cooperativity factor and γ is the number of beginnings of sequences of base pairs in the Z-form. Also,

$$I_0 = \exp(-2\pi^2 q^2 C_B \beta / N), \tag{6a}$$

$$I_n = \left(\frac{2\pi(N-n)}{NnC_B\beta} \right)^{1/2} \exp\left(\frac{-2\pi^2 C_B \beta (q + n/A)^2}{N} \right), \quad 0 < n \leq N_Z \tag{6b}$$

From this partition function one can determine transition profiles, the expected value of τ_B and other equilibrium properties of the system as described in ref. 6. Figure 1 shows the results of a sample calculation carried out on a sequence of 80 base pairs, of which 8 were susceptible to the transition. Note that because the enthalpy of the B–Z transformation is zero[4], this two-state transition is not thermal in character, but rather depends primarily on the imposed torsional deformation q.

We have presented two theoretical analyses of transitions between B-form and Z-form in torsionally stressed DNA. In this initial formulation the possible role of local denaturation (perhaps necessary at the junction between B-form and Z-form regions, for example) has not been considered. A three-state treatment of this problem will be presented elsewhere. Despite lack of precise knowledge of several important parameters (torsional stiffness C_Z, cooperativity factor σ), the present analysis predicts that B–Z transitions could occur in response to the torsional deformations consequent on (negative) DNA superhelicity. In principle, it is possible that similar transitions also occur between other conformational states of the DNA. It has been suggested that stress-induced conformational transitions at defined sequences may serve diverse regulatory functions by altering the accessibility of the bases[5].

Metarhodopsin I/metarhodopsin II transition triggers light-induced change in calcium binding at rod disk membranes

U. B. Kaupp, P. P. M. Schnetkamp & W. Junge

Universität Osnabrück, Schwerpunkt Biophysik, Postfach 4469,
D-4500 Osnabrück, FRG

The hypothesis of Yoshikami and Hagins[1] that calcium ions act as diffusible transmitter molecules between the photochemistry of rhodopsin and the subsequent electrical events at the outer plasma membrane of rods initiated many investigations on light-stimulated calcium release in vertebrate photoreceptor cells (see refs 2, 3). Although it now seems firmly established that light has some effect on the redistribution of calcium in various disk preparations[2,4,5], reconstituted systems[6,7] and intact rod outer segments[3,8], the physiological significance remained unclear. We previously reported a rapid, light-triggered calcium release from binding sites at the disk membrane in the presence of calcium ionophore A23187 (refs 3, 8). However, there is no evidence for rapid calcium release into the cytosol in the absence of ionophore. On fragmentation of intact rod outer segments, calcium release due to a light-regulated change of calcium binding appeared almost completely abolished[3,8]. We describe here experiments with sonicated rod outer segments in which the previously observed loss of the calcium release capacity has been prevented. Calcium release in sonicated disks in the presence of A23187 kinetically follows the metarhodopsin I/metarhodopsin II transition ($\tau_{1/2} = 10$ ms, activation energy $E_A = 34$ kcal mol^{-1}), suggesting that calcium release is triggered by this photochemical transition.

Intact cattle rod outer segments have been isolated according to Schnetkamp *et al.*[9]. Disk vesicles were obtained by sonication of intact rod outer segments in a medium containing sucrose, 600 mM; Ficoll 400, 5% v/v; HEPES, pH 7.0 2 mM, for 30 s at 40 W. The suspension also contained about 3–4 μM of free calcium introduced by the stock suspension of rod outer segments.

Inhibition of calcium release can be prevented by keeping the ionic strength of the final suspension medium below 5 mM of 1:1 electrolyte, irrespective of the fragmentation procedure (lysis or sonication) and the fragmentation conditions (for example, high or low ionic strength). We conclude that the apparent abolition of the release capacity in fragmented rods is caused by regulation of calcium binding by cations other than calcium which had no access to the site of calcium release in both rods with a leaky and an intact plasma membrane.

Rapid calcium release was followed by means of kinetic flash spectrophotometry with the calcium indicator arsenazo (III). Details on working with arsenazo (III) and the principle and instrumentation of flash spectrophotometry have been reviewed elsewhere[3,10]. In a suspension of sonicated disks buffered with only 2 mM HEPES at pH 6.8, pH measurements with the pH indicators bromcresol purple and Mg-arsenazo (III) (ref. 11) demonstrated that the total proton buffering capacity (membranes and HEPES) is sufficient to suppress light-induced pH changes which might give rise to pH-induced absorption changes of arsenazo (III) (not shown). To obtain kinetically undistorted recordings of calcium release in sonicated material at higher time resolution (Fig. 1*a*), signals due to the intrinsic photochemistry of arsenazo (III) (ref. 3) have been recorded separately and subtracted from the superimposed calcium-indicating signals by means of a signal averager with a data reduction program (Nicolet 1072). The signal-to-noise ratio was improved by sampling of signals over several repetitions from one cuvette.

0028–0836/80/320638—03$01.00

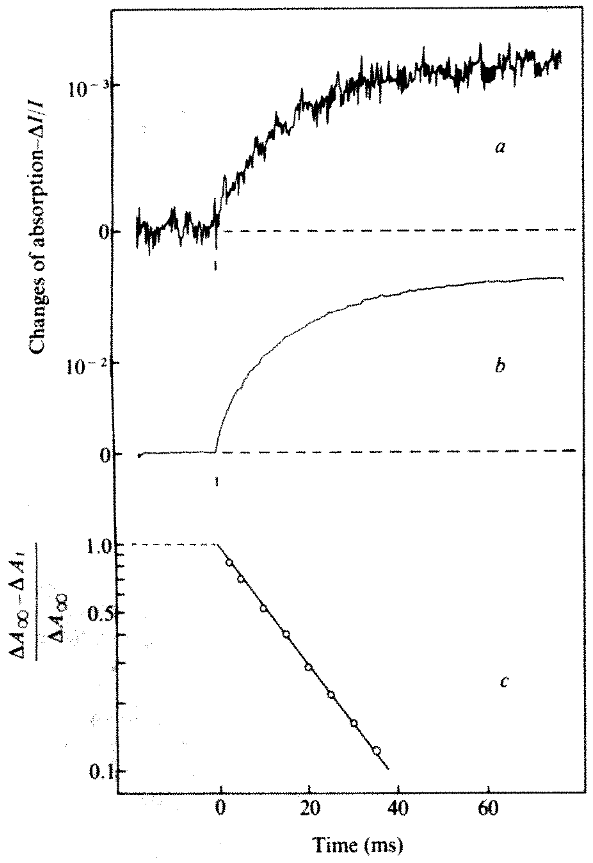

Fig. 1 Time course of the light-induced absorption changes at: *a*, 655 nm and *b*, 382 nm after excitation of sonicated rod outer segments by a flash at $t = 0$ in the presence of arsenazo (III) and A23187. Signals were obtained by averaging from one sample over 16 repetitions for *a* and four repetitions for *b* at a frequency of 0.5 Hz. The optical bandwidth of the measuring beam was 16 nm, the electrical integration time 200 μs. Further conditions as in Fig. 2. *c*, Semilogarithmic plot of the calcium-indicating absorption change from part *a*.

The half-rise time of flash-induced calcium release in the presence of equal amounts of A23187 (10 μM) depends on the structural integrity of rod outer segments (Fig. 2). In intact rod outer segments, calcium release occurs more slowly ($\tau_{1/2}$ = 300 ms) than in sonicated disk vesicles ($\tau_{1/2}$ = 10 ms). Unlike its kinetics, the stoichiometry of calcium released/rhodopsin bleached is comparable in both preparations (~0.4 calcium/rhodopsin*). Light-triggered calcium release in sonicated material is depicted in Fig. 1*a* at a higher time resolution. A semilogarithmic plot of the absorption changes from Fig. 1*a* reveals that the time course of calcium release can be described by a single first order reaction (Fig. 1*c*). Concomitantly in intact rod outer segments and sonicated suspensions the metarhodopsin I/metarhodopsin II transition has been recorded at 382 nm. A half-rise time of about 10 ms at 20 °C and at *p*H 7 was observed for both preparations. The time course of this photochemical transition is shown for sonicated disk vesicles in Fig. 1*b*. From inspection of Fig. 1 it is evident that the time course of rapid calcium release in sonicated rods in these conditions closely parallels that of the metarhodopsin I/metarhodopsin II transition.

To determine the energy of activation for both processes, the temperature dependence of the respective rate constants has been investigated in similar conditions (Fig. 3). Rate constants have been calculated from overall half-rise times according to $1/\tau_{1/2} = \mathrm{k}(\ln 2)^{-1}$. The metarhodopsin I/metarhodopsin II transition exhibits *p*H- and temperature-dependent biphasic kinetic behaviour (ref. 12 and our unpublished observation) and therefore two ways of analysing the data have been adopted. First, the overall rate constants of the metarhodopsin I/metarhodopsin II transition are shown in Fig. 3 (closed circles). They match reasonably well with the calcium release data (triangles). If only the rate constant of the slower kinetic component is considered (Fig. 3, open circles) the correspondence, especially for higher temperatures, is even better. This is due to the temperature dependence of the relative amplitudes of the two kinetic phases of the metarhodopsin I/metarhodopsin II transition which favours the rapid component at higher temperatures[12]. Notwithstanding this subtlety of a biphasic kinetic behaviour of the metarhodopsin I/metarhodopsin II transition, it is obvious from Fig. 3 that both reactions have a similar activation energy of about 34 kcal mol^{-1}.

The similarity of activation energies and time constants of both reactions strongly suggests that the calcium release system is intimately coupled to the metarhodopsin I/metarhodopsin II transition. In agreement with this notion is the linear relationship between metarhodopsin II formation and the amount of calcium release reported earlier[3,8].

The rapid rise time of the calcium-indicating absorption changes in sonicated vesicles probably reflects the actual time required for the trigger step to occur. The diffusion time of calcium ions from binding sites through the suspending medium to an indicator molecule[13] as well as the relaxation time of complex formation between arsenazo (III) and calcium[14] are too short to contribute significantly to the time course of the calcium-monitoring absorption changes. The mechanism underlying the slower kinetics in intact rod outer segments probably involves an additional reaction step and will be considered elsewhere[15], but from the present study it is obvious that in the presence of 10 μM A23187 the kinetics of calcium release are not rate limited by the ionophore.

For the actual release step two distinct mechanisms may be considered. In the first model, calcium is bound directly to rhodopsin and released during the metarhodopsin I/metarhodopsin II transition due to a change of the electrostatic interaction between calcium and its coordination groups at the rhodopsin molecule. This change could involve spatial separation of chelating groups accompanying conformational changes

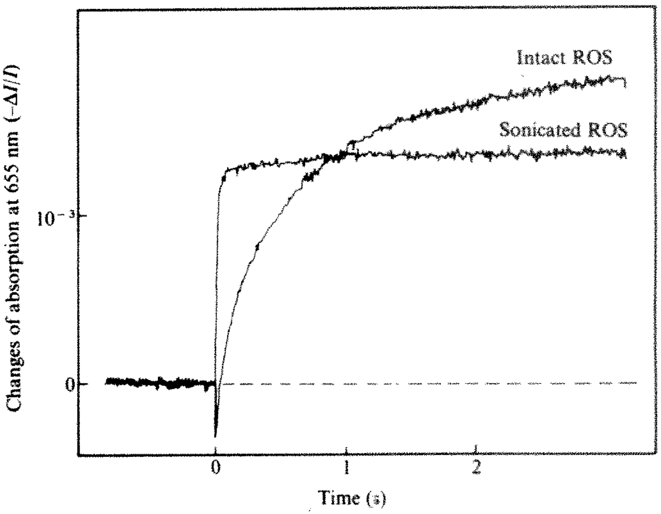

Fig. 2 Time course of the light-induced absorption changes at 655 nm after excitation of intact and sonicated rod outer segments (ROS) by a flash at $t = 0$ in the presence of arsenazo (III) and ionophore A23187. Suspension medium contained: sucrose, 600 mM; HEPES, 2 mM; Tris, 0·5 mM at *p*H 7.0; arsenazo (III), 30 μM; A23187, 10 μM; free calcium concentration 3–4 μM and rhodopsin, 3.5 μM. Fraction of rhodopsin bleached/flash about 4%. Cuvette path length 10 mm. Temperature, 20 °C. Excitation wavelength, 530 nm; half duration of excitation flash 10 ns. Signals were obtained by averaging from one sample over four repetitions at a frequency of 0.1 Hz.

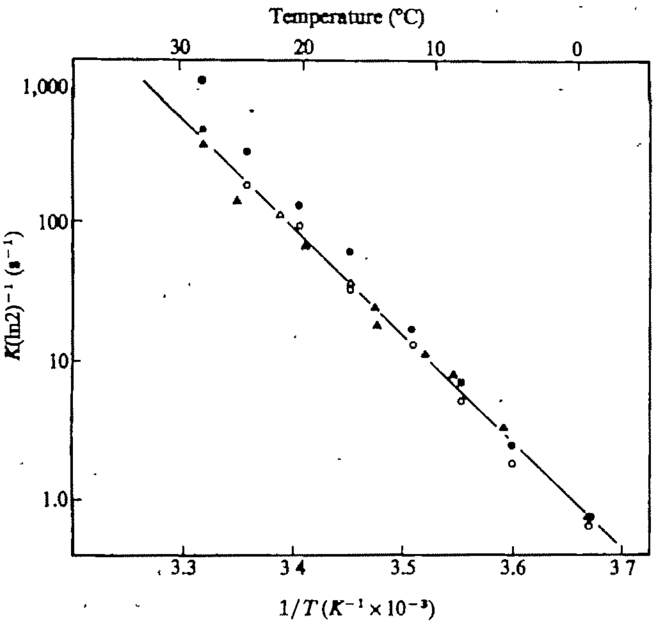

Fig. 3 Arrhenius plot of the temperature dependence of the calcium release (△), the metarhodopsin I/metarhodopsin II transition (●), and the slow component of the metarhodopsin I/metarhodopsin II transition (○) in sonicated rod outer segments. Further conditions as in Fig. 2.

within rhodopsin. In the second model, a reorientation of molecular dipoles within the rhodopsin molecule or rapid proton uptake[16] could decrease an interfacial potential at the disk membrane. According to $K_D = K_D^0 \exp(-2e\varphi/kT)$ the apparent binding constant K_D of calcium binding sites (not necessarily on rhodopsin) is dependent on the surface potential φ(K_D^0 = binding constant in the absence of any interfacial potential). Consequently any change of an interfacial potential will result in a redistribution of calcium bound to the membrane.

It is difficult to decide between the models outlined above. The close correlation between calcium release and the metarhodopsin I/metarhodospin II transition could be interpreted in favour of the first model. However, the fact that rapid calcium release is completely abolished when rod outer segments are dissolved in either nonylglucose (gift of Dr W. J. de Grip, Nijmegen) or Triton X-100 (not shown) would be difficult to explain if calcium were directly bound to rhodopsin. A more detailed account of the interrelationship between calcium release, rapid proton uptake and interfacial potentials will be published elsewhere[15].

A novel conformation of valinomycin in its barium complex

S. Devarajan, C. M. K. Nair, K. R. K. Easwaran & M. Vijayan

Molecular Biophysics Unit, Indian Institute of Science,
Bangalore–560 012, India

Knowledge of the molecular mechanisms involved in ionophore-mediated cation transport would be valuable for understanding many essential functions of biological membranes[1–3]. Cations are transported in several stages, such as formation of the ionophore–cation complex, diffusion across the cell membrane and subsequent release of the cation. Several conformational rearrangements are involved in this process, and so a detailed understanding of all the conformational possibilities of the ionophore seems to be essential for elucidating the molecular mechanism of ion transport. We are carrying out spectroscopic and crystallographic studies to explore the possible conformational stages of ionophores by complexing them, in different solvents, with cations of various sizes and charges. We report here a novel conformation of the ionophore valinomycin in its barium complex. It can be described as an extended depsipeptide chain, without internal hydrogen bonds, wound in the form of an ellipse with the two barium ions located at the foci.

Spectroscopic studies in solution (for example, circular dichroism (CD) spectra shown in Fig. 1) carried out by us indicated that the conformation of valinomycin in its barium complex was different from those in uncomplexed valinomycin and its complex with monovalent cations. Barium perchlorate and barium thiocyanate were used to investigate complexation

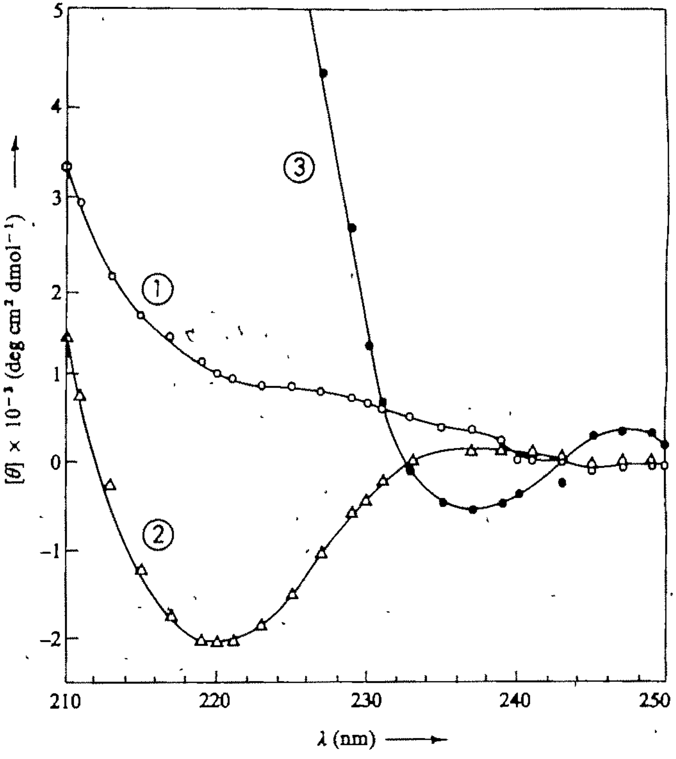

Fig. 1 CD spectra in acetonitrile of free valinomycin (○), its 1:2 barium perchlorate complex (△) and its 1.1 potassium perchlorate complex (●). The concentration of valinomycin was 29 mM (○, △) and 9 mM (●). In the potassium perchlorate complex the molar ellipticity, [θ], continuously increases with decrease in λ with a [θ] value of 25,000 deg cm^2 per dmol at λ = 210 nm.

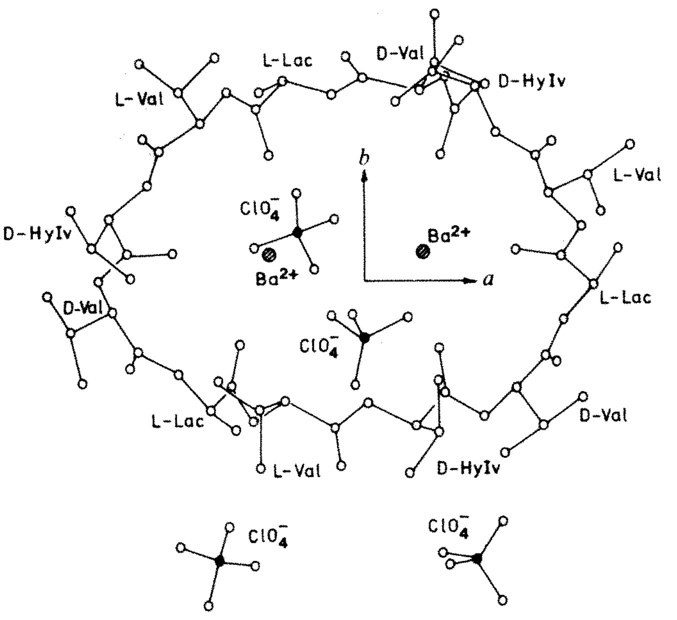

Fig. 2 The location of the valinomycin molecule, the barium ions and the perchlorate groups as viewed along the *c* axis in the crystals of a 1 : 2 valinomycin–barium perchlorate complex.

of valinomycin with Ba^{2+}. CD data on the titration of barium perchlorate with the ionophore in acetonitrile indicated valinomycin–Ba^{2+} complexes with 2 : 1, 1 : 1 and 1 : 2 stoichiometries, although the conformation of the molecule stabilized only at high salt concentrations (S.D. and K.R.K.E., in preparation). CD could not be used with barium thiocyanate because of the high UV absorption of the thiocyanate group. However, proton NMR indicated a stable 1 : 2 valinomycin–barium thiocyanate complex, although the titration curve based on NMR data for the thiocyanate salt was different from that for the perchlorate salt (S.D. *et al.*, in preparation). Thus, it seemed that valinomycin could form 1 : 2 complexes with barium perchlorate as well as barium thiocyanate and we decided to attempt X-ray crystallographic studies on these complexes.

Complexes (1 : 2) of valinomycin with barium perchlorate and barium thiocyanate were crystallized by slow evaporation of slightly aqueous acetonitrile solutions containing the respective components in molar proportions. The crystals were mounted in thin-walled glass capillaries together with the solvent. X-ray diffraction photographs showed that the valinomycin–barium perchlorate complex crystallizes in the orthorhombic space group $P2_12_12_1$ with $a = 28.304$ Å, $b = 16.938$ Å, $c = 19.543$ Å and $z = 4$, whereas the thiocyanate complex crystallizes in the monoclinic space group C2 with $a = 29.48$ Å, $b = 16.49$ Å, $c = 19.92$ Å, $\beta = 111.4°$ and $z = 4$. X-ray intensity data from both the crystals were collected on a computer controlled four-circle CAD-4 diffractometer using graphite monochromatized MoKα radiation to a maximum Bragg angle of 23°. The structure of the barium perchlorate complex was subsequently determined by the heavy atom method and refined by the block-diagonal structure factor least squares technique to an R value of 0.13 for 3,504 observed reflections ($I > 2\sigma(I)$). So far, the two barium ions and all the non-hydrogen atoms belonging to the valinomycin molecule, the four perchlorate groups and four water molecules have been located.

The location of the barium ions, the valinomycin molecule and the perchlorate ions in the crystal structure is shown in Fig. 2. The main-chain dihedral angles[4] in the valinomycin molecule correspond approximately to those for an extended chain. The molecule can be described as an extended depsipeptide chain, with no internal hydrogen bond, wound in the form of an ellipse with the barium ions located at the foci. Three consecutive amide carbonyl groups coordinate to one of the barium ions whereas the remaining three consecutive amide carbonyl groups coordinate to the other barium ion. The coordination of the cation is completed by perchlorate and water oxygens. The conformation of valinomycin observed in the structure is totally different from those found in the crystal structures of uncomplexed valinomycin[5,6] and its potassium complex[7]. It is also different from the conformations unambiguously characterized so far in solution studies[1-3].

We thank the University Grants Commission and the Department of Science and Technology, India, for financial assistance, and Dr A. M. Shaik for help with data collection. The atomic coordinates have been deposited in the Crystallographic Data Bank, University Chemical Laboratory, Lensfield Road, Cambridge, UK.

Circular polarization observed in bioluminescence

Hans Wynberg*, E. W. Meijer*, J. C. Hummelen*, H. P. J. M. Dekkers†, P. H. Schippers† & A. D. Carlson‡

While investigating circular polarization in luminescence[1,2], and having found it in chemiluminescence[3,4], we have studied bioluminescence because it is such a widespread and dramatic natural phenomenon[5,6]. We report here that left and right lanterns of live larvae of the fireflies, *Photuris lucicrescens* and *Photuris versicolor*, emit circularly polarized light of opposite sense.

Firefly larvae (Fig. 1) were gathered in the US and sent by airmail to The Netherlands. They were alive up to and during most of the experiments. In our first attempts to detect polarization of luminescence, we measured the total light emission from both lanterns of the larvae. The results were puzzling and disappointing; vanishingly small circular polarization was observed, with only a few exceptions. To our surprise, we noted—fortuitously—that measurements of the light emission from the left or right lanterns separately gave more constant and encouraging results. During the latter experiments one important fact was established. By shifting and rotating the lanterns through many angles and positions with respect to the optical axis of the apparatus, we found that orientational artefacts could not be the origin of the circular polarization subsequently measured. Whereas in these early experiments we used excised lanterns rigidly mounted in a cell, in the later experiments we preferred to attach entire larvae with fine wire to a holder. The holder was positioned in front of a diaphragm so that one lantern only was fixed onto the optical axis of the apparatus. Continuous bioluminescence, lasting from several minutes to an hour, was achieved by feeding the larvae with a concentrated solution of racemic amphetamine hydrochloride in water. Luminescence usually began 5–30 min after the addition of amphetamine. Measurements were then made immediately.

The circular polarization of luminescence was measured as the anisotropy factor or g_{lum} factor $(I_L - I_R)/\frac{1}{2}(I_L + I_R)$. The difference in the numbers of left and right circularly polarized

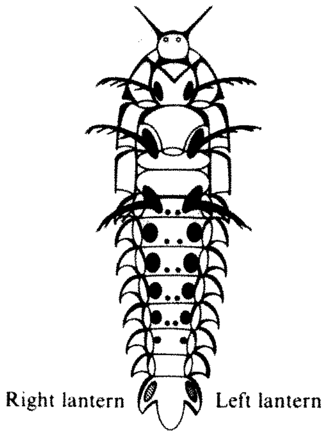

Fig. 1 Sketch of the firefly larva (ventral view). The shaded spots at the bottom represent the lanterns.

photons emitted, $I_L - I_R$, was modulated at a frequency of 50 kHz and detected as alternating photocurrent; the average luminescence $\frac{1}{2}(I_L + I_R)$ was measured as direct photocurrent[1,2,7-9]. Measurements of circular polarization of bioluminescence (CPBL) of 16 firefly larvae lanterns are shown in Fig. 2, revealing that the left and right lanterns emit polarized light of opposite sense. Within each group there is a considerable variation in the total light emission and values of g for the individual lanterns. In these experiments, the construction of the sample holder prevented a detailed investigation of orientational effects. However, on the basis of results of earlier experiments, we believe that neither position effects nor those due to linear polarization could have decisively affected our result.

What is the origin of the CPBL, and what is the origin of the difference in handedness shown by the left and right lanterns? According to the accepted mechanism of firefly bioluminescence mediated by luciferin, an achiral emitting state, III* (see Fig. 3), is involved[5,10-13]. This achiral excited state, by itself, offers no possibility of explaining the CPBL. It may be argued however, that the true excited state consists of a complex between the achiral III* and the enzyme luciferase. Such a chiral excited state complex should, in principle, be capable of emitting circularly polarized light[3,4]. A second explanation would invoke a circularly dichroic medium capable of partially absorbing the emitted light. Neither of these two modes can explain why the left and right lanterns emit polarized light of opposite sense, unless enantiomeric enzymes, active sites or membranes are proposed. In the absence of any evidence for enantiomeric structures, we are forced to conclude that the CPBL of opposite sense must, at least in part, be based on a macroscopic phenomenon rather than on molecular chirality.

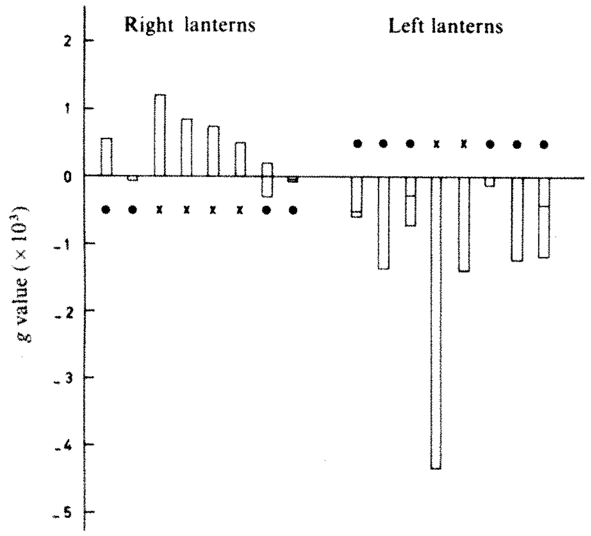

Fig. 2 Results of measurements of circular polarization of bioluminescence of firefly larvae lanterns with sufficiently high emission intensity. The height of each bar represents the g value for an individual lantern of *Photuris lucicrescens* (X) or *Photuris versicolor* (●). Superimposed bars refer to the effect of orientational changes (see text). The circular polarization is measured at the peak of the emission band at a wavelength of 540 nm using a spectral bandwidth of 40 nm. The r.m.s. noise level corresponds with $g \leq 5 \times 10^{-4}$.

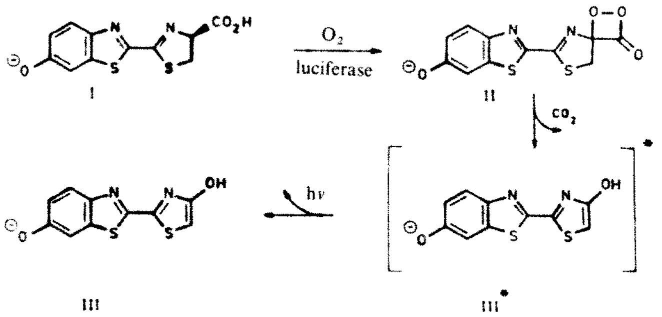

Fig. 3 Schematic mechanism of luciferin/luciferase bioluminescence. Oxygenation of luciferin (I) yields the intermediate II which in turn releases CO_2, resulting in the production of III (or, by H^+-abstraction, the enol dianion) in an electronically excited state. This state emits a quantum of light as it goes to its electronic ground state.

We propose the following hypothesis. The light from a bioluminescent emitter may be (partially) plane polarized due to anisotropy of an absorbing medium or, more likely, by inhomogeneous formation of excited states due to local molecular organization within a photocyte[14]. This plane polarized light will become elliptically polarized when it passes through a linearly birefringent medium. Orientated biopolymers can serve as such a medium. On a macroscopic scale the larvae, like many living organisms, have a symmetry plane dividing the lanterns. In this sense the lanterns are enantiomeric, even though their constituent molecules are of the same chirality; they may be viewed as macroscopic meso-structures. It is reasonable to assume that this macroscopic mirror image relationship holds on the level of the membrane structure and orientation of the emitters. This will result in circularly polarized light of opposite sense. The emitters from one lantern emit partially plane polarized light making angle $+X°$ with the fast axis of its linear birefringent medium. The result is ellipticity of one sense $(+Y)$. The mirror image relationship of the emitters in the other lantern results in partially plane polarized light with angle $-X°$ with respect to the fast axis of its linear birefringent medium. This must result in ellipticity of opposite sense $(-Y)$. We may expect, then, that the meso-orientated lanterns in any bioluminescent organism will emit circularly polarized light of opposite handedness, provided the chirality on the molecular level does not exceed the effect. The results described above suggest experiments dealing with the linear polarization of firefly larvae bioluminescence. Such experiments are planned.

BOOK REVIEWS

Fuel for the 'back-end' debate

Ian Smart

Nuclear Nonproliferation: The Spent Fuel Problem. Edited by Frederick C. Williams and David A. Deese. Pp.221. (Pergamon: New York and Oxford, 1980.) $30, £15.

THE 'back end' of the commercial nuclear fuel cycle, covering what happens to fuel material after its irradiation and withdrawal from power reactors, has had more attention and words lavished on it since 1976 than, arguably, it deserves. It contributes a trivial proportion to the cost of nuclear electricity. It offers more technical choices, and fewer imperatives, than earlier stages in the cycle. And, while no one doubts that plutonium from spent power reactor fuel can be used in nuclear explosives, the danger of that particular route to nuclear proliferation, in relation to others, has frequently been exaggerated. Yet the floods of emotion and typescript continue to rise around the fuel cycle's back end: around nuclear waste management, around reprocessing and the recycling of its products, and around the handling of spent fuel itself.

Reasons for this almost obsessive concern are obvious: the prospect of a so-called 'plutonium economy', based on exploiting back-end opportunities, is genuinely arresting. On the one hand, the consequential introduction of commercial fast breeder reactors is seen by some as a necessary graduation from nuclear infancy, but by others as a leap into economically uncharted and technically dangerous obscurity. On the other hand the issue of nuclear weapons proliferation raised by widespread commercial separation of plutonium is quantitatively, even if not qualitatively, new. And, to cap it all, any discussion of the back end, with or without reprocessing, touches the problem of nuclear waste, management of which provokes more environmental fears — together with more complacency, superstition and reciprocal condescension — than any other topic in the nuclear debate. One may regret that so much time is spent in writing or reading about the back end, at the risk of ignoring what may be more pressing difficulties in the rational and safe development of nuclear power, but one cannot be surprised.

The pathetically familiar polarization of the back-end debate is well illustrated by conflicting images of spent reactor fuel itself: on one side the image of spent fuel as a 'plutonium mine' of immediately valuable fissile material, to be extracted and exploited for good or ill, on the other the image of it as merely one form of nuclear waste, to be buried away out of sight and reach as quickly as possible. Both views are caricatures, justifiable only by ignoring the time factor. In the main, spent fuel is currently a nuisance, encumbering storage ponds at reactor sites and imposing additional costs on utilities. Yet the reactors concerned have extracted less than 1% of the energy potentially available in the uranium originally mined. The rest remains locked up in the spent fuel, as plutonium and depleted uranium, or in the tails at enrichment plants, to be extracted only if and when fast breeder reactors are commercially feasible and widely available. That day may not come, and spent fuel may remain a radioactive nuisance. Meanwhile, however, to treat it as nothing but waste would be like refining crude oil merely to extract bitumen for roads, and then setting fire to all that remained because the internal combustion engine was not yet ready for commercial service. Today's burden may be tomorrow's scarce resource.

One merit of this book is that it studiously avoids caricaturing spent fuel as either immediate gold or permanent dross. Although it starts from the premise, espoused by the Carter administration, that commercial reprocessing is currently uneconomic and politically undesirable, it acknowledges that circumstances may change, and that the ways in which spent fuel is handled today must not preclude using its plutonium content in the future. From there, it moves to the judgement that, to ease pressure on storage at reactors while also preventing an allegedly dangerous increase in the volume and distribution of reprocessed plutonium, more ambitious provision must be made for away-from-reactor (AFR) storage, which could usefully be under some kind of international control. The task it then sets itself is to explore the manner in which an international spent fuel storage arrangement might be set up in different regions of the world.

So far, so good. Whether or not too much time has recently been spent in agonizing over the back end, nothing like enough careful thought has yet been given to how, in the real world, international or multinational arrangements might reduce the fears of proliferation, environmental damage or public rejection which surround various stages of the fuel cycle. It is encouraging, therefore, to find that "a working group of fifteen scholars and professionals, representing a diversity of academic levels, professions, experience, and nationalities, met biweekly over the course of a year" at Harvard, and that here we have 11 of their papers, dealing not only with politics, technology and economics at a general level but also with five major world regions. Marvin Miller shows that, although more development is needed, there are technical methods of storing spent oxide fuel safely (and retrievably) for at least 25 years. Boyce Greer and Mark Dalzell outline an ingenious economic model which suggests that all except the largest reactor-operating countries might well save a lot of money during that period by sending their spent fuel for storage in large international facilities, even at a considerable distance. The editors, David Deese and Frederick Williams, provide an introductory discussion of the political options available and of the political criteria which are likely to determine the location of any international spent fuel store, and reach the sensible conclusion that the right approach to building an international regime is a gradual and incremental one, serving energy as well as non-proliferation concerns and eschewing dramatic or, above all, unilateral, policy excursions. And Tariq Osman Hyder adds a crucial warning that no such regime will be created unless developing as well as developed countries are convinced in advance of its equity. A foundation of realism and feasibility seems to have been laid.

Thereafter, unfortunately, everything slides downhill. The papers on political prospects in specific regions, clearly drafted as essays for a biweekly seminar, are altogether slighter contributions, uneven in technique and quality and sometimes uncertain on fact. All are ultimately pessimistic. Melvyn Nathanson, while offering the eccentric thought that the USSR might store spent fuel from outside Comecon, regards internationally controlled storage arrangements as irrelevant to Eastern Europe. Onkar Marwah sees none but the remotest prospect of Indian Ocean countries subscribing to such an arrangement, and then only if a regional store on a remote French or Australian island accepted nothing but fuel from a few fully safeguarded plants. Victoria Johnson and Carlos Astiz are driven back to suggesting Paraguay or Uruguay as the only possible hosts for a Latin American store. Richard Broinowski is hardly more optimistic about Asia and the Middle East, and Robert Gallucci even less encouraging, if that is possible, about Western Europe. At the end, therefore, the editors, concluding sadly that there is little chance of rational economic arguments overriding "the centrifugal forces of international politics", leave one asking whether the dinner was worth the detour.

It may be because their surveys of regional politics so depressed them that the editors and authors found no reason even to consider some of the most obtrusive problems in working towards international or multinational fuel cycle arrangements. There is no discussion here of the criteria which should govern the release of spent fuel from international custody. There is almost nothing about institutional form or organization: how rights, responsibilities, costs or authority might be pooled, distributed or devolved. These are glaring omissions, which inevitably detract from the book's value. They might nevertheless be justified if the political prospects were as impenetrably gloomy as here indicated. The hard fact, however, is that the political analyses in the volume often verge on the simplistic, and are forced, moreover, towards pessimism by questionable underlying assumptions: that international arrangements for spent fuel storage must, for example, be addressed in isolation from other fuel cycle functions, or that membership of any multinational fuel cycle institution must be drawn from a single geographical region. Above all, those responsible for the study have steered so far away from the Scylla of believing that political obstacles will vanish in the face of an intellectually coherent scenario that they have fallen victim to the Charybdis of equating the politically difficult with the palpably impossible.

The authors are to be praised for venturing into turbulent waters which it may be politically essential for governments to explore thoroughly during the next few years, and for setting up some preliminary aids to navigation. At the end of the day, however, their courage seems to have failed, because they have judged the icebergs of politics to be immutable. It is not necessary, and it may not be wise, to assume that national policies must be as unalterable, or diplomacy always as impotent, as their conclusions would suggest. □

Ian Smart is an independent adviser on international energy affairs, and was Chairman of the International Consultative Group on Nuclear Energy (1977–80).

Learning from the Arctic peoples

John Ebling

The Human Biology of Circumpolar Populations. International Biological Programme 21. Edited by F.A. Milan. Pp.367. (Cambridge University Press: Cambridge, 1980.) £35, $75.

THE Arctic regions were the last major environment to be conquered by *Homo sapiens*. The radiation of human beings into colder climes northwards and southwards from the tropics probably started about half a million years ago and extended into western and central Europe under conditions of great cold during the Pleistocene. At the end of the Old Stone Age, the use of clothing enabled the human hunters to follow the retreating ice of the Third Würm Glaciation into the Eurasiatic land mass and finally to move into the New World. What adaptations were involved? In general, the physiological differences between modern circumpolar peoples and those more favoured climatically are not striking. They may, perhaps, show an earlier onset of cold vasodilation and have uniformly warmer fingers, but their eyes differ little, even though they are exposed to continuous low temperatures, blowing snow in winter and high ultraviolet radiation in spring. In the far Arctic, people survive mainly on protein, without any obvious source of essential vitamins, and generate necessary glucose from amino acids. The polyunsaturated fats from seal and whale oils keep plasma cholesterol and heart disease at enviably low levels.

The Human Biology of Circumpolar Populations is an admirably edited source book with contributions from Canada, the USA, Denmark, Norway, Finland, France and the USSR. The chapters deal in turn with the demography, genetics, craniofacial features, ophthalmology, anthropometry, nutrition, physiology and behaviour of the 16 indigenous Arctic peoples, ranging from the Lapps of Scandinavia to the Eskimos of Greenland and including the lesser known Siberian groups and the Ainu.

The publication of such a book, and the special studies of the International Biological Programme which went into its making, are timely. The circumpolar peoples are changing. Alcoholism, leading to accidents, violence and other social disorders, is on the increase. There is much that our society needs to learn from them before they are destroyed by contact with us. □

Ecological view of marine animal diseases

R.J. Roberts

Diseases of Marine Animals. Vol.1. Edited by O. Kinne. Pp. 466. (Wiley: Chichester, UK, and New York, 1980.) £25, $73.15.

BECAUSE of the span of our knowledge, and the complexity of the subject, pathology books are nowadays generally multi-author volumes which deal with a single species (usually human beings) or even a single organ system. Comparative pathology texts are few and generally relate to specifically defined groups of economic significance such as domesticated animals or teleost fish. Only a brave, or naive, person would attempt to write a textbook covering the diseases of virtually the entire animal kingdom in so far as it inhabits the marine environment. Surprisingly this brave man is not Otto Kinne, whose name appears as editor on the cover of this first volume in a series of four, but one G.H. Lauckner who has apparently been responsible for the entire content of all four volumes apart from the two very general introductory chapters. He appears to have received less than adequate credit for this mammoth task.

Dr Kinne is a distinguished marine ecologist and in the foreword to this first volume he gives his view that disease is primarily an ecological phenomenon. This is a very different attitude to that of the majority of comparative pathologists and, I suspect, of commercial aquaculturists and fishery biologists as well. It is true, however, that marine ecologists have too often focused exclusively on holistic ecosystem properties and food-web interrelations in ignorance of the impact of diseases on populations. It is a stated aim of this series to synthesize all of the information available to allow the ecological significance of diseases in the marine environment to be appreciated.

This first volume covers the lower invertebrates, ranging from the Protozoa to the Gastropoda. These are the groups covered by the smallest amount of published literature in comparative pathology, and thus for many of them the scarcity of documentation is perforce out of all relation to their importance to the marine ecologist. This is no fault of Dr Lauckner's but it does impede the objective of helping biologists to give disease its appropriate place within the marine ecological model.

Since very few of the invertebrates covered in this volume are cultured, or even fished, the economic incentive for the detailed scientific study of their diseases has been absent. Most of the records of such diseases are one-off observations rather than systematic studies and often even Dr Lauckner is unable to do more than detail the paucity of available information.

Although the book is well produced and beautifully printed, most pathologists (though not, I suspect, parasitologists) would jib at the extensive use of line drawings rather than photomicrographs in all but a very limited number of instances.

The gathering together of such a mass of information, often related only by its ecosystem, and its synthesis into a review of this magnitude indicates great determination. As a source of information for scholars of a wide range of subjects it will be invaluable. I doubt, however, if it will substitute for a specific monograph on any of the groups covered. It is neither specialized enough nor complete. I do expect, though, that the complete series will find its place in any library attempting to cover the field of marine biology. □

An 'axiomatic' approach to quantum mechanics

J.L. Martin

Quantum Mechanics. By A. Böhm. Pp. 522. (Springer: Heidelberg and New York, 1979.) DM 58, $31.90.

IN WRITING about quantum mechanics, where does an author begin? There are several possibilities. He may struggle through the historical development of the subject, with all its gropings and false starts — excellent in its place, but not in a standard text. He may begin with elementary physical examples, and using a judicious mixture of assertion, intuition, correspondence principle and Ehrenfest's theorem — uncluttered with too much mathematics — attempt to lead the reader into a 'feel' for the subject. Or he may adopt an 'axiomatic' approach: 'Here are the rules; where do they lead?'. The trouble with this last option is that the reader who is looking for enlightenment may have to journey for too long in the dark before the dawn of what it is all about.

This is an 'axiomatic' book, and I would hazard the opinion that it is not for the physicist — not even for the theoretical physicist — but for the mathematician who is already familiar with the basic structure of quantum mechanics. Moreover, the selection of topics obviously reflects the author's personal interests to a degree; thus I find it difficult to recommend the book as a text, as the coverage is so uneven. It may well be useful to anyone with an interest in the mathematical aspects of quantum mechanics, developed from a particularly algebraic point of view. (The very first mention of a physical system, p.10, runs: "The mathematical image of a physical system is an operator *-algebra in a linear scalar-product space $\mathscr{H}$". This sets the tone of the book as a whole.) The reader who wishes to learn to use quantum mechanics as a tool will be disappointed; a glance at the problems at the end of each chapter will confirm this. Compare them, for example, with those in classics such as Schiff (*Quantum Mechanics.* McGraw-Hill: New York, 1968).

In reading the book, I felt I was listening to the lectures. The presentation in parts was too discursive and rambling for my taste: after all, the reader can re-read the text if he needs to, and writing a book is a golden opportunity to tighten up a lecture style into something more terse and tidy, in which the wood can be seen in spite of the trees.

There are many small and usually unimportant misprints which betray a lack of care at the proof-reading stage — "communication relations" (p.41); in the index under "Selection rules", "hydrogen bomb" should surely be "hydrogen atom". And by the way, the Argand diagram was not introduced to help us understand the scattering amplitude. Jean Robert Argand did his work in 1806! □

Controversial view of primate evolution

R. D. Martin

Evolutionary History of the Primates. By Frederick S. Szalay and Eric Delson. Pp.580. (Academic: New York and London, 1980.) $48, £31.20.

THERE has been a great proliferation of research into the evolutionary radiation of the primates over the past 15 years. Reanalysis of the evidence has benefited from new palaeontological work, from a virtual explosion of new information on living primates (notably including biochemical data) and, above all, from reassessment of the methods used to infer phylogenetic relationships. As primate palaeontologists, Frederick Szalay and Eric Delson have both made significant contributions in the first of these areas, and *Evolutionary History of the Primates* is accordingly an authoritative and competent guide to the great array of recognized primate fossils.

A brief introduction includes, among other things, a handy chronological catalogue of known primate fossil sites and a simple outline of primate molar tooth morphology. The methods used for inferring evolutionary relationships, which owe much to Hennig, are touched upon; but this all-important aspect should have been discussed in full detail, especially since the authors themselves admit to a divergence of opinion. The bulk of the book consists of a systematic survey of primate groups, with notes on extant forms and extensive, well-illustrated descriptions of the fossils. In this respect, the book will undoubtedly serve as a valuable reference source and its usefulness is enhanced by a selective bibliography and a glossary of terms. Numerous good-quality scaled photographs combine to make this the most comprehensive primate fossil guide available to date, and it is to be recommended to anyone with an interest in primate evolution.

A sharp distinction must be drawn, however, between the mere description of fossil primate material and its interpretation within a comprehensive evolutionary framework. A severe limitation of this book lies in the exclusion of virtually all information other than that derivable from teeth and bones. It is particularly surprising that there is barely a reference to the evolution of the primate brain, since endocasts are now available to document fundamental features in numerous fossil primate species. In their introduction the authors accept that the reliability of phylogenetic inferences increases with the scope of the data analysed, yet they ignore or even discount out-of-hand much relevant information (e.g. immunological data) derived from living primates. A proper synthesis of both palaeontological and neontological data must be achieved before maximal accuracy can be expected.

The rationale underlying the classificatory scheme used in the book is also inadequately explained. In places, new taxonomic groupings have been established as direct concomitants of the authors' personal hypotheses regarding evolutionary affinities, whereas elsewhere this strict Hennigian approach has not been followed. Some innovations have much to commend them; others will generate little but confusion. It is probably a wise move to erect a separate suborder Plesiadapiformes to accommodate *Plesiadapis* and its apparent relatives, thus emphasizing the enormous morphological gulf between these early Tertiary forms and the "primates of modern aspect" (Simons). Indeed, it is by no means certain that the plesiadapiforms exhibit anything other than convergent dental and basicranial similarities to the more obvious primates.

On the other hand, there are several taxonomic changes which could well have been omitted without in the least detracting from the authors' provisional evolutionary hypotheses. Szalay and Delson do not combine all of the primates of modern aspect (their "euprimates") into a formal taxonomic category, despite abundant evidence that this is a monophyletic grouping, so it is difficult to see why other classificatory novelties were required. Two examples illustrate the problems. Firstly, in line with a few other authors, the lemur family Cheirogaleidae has been moved from the superfamily Lemuroidea (containing all the other Malagasy lemurs) to join the Lorisidae in the superfamily Lorisoidea. Szalay's interpretation of certain morphological evidence, which is shared by some but has been disputed by others (and which is in direct conflict with available biochemical evidence), suggests a recent common ancestry for cheirogaleids and lorisids. Whether or not this hypothesis proves to be tenable in the long term, the immediate practical outcome of the taxonomic upheaval is that the term 'lorisoid', which has had a distinct and useful meaning for decades, has been rendered ambiguous. According to which classification one now follows, the word 'lorisoid' may or may not subsume the mouse lemurs and their relatives. Similarly, Szalay and Delson have reduced the marmoset and tamarin group from family level to the tribe Callitrichini and have lumped them together with *Callimico* and the Cebinae *(Cebus + Saimiri +* conjectured fossil relatives) into the family Cebidae. This drastic modification is based on Rosenberger's tenuous interpretation of minor dental and cranial features as "shared derived characters" linking marmosets and tamarins to cebines and is once again in conflict with immunological evidence. Henceforth, to the confusion of many involved in research upon marmosets and tamarins, the term 'cebid' might denote *either* 'all New World monkeys other than marmosets and tamarins' (this being the almost universally accepted meaning to date) *or* 'marmosets, tarmarins, *Callimico* and cebines'.

Must we pay the price of such linguistic confusion as provisional hypotheses are generated in the pursuit of a more scientific understanding of primate evolutionary history? □

Conformation of saturated heterocycles

A.R. Katritzky

The Conformational Analysis of Heterocyclic Compounds. By Frank Riddell. Pp. 153. (Academic: London and New York, 1980.) £17, $39.50.

THIS SMALL book will be of considerable help not only to organic and physical chemists, but also to workers in biochemistry and in other biological areas who need to understand something of the conformational analysis of saturated heterocycles. The first two chapters set the scene by summarizing the fundamental concepts on which conformational analysis is based, and then by picking out and emphasizing the differences which characterize the treatment of saturated heterocycles as compared with their carbocyclic analogues.

The remaining two-thirds of the book is organized into five chapters dealing with (1) 4- and 5-membered rings, (2) 6-membered oxygen-containing rings, (3) 6-membered nitrogen-containing rings, (4) 6-membered rings containing sulphur or phosphorus, and (5) 7-membered and larger rings. To treat this variety of topics within 150 pages, the author must of course be selective: he has rightly chosen to discuss the most important and fundamental ring systems, and thus little attention is paid to polycyclic derivatives. He has wisely decided to describe, clearly and in some detail, a smaller number of compounds rather than to attempt an encyclopaedic treatment which could have degenerated into mere lists.

The work has obviously been a labour of love; the proof-reading has been carried out excellently, the diagrams are well drawn and clear, and the book has an authoritative ring about it. Further, the subject has not been without its controversial features and on the whole the author deals fairly with these aspects. □

A.R. Katritzky is at present Professor of Organic Chemistry and Dean of the School of Chemical Sciences at the University of East Anglia, UK, but will be taking up a new appointment as Kenan Professor of Organic Chemistry at the University of Florida, Gainesville, in September 1980.

Soviet physics

A. J. Leggett

Soviet Scientific Reviews. Section A: Physics Reviews Vol. 1. Edited by I.M. Khalatnikov. Pp.305. (Harwood: Chur, Switzerland, 1979.) Dfl.125, $67.75.

THIS book is one of a new series which is intended to bring to English-speaking physicists some of the highlights of current research in the Soviet Union. This first volume contains six review articles which concentrate primarily on advances made by Soviet physicists in papers published in 1977, although reference is made to earlier, and contemporary non-Soviet, work as appropriate. The reviews fall conveniently into three groups of two papers each: Belavin (on instantons) and Zakharov and Manakov (on solitons) concentrate on mathematical developments in field theory, particularly the use of algebraic geometry, and make little if any reference to experiment; the papers by Volovik (superfluid ^{3}He) and Ivlev (nonequilibrium phenomena in superconductors) are largely theoretical but refer to relevant experiments from time to time; while those by Pokrovskii and Timofeev (exciton condensation in semiconductors) and Borovik-Romanov and co-workers (spin waves in antiferromagnets) are mainly experimental in content.

These reviews are definitely not of the type which could usefully be picked up by a non-specialist as an introduction to the subject in question. They will probably be most useful to those who, while not actively enough involved in a particular area of research to wish to spend a lot of time reading the original Soviet literature, are nevertheless close enough to it to want to keep up with important developments in some detail. For them, this book may play the role as regards Soviet physics that occasional lectures and the 'grapevine' play for much of non-Soviet research. However, although the editor states that he has tried to include "those fields in which Soviet physics is pursuing a direction of its own" it is not clear in most cases that a review covering non-Soviet (or all) work in the area would necessarily be very different in style or emphasis — which perhaps goes to show that the communication gap is not all that serious after all!

The translation is mostly of a high standard, but I hope that in future volumes the series editors will allow more time for proof-reading and also do something about the type-face used; in the present volume the symbols for italic vee and Greek nu are almost indistinguishable, which leads on occasion (e.g. p.261) to extreme confusion. □

14 August 1980

Open season for nuclear diplomatists

The world's nuclear diplomatists are in for a long hot summer. Many of them, still recovering from the meeting of the UN Committee on Disarmament which ended only a week ago, will have been back in Geneva on Monday for the Second Review Conference of the Non-Proliferation Treaty, which is planned to last four weeks. Once that is over, many of the same people will be off to Vienna for the annual General Conference of the International Atomic Energy Agency (IAEA), which on past form is likely to be much occupied with the adequacy (and the cost) of the international nuclear safeguards system. This year, however, two weeks in Vienna will not for many be sufficient — they may have to stay on for the first meeting of the new Committee on Assurance of Supply, the body whose existence was decreed in June by the Board of Governors of the IAEA, whose composition and agenda are not yet decided but which could play a crucial part in helping to bolster up the Non-Proliferation Treaty. What, it is natural to ask, will this bout of activity accomplish? Will the families of the diplomatists who will thus be giving up vacations think their sacrifice has been worthwhile?

As always, it is too soon to say, but the prospects for the weeks ahead should be clarified by what happens in Geneva between now and 5 September. Inevitably, the NPT conference will be a quarrelsome affair. Many harsh things will be said, especially by non-nuclear parties to the treaty (see *Nature,* 12 June). Some will complain that the three nuclear powers which have signed the NPT (the Soviet Union, the United Kingdom and the United States) have done too little to implement their promise to negotiate measures of strategic disarmament. If Salt II were not in limbo, the nuclear powers might have been able to reply convincingly. The best they have to offer now is the tripartite report on the negotiations towards a Comprehensive Test-Ban Treaty, submitted to the Committee on Disarmament at the end of July. Plainly, there has been some progress, but a cheerful interim statement is no substitute for a treaty. That is what the non-nuclear parties to the NPT will be saying. The same states will complain that too little has been done, both by the nuclear powers and those signatories of the NPT in a position technologically to do so, to foster the development of civil nuclear power elsewhere. The nuclear powers are no doubt hoping to blunt the edge of this complaint by referring to the meeting planned for Vienna at the end of September. They must expect to have to make some promises about the scope and speed of those proceedings. But the test by which the success of the Review Conference should be judged is that of whether the non-nuclear signatories of the NPT leave Geneva having been persuaded that non-proliferation has come to stay — or at least that the present regime will last for another five years.

It is therefore important that, in at least two respects this second conference will not be much occupied with two of the issues that perplexed the first, in 1975. Then, the non-nuclear signatories of the treaty were still grumbling about its discriminatory character. Is it not an outrage, they were inclined to ask, that safeguards should be rigorously applied to non-nuclear states but not to the real black sheep, the nuclear powers themselves? The treaty has not changed in the past five years, but it does appear that all parties to the treaty have come to accept that it must be discriminatory in this narrow sense. It cannot be otherwise unless and until the nuclear powers have agreed to forsake nuclear weapons altogether. With the fate of Salt II in mind, few at Geneva will be asking for that moon now. The vigour with which they would have complained at discrimination will no doubt be diverted into the more legitimate complaint that the nuclear powers, having dragooned and cajoled non-nuclear powers into signature of the treaty, have then chosen to impose separately agreed restrictions on international trade in nuclear equipment even when the would-be recipients have signed the NPT and come to safeguards agreements with the IAEA.

The other bone of contention which has been resolved in the past five years is the issue of peaceful nuclear explosions. Largely at the insistence in the 1960s of countries such as Brazil and India (which, ironically, is not a signatory of the treaty), the NPT requires that the nuclear powers should provide, through the IAEA, peaceful nuclear explosions to those non-nuclear powers able to persuade the IAEA that they have a need of them. Mercifully, the suspicion that peaceful nuclear explosions would be an economic blessing in disguise is fast melting away. Only in the Soviet Union, where as many as eight of the 28 nuclear explosions in 1979 may have been "peaceful", does enthusiasm persist. The government of India, which used the PNE argument to justify its nuclear explosion in May 1974, has not thought it worthwhile repeating its indiscretion. The nuclear powers need not expect a drubbing at Geneva because they have not been trudging the world for the past decade, offering to blow out harbours and other holes in the ground for all and sundry.

For small mercies, the nuclear powers will no doubt be grateful. What can they say on the major issues they will be confronted with? By now, fortunately, there is enough experience of the NPT for its true nature to be widely understood. The treaty itself is no more a guarantee that anxiety about nuclear proliferation can be banished than was Prohibition a guarantee against alcoholism. From the start, the principle underlying the treaty has been that of a bargain between the nuclear and non-nuclear powers. The nuclear powers would work towards strategic arms control, the non-nuclear powers would meanwhile not embark on military programmes. The bargain is, of course, not comprehensive. China, France and India remain outside the treaty, as do a great many supposedly non-nuclear powers that are presumed to have an interest in nuclear weapons — Pakistan, Brazil, Argentina, Egypt, Israel and South Africa, for example. Worse still, some of the signatories of the NPT are rightly regarded with suspicion. Is it possible that countries such as Libya or Iraq, dutiful signatories of the NPT, have it in mind that they can use the benefits of access to nuclear technology which the treaty offers so as to build up a stock of fissile material and then simply give notice, as the NPT allows, that they are withdrawing from its provisions and its safeguards? In such circumstances, it is wisest that even the staunchest supporters of the NPT should recognize its weaknesses. The only realistic objective is somehow to contain the pace of nuclear proliferation — which, paradoxically, requires that the NPT system should be robust enough to survive the emergence of the next nuclear power, whichever it may be. At the same time, it is essential that states not yet party to the treaty should be provided not merely with a sense of pressure from the non-proliferators but also that they should be given incentives in due course to sign on the dotted line.

This is the sense in which the meeting of the Committee on the Assurance of Supply at the end of September may be crucial. Unlike the review conference of the NPT, the committee will in principle bring together all members of the IAEA, France and China among them — although nobody knows as yet which will turn up. This broadening of the scope of discussions about proliferation is greatly to be welcomed. The committee's most

0028-0836/80/330647-02$01.00

urgent task is to restore the confidence of the non-nuclear states in the willingness of potential suppliers to sell nuclear equipment and raw materials. President Carter's unilateral out-of-the-blue non-proliferation policy of 1967, and the tactless US Nuclear Non-Proliferation Act of 1968, has been the chief but not the only offender. The US Administration's difficulty in living with the Act it has sponsored in Congress (see *Nature*, 31 July) should be a sign to people elsewhere that there is no future in an agreement among suppliers to trade only with states that have accepted full IAEA safeguards. The government of France would not even consider such a proposal. The best hope for the CAS meeting is to devise incentives that will persuade states outside the NPT system that it would be in their best interests to join the club. An international convention to regulate the nuclear business on a multilateral basis, however desirable, is probably for similar reasons unattainable. Uranium banks under international auspices, or internationally managed reprocessing plants, offer more scope for imaginative negotiation. And is it too much to ask that the nuclear powers and the nuclear suppliers can use the two months ahead to repeat the message they were trumpeting a quarter of a century ago — that nuclear power is indeed a way of helping forward economic development in all kinds of states? One of the other circumstances that have changed in the past five years is that non-nuclear states are now in a mood again to believe the message.

The question remains of what the nuclear powers will have to report at the review conference about progress towards strategic disarmament. Last month's report to the Committee on Disarmament shows that the Comprehensive Test-Ban negotiations have made substantial headway toward verification. If the treaty is signed, there will be arrangements for the exchange of seismic data, a committee of "experts" to assess them and procedures for dealing with challenges raised by one party or another. So much has been agreed. So why not sign the treaty right away? That is what some non-nuclear powers will be asking in Geneva in the next few weeks. In doing so, they will enormously underestimate the problems with which the three nuclear powers are grappling. States such as the Soviet Union and the United States are considering, apparently in good faith, binding themselves to forswear the further development of nuclear weapons, thus ensuring that, in the course of time, weapons now considered central to their security will be built less confidently than at present — and are doing this while there remains no assurance that China and France would follow suit. It is a huge political enterprise — and one that may not succeed. To have travelled so far along such an unpromising road is creditable.

Putting Finniston's cart before the horse

The British government's response to the Finniston report on engineering education is best described as frivolous. That may have been inevitable. The report was commissioned by a Labour government with an earnest conviction that governments have a duty to ensure that social institutions of all kinds are well suited to their purpose. Sir Monty Finniston and his colleagues on the committee of inquiry, set up in 1978, responded with gusto to the implicit invitation to reconstruct the whole pattern of engineering education. They were nothing if not radical. They set out to diminish the influence of the engineering institutions by proposing that there should be a new body, called the British Engineering Authority, to be responsible both for the certification of professional engineers and the validation of engineering courses, in universities and elsewhere in higher education. The committee also asked for changes in the educational system itself; engineering students would follow courses much like those now available, but with more work experience, but a minority would stay on for an extra year and come away with a higher qualification. The underlying objective of the Finniston Committee was to enhance the reputation of engineers in British society as a whole, whence (in part) the proposals that the state should pay larger stipends to engineering students than to others, that public authorities should not let contracts without insisting that only registered engineers are employed on them, and that properly registered engineers should be entitled by statute to regular periods of sabbatical leave (admittedly in the good cause of continuing education). Looking back over the past two years, and at the host of these fondly conceived but now stillborn proposals, the committee will no doubt rue its bad luck. It has fallen to a non-interventionist government, and to the most zealously non-interventionist minister of that government (Sir Keith Joseph) to respond.

An engineering authority of some kind will indeed come about, but not yet and not in the form the Finniston Committee asked for. Certainly it will not be the body "with teeth" that Sir Monty Finniston and his colleagues have been asking for since their report was published. Instead, the Privy Council (which can grant Royal Charters and thus legitimize the activities of non-governmental public bodies, universities for example) will be asked to set it up. The government will appoint the first slate of members, and help with petty cash for the first year or two. After that the authority will be expected to make its own way in the world, persuading universities that it is in their interests to have their courses validated by the new organization, qualified engineers that they had better be registered under the new rules (still to be written) than with the existing engineering institutions and employers that the new certificate of registration is a worthwhile professional qualification. The prospect is daunting. There is a high chance that the new authority will be no more successful than the Council of Engineering Institutions, set up for similar purposes by the engineering institutions themselves (and which, apparently, will continue to exist, no doubt sniping from the wings from time to time). Many will say that it would have been better not to have had an engineering authority at all than to have so willingly courted the chance of failure. And that is the sense in which the government's decision is frivolous. For whatever the faults of the Finniston proposals, and there are several, the new arrangements are certain to be regarded — as was the Finniston Committee itself — as the best hope for the improvement of the engineering profession. Once the new authority exists, it will for a time at least tend to stifle other instruments of change.

This is a sad solution to have been wrought from the widespread recognition, in the past few years, that something should be done to change the pattern of engineering education and professional recognition. The explanation seems to be that first Finniston and now the government have put the cart before the horse. The most urgent need is for a more imaginative experiment in engineering education in the universities, and for level-headed evaluation of the consequences. Everybody accepts that intending engineers, like intending doctors, profit from first-hand knowledge of the problems with which they will have to deal in later life. There is, however, no assurance that the pattern of four-year courses now being tried out in English universities (and which Finniston endorsed) will be a substantial improvement on the present. To the extent that these courses will continue to skimp on basic science, the result may well be engineers whose education is more expensive but who are no better fitted for the needs of modern industry. For the truth is that a profession such as engineering should be a cadre of people with very different backgrounds and skills. The objective would have been better served if the government had encouraged the universities, through the existing machinery of the University Grants Committee, to develop courses that differ among each other but which collectively mightyield the diversity the profession needs. The trouble is, of course, that such a development would require extra funds for the universities. This is hardly the time to be asking for more.

Another violation of NIH guidelines

Washington

Cross-contamination between vials containing viruses being transported from Britain to California may have caused a San Diego scientist inadvertently to carry out experiments prohibited under the National Institutes of Health's guidelines for recombinant DNA research. This, at least, is the "working hypothesis" which Dr Samuel I. Kennedy, of the University of California at San Diego, offered last week to explain what may prove to be the third violation of the guidelines.

Dr Kennedy, who moved to California from the University of Warwick in 1977, has been studying the activity of several arboviruses. In particular, he has been looking at the ways in which virus reproduction is inhibited by naturally produced "defective interfering particles" containing only a fragment of the virus genetic material. Earlier this year, Dr Kennedy and his research assistants cloned what they thought were subgenomic fragments of the Sindbis virus, a cause of fever and skin rash carried by mosquitoes in parts of Africa, India and Australia.

Following "confusing" results of attempts to characterize the nucleotide sequences in the resultant recombinant DNA produced in disabled *Escherichia coli*, the cloned material was sent to the Public Health Laboratories in Berkeley for analysis. There it was discovered that the cloned fragments appeared to have derived not from Sindbis virus but from Semliki Forest virus, another arbovirus being studied in Kennedy's laboratory.

This raised difficulties, for although the Sindbis virus has been classified by the Center for Disease Control (CDC) as a Class 2 agent — which under the NIH guidelines could be cloned under P2 physical containment conditions — the classification of the Semliki virus was ambiguous.

Until recently, the Semliki virus, known primarily as a cause of headaches and fever, was considered even safer to work with than Sindbis virus. Three years ago, however, a German research worker died after being infected by a wild-type strain of the virus. As a result of this incident, CDC is considering classifying the Semliki Forest virus as C3, although subject to certain qualifications.

At the end of last month, NIH announced changes in their guidelines to allow viruses in this class to be cloned under P3 containment conditions. However, at the time when Dr Kennedy's experiments were carried out, the cloning of C3 agents was prohibited.

As soon as the university suspected that the NIH guidelines might have been violated, both the Institutional Biosafety Committee and the NIH's Office of Recombinant DNA Activities (ORDA) were informed. ORDA is now carrying out an investigation, and will eventually make recommendations to NIH Director Dr Donald Fredrickson on what action should be taken.

The ORDA investigation seems likely to concentrate on three aspects. First, how could the confusion between the two types of virus have occurred and was this the result of cross-contamination during transit from research laboratories in Britain?

Second, ORDA must determine what classification it would have given to the Semliki Forest virus if a cloning application had been made at the beginning of the year. Approval as a Class 2 agent would have permitted the experiment; approval as Class 3 would have disallowed it. This problem is complicated by the fact that CDC classification of arboviruses is under revision. A European scientist was told by NIH earlier this year that although the Semliki virus would probably be considered to fall within Class 3, in certain geographic locations and conditions of use it might be considered C2, permitting cloning under P2 containment.

Finally, ORDA will be looking closely at the procedures followed by Dr Kennedy and the university once a violation of the guidelines was suspected. Dr Kennedy stopped work on the cloned fragments, and informed the Institutional Biohazard Committee of the apparent mix-up, as soon as the results of the laboratory tests were received at the end of last month. Some of his graduates students, however, had previously approached the head of the biology department, Dr Donald Helinski, expressing concern about preliminary results and taking a different view of the actions that ought to be taken.

Both university and NIH officials stress that there was no public hazard involved. "We were not even cloning the entire genetic information in the virus" says Kennedy, pointing out that even if it was Semliki virus, the guidelines allow this to be safely cloned under the P3 containment conditions that were in fact used.

The biggest impact of the incident is likely to be on public perception of how the guidelines are working. Since the NIH guidelines were introduced in 1976, there have been two reported violations. In one a scientist from the Harvard Medical School carried out experiments without the necessary prior clearance from NIH. In the other, San Francisco scientists conducted experiments with a plasmid vector before it had been officially approved.

David Dickson

Small beer for scientists

Scientists working for the British Civil Service are unlikely to be satisfied by the outcome of the arbitration on salary scales for 1980, which was completed last week. After the arbitration award was made known, Mr William McCall, General Secretary of the Institution of Professional Civil Servants (IPCS), said that the outcome was disgraceful and that "if this is what the system now in force for settling the pay of scientists in the Civil Service produces, then the system will have to be changed".

There have been several bones of contention between the IPCS and the Civil Service Department since the first offer of salaries for 1980. The department's proposals (see *Nature*, 24 July) were especially mean to the higher grades of the scientific Civil Service — those in the grade of Senior Principal Scientific Officer were, for example, offered no increase except the annual increments to which they were contractually entitled.

The IPCS has complained consistently that the device of pay research for relating the salaries of higher civil servants to those of comparable groups of workers in the private sector undermines the principle that scientists within the Civil Service should be paid the same as other civil servants of comparable rank and that, in any case, the data on salaries earned by scientists in the private sector are insufficient as an accurate foundation for pay research.

The Civil Service Arbitration Tribunal appears to have gone only a little way to meet these protests. The salaries of Senior Principal Scientific Officers will after all be increased by 3.2 per cent in 1980 compared with 1979, taking the maximum salary in this grade to £16,250 a year, compared with the claim by the union for £18,248.

The salaries of Principal Scientific Officers, which ranged from £8,613 to £11,343 at the beginning of the year, are to be increased to between £9,690 and £12,540, figures which are increased by between 1.5 per cent and 4.1 per cent as a result of the tribunal's intervention.

Scientific Officers, earlier in the year earning between £6,332 and £8,705, are now to receive salaries increased by between 20 per cent (at the bottom of the scale) and 10 per cent (at the top). The salaries of lower grades will be increased by proportions not very different from the rate of inflation.

Even so, this will not go far to meet the complaint that the salaries of scientists in the Civil Service are less than those of people of similar rank — Principal Scientific Officers will, for example, be paid £1,260 a year less than Administrative Officers.

The reason why the arbitration tribunal made this new award are not known, and may never be, although a report on the issue will be published next month.

Nuclear Iraq

Perrin protests

Anxieties about French nuclear collaboration with Iraq have now burst into the open. Last week, the grand old man of nuclear power in France, Francis Perrin, contradicted his government's statements about the supply of a research reactor and highly enriched uranium to Iraq, in a deal to exchange oil for technology. "It cannot be said", Perrin argued in an interview with *France-Soir*, "that the provision of this reactor will not enable a country like Iraq to produce an atomic weapon in a few years' time".

Without addressing the question directly, however, the French government had earlier insisted that its cooperation with Iraq is directed to "perfectly legitimate ends", and that the agreement is also covered by guarantees. The government said it was "astonished" at the accusations that had been made against it, and asked by what principle Iraq's right to nuclear power could be refused.

Perrin, who was president of the Commissariat à l'Energie Atomique from 1951, and who was confirmed in that post by President de Gaulle in 1960, does not believe that nuclear peace and war can be separated so neatly. He believes it unlikely that Iraq would directly divert any part of the 11-kg charge of 93 per cent uranium-235 to be supplied by France, for this would fly directly in the face of too many international agreements. "But evidently, if Iraq trains personnel with this reactor, they could prepare plutonium by irradiating [unenriched] uranium." This plutonium might be prepared initially for research; then, when they had enough plutonium and technicians, they could break their agreement (under the Non-Proliferation Treaty, which Iraq signed in 1969) not to build weapons.

The controls of the International Atomic Energy Agency — which requires monthly flow-sheets of fissile materials belonging to NPT signatories, and whose inspectors make regular visits to their nuclear establishments — are effective, says Perrin, but a country can always decide to reject them.

Iraq already has a small Soviet reactor, using 80 per cent enriched fuel, under IAEA safeguards. The details of the new French reactor have not yet been received at the IAEA, but the safeguards provisions require that they should arrive more than six months before the reactor is charged with fuel. Charging is, however, unlikely before the end of 1981, the date set before Iraq's chief nuclear expert, Yihya al Meshad, was murdered in Paris on 13 June. It is, however, known that the reactor will be based on the French 50-MW thermal reactor Osiris at Orsay, which takes a charge of 9½ kg of 93 per cent uranium-235. Osirak, the Iraqi version, is planned to be slightly bigger — 70 MW with an 11-kg charge.

Italy is also supplying nuclear facilities to Iraq in exchange for oil, including an isotope laboratory with a hot cell which in principle could be used for reprocessing and plutonium separation but, says the Italian government, it is much too small to have a bearing on weapons production.

President Saddam Hussein of Iraq has rejected all speculation that Iraq may be building a weapon, and has pointed out that Israel is generally regarded as already having the bomb, and has never signed the NPT. "Other countries" said an IAEA spokesman "have been less cooperative than Iraq".

President Hussein, with a $75,000 million five-year plan, also dreams of a technological transformation of his country, and recognizes that Iraq's principal need is technically trained manpower. He believes that Osirak will contribute to such a pool. Now that Iraq is increasingly turning from its East European and Soviet partners towards OECD countries for technology, it may be wise to take Hussein seriously.

Troubled seer

Remote sensing

Going private?

Washington

Fierce arguments have been generated in Washington by plans under discussion in the Carter Administration to create a fully operational system from the remote-sensing satellites developed by the National Aeronautics and Space Administration.

Few challenge the idea that responsibility for remote sensing should eventually pass to the private sector, but there is disagreement about the pace at which the transfer should occur and the degree of control which the federal government should retain.

Responsibility for coordinating the transfer from NASA to the private sector has been given to the National Oceanic and Atmospheric Administration (NAOO). The NAOO proposes a two-stage process, involving an initial stage for developing the sensor technology, that would extend to the end of the decade, before a fully operational system would be available for private use.

Several companies, keen to establish themselves in a potentially lucrative market, argue that this time scale is unnecessarily slow. In particular, executives from the Comsat Corporation, which has already successfully taken over responsibility for telecommunications satellites, are arguing that it could start doing the same for remote sensing by 1983.

The temptation to use telecommunications as a model for successful commercial exploitation is strong, but remote sensing is likely to have a rougher ride. The market is undeveloped and heterogeneous.

Thus at a Senate hearing two weeks ago, a spokesman for the National Governors Association said that the remote-sensing system "should be considered in the same context as census, cartographic, geological and meteorological data which are provided as a public service of the federal government".

Aware of this public responsibility, NOAA is considering two ways of allowing federal agencies to buy data under guaranteed purchase contracts. One would transfer responsibility for this entirely to a private corporation, the other would set up a new "for-profit" corporation with both privately and publicly appointed members.

The cost of remote sensing is another problem. According to NOAA administrator Dr Richard Rank, the remote sensing system will probably not be self-financing until the end of the century, and thus will rely on subsidy for the foreseeable future.

But there will still be a temptation to maximize returns, even in the early stages, and state governments are worried that high prices could discourage potential state and local government users from even exploring the potential usefulness of Landsat data, particularly if — as NOAA has suggested — experimental data during the interim period are priced the same as operational data.

Excessive pricing could also have important international implications. Some countries could complain that they are unable to afford information about their own natural resources which can be bought on the open market by multinational mining corporations. The State Department accepts the principle that prices should be consistent for both domestic and foreign users, but warns that price increases should be gradual so that foreign users can adjust to them.

Present users are, however, more concerned at the quality of the service. NASA now has two Landsat satellites in orbit, but both are having problems which have restricted the amount of data being received. Unexpected difficulties have also arisen in the next satellite, Landsat D,

0028-0836/80/330650-02$01.00

scheduled to be launched in 1982. Development of the instrument called a "thematic mapper", and intended to provide direct information on crop differentiation, is so much delayed that Landsat D may have to be launched without it.

The delays in both technical plans and administrative arrangements have created inevitable frustrations. Those who have already experienced the benefits of remote sensing technology are keen to exploit it as rapidly as possible, and are already hinting that they may look to other countries — such as France and Japan — as an alternative source of remote sensing services. Moreover, some members of Congress claim that the delays reflect a general lack of imagination in the White House about the US space effort.

NOAA is at present working out the details of the transition plan in preparation for its submission as part of the 1982 budget request early next year. It seems more likely to include only limited private involvement — perhaps restricted to processing and marketing the data produced by federally operated satellites.

David Dickson

Lords committee

Dumping ahead

The House of Lords Select Committee on Science and Technology embarked on its summer break last week with the promise of a new inquiry in October into the disposal of hazardous waste. The inquiry will be the committee's second quick investigation — the report of the first, on electric vehicles, is due to be published at the beginning of September. A longer investigation of forestry in the United Kingdom will continue until the end of the year.

The suggestion of an inquiry into hazardous waste disposal came from Basildon District Council in Essex, where a large proportion of Britain's toxic industrial waste is dumped. When the House of Commons Select Committee on the Environment declined to take the matter up because of other commitments, the Lords committee stepped in, believing the topic to fit well into its remit of investigating areas of science and technology of public concern.

The worry of Basildon District and Essex County Councils is that there is no coherent national policy for hazardous waste disposal, largely because the relevant section of Part II of the 1974 Control of Pollution Act has never been implemented. The councils also believe that Essex has become a main centre for hazardous waste disposal by historical accident rather than for good practical reasons.

Dumping at Pitsea

The government has laid down guidelines for dealing with the disposal of hazardous waste but no regulations as to who should be responsible for arranging disposal. The 1974 Act says that local authorities should take that responsibility and should inform the Secretary of State for the Environment of the arrangements they have made. The Act empowers the Department of the Environment to bring these and other provisions (affecting water quality, for example) into force when it chooses. So far it has chosen not to do so, allegedly on the grounds of cost. Redland Purle, Britain's largest waste disposal company, owns the country's largest dump at Pitsea in Essex. The council has power to monitor the sites and has taken measures to restrict the quantities dumped, but it would take other local authorities to take some of the load.

The Lords committee will no doubt be looking at the institutional arrangements for coping with hazardous waste. It also intends to investigate the basis for some of the technical arrangements, for example the criteria used for choosing suitable sites and deciding what can be dumped where. The Select Committee hopes the inquiry can come to grips with new methods of disposal and suggest how more use could be quickly made of them.

Judy Redfearn

Energy alternatives

German plans

A West German commission on "future nuclear energy politics", set up two years ago by the Bundestag to resolve the nuclear question, has reached its eagerly awaited conclusions. They are equivocal.

West Germany should shelve a final "decision" on nuclear power until 1990, says the commission. But in the meantime the country should build as many reactors as it needs, provided it makes due effort on the development of coal, conservation and renewable sources.

The all-party parliamentary commission, consisting of seven members of the Bundestag and eight technical experts from industry, environmental groups and the trades unions, considers that it will be impossible to judge — for ten years — whether nuclear energy should be expanded in Germany. The growth rate of electricity consumption, the effectiveness of conservation measures and the impact of renewable energy are too uncertain to make commitments to any particular source.

The commission does however spell out its demands for immediate and increased government powers to enforce energy conservation — the abolition of mileage rates for business cars, an energy tax, more bicycle paths and tighter controls on insulation standards in new homes and factories. The commission also asks for an "energy service" to provide, free of charge, an infrared survey of buildings to show where the heat leaks out. These and other measures have been described by the Christian Democratic Union, the main opposition party, as introducing "a totalitarian energy conservation state".

Elsewhere, the recommendations have been seen as vague and offering all things to all men — especially with the recommendation that reactors should be built if energy demand requires them. The major nuclear construction company in Germany, Kraftwerk-Union, has argued that it will be running out of work in 1983 — it has lost its contract for four reactors in Iran, and there is doubt as to whether Brazil will take up its full option for eight. Thus some suggest that a construction programme of one or two reactors a year over the next decade, a programme similar in its scale to the British, is quite consistent with the commission's view.

At the same time, the report has bee interpreted by environmentalists as recom mending a further delay in the country' nuclear development. (Germany now h five power reactors above 500 MW electri in total 15 reactors produce about 9 GW It is not surprising that the commission h been represented in the German press a man wearing two badges, one say "nuclear no thanks" and the ot "nuclear power — yes please".

The forthcoming October gen

0028-0836/80/330651-02$01.00

election may have played some part in the commission's equivocation: there has been an understanding among the parties that nuclear power should not be an election issue. The debate on the report was eclipsed the same day by another on Chancellor Schmidt's visit to Moscow.

The commission also recommended that it should reconstitute itself after the election, to complete its task. It was set up in December 1978 after a lengthy debate on the future of the Kalkar 300 MW prototype fast breeder, now under construction. It was decided then to construct Kalkar, but not to charge it with plutonium until expert advice had been received on Germany's need for a "plutonium economy". The nuclear energy futures commission was set up to provide that advice, but (beginning work in 1979) it decided that there was not time before the election for such a broad investigation. Hence the fast breeder is not mentioned in the commission's recommendations.

The result is that Germany remains without a strong federal lead on nuclear power. It will remain so until the majority of the ruling coalition — only ten in the present Bundestag — cannot be threatened by the strong minority in the coalition which will always vote against nuclear development.

The election is thus critical for nuclear energy, despite the parties' intention to keep it out of the limelight. A number of decisions await a nuclear majority, not the least of them the location of intermediate storage facilities for spent fuel. The CDU Prime Minister of West Saxony, Herr Albrecht, where the Gorleben salt-dome offers a potential long-term geological store, is hoping to give hospitality to the waste after the election. Other current battles (against environmentalist opposition) such as that to increase the density of spent fuel storage, by a factor of four, on reactor sites, by inserting cadmium sheets between the rods to absorb neutrons, may be more easily won if a federal government is returned which can give a more definite "yes" to nuclear power.

Robert Walgate

Pesticide safety

No numbers

Washington

Stepping out of line with the fashionable wisdom — at least among congressional egislators — a little-noticed report from he National Academy of Sciences has ome out with some harsh words about the angers of squeezing data on the health ffects of agricultural pesticides into a neat ost-benefit mould.

The report was prepared by a committee the academy's Environmental Studies Board as a follow-up to earlier studies by the Environmental Protection Agency (EPA). In general it supports the agency's concern that environmental regulations should be as explicit, and as well quantified, possible.

It also points out, however, that in attempting to produce legally defensible decisions, agency administrators often underplay the uncertainties and qualifications that surround scientific assessments of risks and benefits, particularly of human morbidity and mortality data. Here, the report says, quantification is carried to "unwarranted extremes".

According to the committee, present understanding of cancer development "does not permit us to draw reliable numerical inferences from the kind of laboratory data normally available about the effects of pesticides and other compounds on the development of cancers in humans".

There is therefore a danger, it says, not only of overestimating risk by the use of too conservative assumptions, but also of underestimating it by neglecting potentially important factors. "We say the error can go either way" said committee chairman Professor Robert Dorfmann of Harvard University's department of economics.

The committee therefore recommends that the EPA abandons its attempts to produce numerical estimates of the impact of pesticide use on human health except where reliable epidemiological data are available. Instead, it proposes the use of "a carcinogenic activity indicator" as a measure of relative carcinogenicity of chemical compounds. This would be based on the results of laboratory bioassays.

In addition, to underscore the uncertainties in risk evaluation, two figures are proposed for every risk estimate. One would be a measure of "most probable" risk, conveying the analyst's best judgement of the level that would be realized in assumed conditions. The other would be a "maximum plausible" estimate taken as the upper limit of a 90 per cent confidence interval.

The EPA has made no official comment on the report. The agency is involved in reviewing its procedures for weighing the risks and benefits of pesticides in the light of recent administrative changes.

Its review could be influenced by an unintended consequence of the new report. As part of its analysis, the committee carried out a detailed review of chlorobenzilate, using its recommended procedures to produce its own assessment of the risks and benefits. Comparing its evaluation with that obtained by the EPA in 1976, it concluded that not only had worst-case estimates of exposures used to assess health risks been highly improbable, but also that the economic benefits of using the pesticide — particularly the costs of not using it — had been wildly overestimated.

When a draft version of the rep circulated last year, these discre were seized on by the Environ Defense Fund (EDF) to challen EPA's decision to allow limited us pesticide. However, an admini court in Washington has since rul the EDF had no legal standing to ta in EPA's rule-making proc Nevertheless, this could have sig impact on rule-making in the agenc in the past many of the restricti pesticide use have followed ch from the EDF and other s environmentalist groups.

Ve

Vietnam in space

Queue-jumping

The recent 8-day sojourn of Vietnamese cosmonaut Pham Tuam aboard the Salyut-6 space station marked a significant change in the Comecon Interkosmos joint space programme. For the first time the non-Soviet participant came from a developing and non-aligned country — a point which both the Soviet and Vietnamese press agencies stressed at the expense of comment on the scientific content.

Phan Tuam's flight, moreover, meant a change in the projected running order of participation, which, most Baikonur watchers had accepted, was related to the size of the contribution the various countries had made to the earlier unmanned stage of the Interkosmos programme (the Interkosmos satellites and Vertikal high-altitude probes). In effect, this meant that the European nations of the bloc would go first, with Cuba and Mongolia bringing up the rear. Vietnam, which joined Comecon in summer 1978, long after all the other members had their cosmonaut candidates installed at the Gagarin space centre, seemed destined for the final place in the programme.

However, with four countries still to go (Romania, and the three non-European members), Vietnam was unexpectedly advanced three places. Both TASS and VNA stressed unequivocally that that there were political implications in this move. Whatever the reason for the changed schedule, however, the interesting question remains: what, precisely could Vietnam contribute to the space programme?

It would be incorrect to suggest that the developing members of Comecon — Cuba, Mongolia and Vietnam — have nothing to offer the Interkosmos programme, or at the most can offer only sites for tracking stations. As early as 1978, the Polish cosmonaut Miroslaw Hermaszewski said that Cuba and Mongolia were working on their experimental programmes for when their turns came. (At that time, Vietnam had still not joined the Interkosmos programme.) Pham Tuam's programme, as reported to date, corresponds remarkably well with those of the other non-Soviet cosmonauts.

First, and inevitably, came the medical programme, the testing of cardiovascular and lung functions under zero gravity. Then, equally routine, experiments on semiconductor crystal growth — in this case, gallium phosphide and a triple bismuth-antimony-tellurium compound. These experiments use a Soviet furnace aboard Salyut-6, but the test capsules come from the non-Soviet participant, which also provides a suitable symbolic name for the project — Morava for Czechoslovakia, Berolina for East Germany and so on. This time, it was Halong, after a gulf in Vietnam.

Not surprisingly, the regular photographic and visual observations carried out from Salyut were given a Vietnamese slant. Silting up of the river mouths, and the effect this has on fish feeding habits, observations of tidal flooding and erosion, and hydrological surveys of the Mekong and Red River Basins were especially stressed. And, most Vietnamese of all, Pham Tuam had taken along samples of azola water ferns, fast-growing, nitrogen-rich plants which are traditionally used as fertilizers for the growing rice crop, and which could prove useful aboard future permanent space stations.

Comecon doctrine concerning its third world projects (including its own three "developing" members) firmly eschew the concept of "aid". All such undertakings are termed "cooperation" projects, although recent bilateral scientific-technological cooperation deals signed between Vietnam and, for example, Czechoslovakia and East Germany consist largely of the European partner providing experts and know-how, and Vietnam reciprocating with raw materials. Nevertheless, no attempt has been made, as far as Interkosmos is concerned, to present the joint Soviet-Vietnamese flight as a partnership of technological equals. While by no means a passenger, Pham Tuam characterized his role rather as a harbinger of things to come. "It is a new demonstration of the effective cooperation within the socialist community", he said before embarking, which "will also demonstrate the abilities of the Vietnamese people".

Vera Rich

Shuttle for orbit

The US National Aeronautics and Space Administration has screwed up its courage and settled on a launching date for the first orbiting version of the space shuttle — March 1981. The decision was taken at the end of last month and in the face of the setback a few days earlier when a fire damaged a shuttle engine during a test firing in Mississippi.

The decision follows a week-long review of the recent ups and downs of the development of the shuttle, and has apparently been taken in the belief that only a tight schedule will sufficiently concentrate the minds of those involved in putting the first shuttle (called Columbia) into an Earth orbit.

The timetable now agreed would move Columbia from the building it now occupies at Cape Canaveral to the shed in which it will be mated with the solid fuel boosters on 23 November. Thereafter it will be mounted on its launch pad and the main engines of the shuttle will be fired for a period of 20 seconds some time in February. Thereafter, there will be five weeks to the final launch date.

Although anxiety persists about the tiles intended to provide thermal shielding for the shuttle, it has apparently been decided not to encumber the first flight with the "tile repair kit" intended to enable the crew of the shuttle craft to replace damaged tiles in flight.

Airport noise

London's out

The Noise Advisory Council (NAC) has provided some timely ammunition for the opponents of the plan to build the third London Airport at Stansted in Essex. Last week, hard on the heels of the formal application for permission to develop the airport by the British Airport Authority, the council announced that the Stansted site will be marginally more of a noise nuisance than the other five sites on the airport authority's short-list.

The application for development permission has gone to the Essex County Council. There will be a public inquiry on the proposals, probably early next year. That will be the second occasion on which the people of Stansted have been divided into hawks and doves.

Choosing a site for London's third airport has already taken 27 years. The chief problem has been that cost-benefit analyses yield equivocal results even when they themselves, like the Roskill Commission of 1968–70, cost more than £2 million. Uncertainty about the growth of demand for air travel has also taken the steam out of what seemed to be an urgent problem ten years ago.

According to NAC, Maplin, situated on the north of the Thames estuary, would disturb nearby residents least but would require the removal of a Ministry of Defence establishment — which might create environmental problems of its own — and the building of new road and rail links into London. It would also disrupt local bird life. Stansted, an inland site north of London, would be the cheapest site to develop — it already has a small airport, which could be extended, and good links with London, but it is situated near several small towns. The NAC report estimates that 17,000 people would find aircraft noise a nuisance if a two-runway airport were built.

Estimates of annoyance caused by aircraft noise are themselves equivocal. The Noise Advisory Council quotes values of the Noise-Number Index, calculated in such a way as to correlate with surveys of the extent to which people are annoyed by aircraft movements. One difficulty in using this index as a basis for assessing the impact of new airports is that the calibration has been based on surveys at established airports, such as Heathrow, where residents have to some degree become accustomed to aircraft noise after long exposure. Further difficulties stem from uncertainty about flight paths, the noisiness of future aircraft and the future volume of air traffic.

The NAC report says that the noise dis-

0028-0836/80/330653-02$01.00

advantage of Stansted over the other sites, excluding Maplin, is only marginal. But it recommends that if Stansted is chosen, local residents should be compensated either in the form of noise insulation or by grants to enable them to move house. It further adds that Stansted could be justified on environmental grounds only if it reduced the total environmental impact of London's airports, especially Heathrow, where about one and a half million people live within the contour of noise annoyance. Hitherto, the case for a third airport has been to absorb increases in demand for air travel rather than to take pressure off existing airports.

The airports authority's proposal for Stansted is for a one-runway airport capable of handling 15 million passengers a year — considerably smaller than a previous proposal thrown out in 1965–66 to build an airport for 100 million passengers a year. One of the additional attractions of the Stansted site is that the existing airport could be enlarged gradually to meet changes in demand.

Judy Redfearn

Polish water

Much and little

Last month's floods, which produced emergency conditions in 22 out of the 49 provinces of Poland and caused a massive loss of crops, especially hay, potatoes and sugar beet, have focused attention once again on the paradox of Poland's water supply. Ranking only twenty-second in Europe in *per capita* water index (1,700 m^3 a year compared with the European average of 4,800 m^3 a year), Poland is nevertheless subject to periodic inundations after which the water runs off uselessly into the Baltic. At best, Poland can store only 5 per cent of the water it receives from natural precipitation and incoming rivers. (Bulgaria, Czechoslovakia and the Soviet Union, by contrast, store 12-15 per cent.) Along Poland's largest river, the Vistula, there is no storage capacity whatsoever.

To remedy this, the Central Committee of the Polish United Workers' Party adopted on 16 June 1978 a resolution calling for a multi-disciplinary development and management programme for the Vistula. "Program-Wisla", as it is called, got off the ground very rapidly, at least on the theoretical and planning side. Polish geographers, hydrographers, economists, agriculturalists and ecologists produced imaginative plans which include hydroelectric stations, irrigation works, the improvement of navigation channels, the construction of retaining walls and some 34 or 35 dams along the navigable course of the river between Oswiecim (Auschwitz) and Gdansk. The whole scheme, which is intended to raise Poland's water storage capacity to 20 per cent, as well as benefiting agriculture, industry and the human environment, is scheduled for completion by the end of the century.

So vast an enterprise, say the planners, is nevertheless beyond the capacity of Poland alone, and there will be major scope for international cooperation. But before the Vistula is confined by the engineers into what will be, in effect, a series of basins, the water must be of acceptable purity, since once the natural scour is eliminated, the ecologists agree that the river would not regenerate itself. The Vistula (like Poland's other major river, the Odra) has no water of class I or II purity anywhere in its course, while one-third of its total length is polluted beyond the limit of toleration. Purification and regeneration of the river is the first priority of Program-Wisla.

The problem, however, is far from simple. The headwaters of the Vistula are subject to natural "pollution" by mineral salts leached out of the soil of Silesia. The river flows through the Silesian industrial belt and the Cracow-Nowa Huta conurbation, with its vast steel mills, and past the open-cast sulphur mines at Tarnobrzeg. It picks up its largest tributary, the Bug, already heavily polluted by the Soviet pulp and paper industry, passes through Warsaw, whose sewerage arrangements are, to say the least, antiquated, through Plock with its mushrooming petrochemical plant and finally arrives in the Bay of Gdansk where pollution is so heavy that water-sports are prohibited.

There are nevertheless some bright spots in this picture. The Tarnobrzeg mines, in particular, are managed on strict ecological principles, with recultivation of the land section by section as soon as the sulphur is stripped. Water control there, say the mine engineers, has to prevent seepage from the river to the mine rather than the reverse. The Bug, the one part of the Vistula basin not entirely under Polish control, has just been made the subject of a special Polish-Soviet cooperation agreement. And week after week, the Polish media stress the emphasis being given to anti-pollution measures, effluent treatment and the introduction of closed cycle technology under the aegis of Program-Wisla.

Such technology or the exchange of know-how could well be a fruitful field for international cooperation, both within and outside the Comecon bloc. But Polish experts have hitherto been cool at the prospect of Western cooperation, feeling that their prospective partners have been more interested in selling existing standard equipment than providing know-how specifically tailored to Polish circumstances. Since the Polish economy suffers from a chronic lack of hard currency, this is a major problem. The latest negotiations, between Poland and the United Kingdom, seem to be taking a different and — from the Polish point of view — a more promising course. It is understood that before any concrete proposals are put forward from the British side, a small investigative team will visit Poland in the autumn to make an on-the-spot assessment.

The cooling Earth

from Henry N. Pollack

WHAT can the exhaust of the Earth's heat engine tell about its internal workings and fuel? The exhaust is the heat lost from the Earth's interior, and the internal workings are the manner by which heat is transported upward from the deep interior. The fuel is thought to be principally nuclear, comprising the radioactive isotopes present in varying trace concentrations throughout the Earth.

Let us look first at the exhaust. The measurement of the heat flux over the Earth's surface is an endeavour of the last two decades, and the global survey is still only half complete. However, an important empirical rule, that heat flow varies inversely with crustal age, has enabled estimates of the heat flow to be made for the unsurveyed areas of the globe. At the present time the Earth seems to be discharging about 40 × 10^{12}W (ref. 1-3).

Does the engine run smoothly, or does it race, or idle on occasion? How characteristic of recent Earth history is the present-day heat loss? Because the heat loss is strongly correlated with the age of the ocean floor, which in turn is related to oceanic crustal accretion rates that are known to be variable, it is likely that the heat flow has fluctuated in the past. Sprague and Pollack[4] have reconstructed the age distribution of oceanic and continental crust over the past 180 Myr and conclude that the heat loss has ranged between 39 and 52 × 10^{12}W, with an average of 43 × 10^{12}W, slightly higher than the present-day value.

The internal workings of the Earth engine are only weakly constrained by knowledge of the heat loss alone. The planetary thermal history models of 20 years ago were principally conductive models, in accord with the then prevailing view of an Earth without global scale horizontal movements. However, even before mobility became accepted in the 1970s, Tozer[5] argued that thermally-activated solid-state creep would, in response to thermally induced buoyancy, lead to large scale mobility within the Earth. The temperature dependent creep serves as a thermostat, with convection relieving the Earth of excessive heat by transporting it to the uppermost mantle where it makes the final journey to the surface by conduction through the upper horizontal boundary layer of the convection. This upper boundary layer comprises the plates of the lithosphere.

While the concept of solid-state thermal convection in planetary interiors is clear enough, a complete mathematical description of the process is difficult. The patterns of the Earth's topography, heat flow, gravity, and plate velocites provide surface constraints, but even so the broad features of the convection remain elusive. However, simpler quantitative treatments, which yield certain general characteristics of the convection system have recently been exploited[6-9]; collectively they are referred to as 'parameterized' thermal history models. At the heart of these analyses is the assumption, suggested by both theory and experiments, that the heat loss from a convecting system depends on the temperature difference driving the convection (the so-called Nusselt number — Rayleigh number relationship). The models yield the history of such properties as the mean temperature and viscosity of the mantle and the mean velocity and radial heat flux of the convective circulation over the lifetime of the Earth. The calculations all explicitly require the specification of the variation with time of the Earth's internal heat production, and thus a link is forged to the Earth's nuclear fuel and its characteristic rate of decay.

The existence of nuclear fuel in the Earth has been known ever since the discovery of radioactivity in rocks in the early part of this century. However, the abundance and blend of the fuel has been a subject of some debate. The principal heat-producing isotopes are ^{238}U, ^{235}U, ^{232}Th and ^{40}K, with respective half-lives of 4.47, 0.70, 14.0, and 1.25 billion years. Their abundances in the crust of the Earth are comparatively well known, and recognized to be significant enrichments over any possible primordial concentrations throughout the bulk of the Earth.

What then can be said of the primordial abundances of each of the principal isotopes? It was first pointed out in the 1950s that if the Earth had an isotopic endowment similar to that of the chondritic meteorites then the internal heat production would be just about adequate to supply the surface heat flow. However, the 'chondritic coincidence' as this near equilibrium between heat production and loss came to be known, was not without some inconsistencies as well. In particular, the relative proportions of U, Th, and K in chondrites are rather different from that in terrestrial rocks. If the primitive Earth were indeed chondritic, most of the uranium apparently now resides in the crust, while most of the potassium must be elsewhere, presumably deeper within the Earth. Wasserburg *et al.*[10] proposed an alternative primordial isotopic endowment which reflected the K:U:Th ratios found in the crust of the Earth. *Yet a third approach has recently been put forward by Sleep*[11] and by Stacey[12] *who use the abundance of* ^{40}Ar, a decay product of ^{40}K, *to estimate* the K abundance of the Earth. *Their* calculations *indicate a K:U ratio* even smaller than the model of Wasserburg *et al.* The significance of the K:U ratio resides in the much longer *half-life* of ^{238}U (the dominant uranium isotope) compared to that of ^{40}K. *An* Earth thermally evolving under the influence of *long lived uranium* and thorium has a slow and *steady* releas of heat, with a decrease by only a factor o two or so during it's lifetime. potassium dominated thermal evolutio such as would derive from the chondri mix, is characterized by a more vigor early history *and an eight-fold decreas internal heat production over the Ear* history. *Thus the thermal and tect history of the Earth is closely tied to blend of the radio-active fuel.*

Now come the new family of p meterized thermal history models, and t tell a disquieting story, at least as far deducing something of the Eart primitive chemistry from the present-d heat loss. It appears that the heat lo derives not only from radiogenic heat, but also in part from 'initial' heat, the energy residual from the accretion of the planet and settling out of the metallic core. The

calculated fraction of the present-day heat loss attributable to the initial heat appears to be highly model dependent; Schubert *et al.*[7] estimate that at least 15-35% of the heat flow is non-radiogenic, while Sharpe and Peltier[6] contend that it is not essential to invoke *any* radiogenic heat to understand the main thermal features of the Earth. Initial heat alone may be adequate to drive the Earth engine. Schubert *et al.* emphasize that while the amount of the non-radiogenic heat loss may be reasonably debated, a significant contribution to the total heat flow is unavoidable.

Some generalities do emerge from all the new thermal histories: 1) the Earth is and has been cooling, albeit very slowly, at a rate probably no greater then 100° C per billion years (the quintessential energy storage device!), 2) the cooling has been accompanied by a stiffening of the mantle and a slowing of the convective circulation, 3) the upper boundary layer of the convection, that part of the circulation moving horizontally at the Earth's surface and comprising the lithospheric plates, has thickened over the Earth's history. But if through these models we have learned a little of the functioning of the Earth's engine, it seems we know less than we thought about the Earth's primitive chemistry. The engine apparently will run on nearly any blend of fuel, and the thermal energy exhausted reveals little of the internal chemistry. The principal sources of geochemical insight, alas, must continue to be the continental and oceanic crustal rocks, salted with occasional bits of the mantle, and the much smaller collection of extraterrestrial samples; less help appears to be forthcoming from the Earth's heat than a generation of earth scientists had hoped for. □

The collagen gene family

from Ellen Solomon

COLLAGEN proteins occur as a family of molecules with closely related structures but varying tissue distributions. At least nine different genes code for protein with collagens unique features of a repeating pattern (every third amino acid is glycine) and large amounts of the unusual amino acids hydroxyproline and hydroxylysine.

The total number of genes in the family may be as high as fifteen or sixteen if some of the less well characterized chains are included, as well as the A,B,C, chains of Clq, and if some of the observed heterogeneity in sequence is due to different gene loci. These genes have almost certainly evolved by duplication and divergence of a common ancestral sequence, but nothing is yet known of their linkage. cDNA and genomic clones have been isolated from the chick proα_2(I) chain (Lehrach *et al. Proc. natn. Acad. Sci. U.S.A.* 75, 5417; 1978; Sobel *et al. Proc. natn. Acad. Sci. U.S.A.* **75**, 5846; 1978; Vogeli *et al. Nucleic Acid Res.* **8**, 1823; 1980). Based on clones panning 55 Kb of the chick genome, de rombrugghe (National Institutes of ealth) estimates that the proα_2(I) gene vers 40 Kb and that there are more than) intervening non-coding sequences that ary in size from 60-70 to 3-4,000 bp. These orkers have analysed six coding regions in ree separate regions of the helical portion f the molecule; five of these are 54 bp (18 mino acids). They propose that the helical ortion of the collagen gene arose by duplication and divergence of a 54 bp equence and that these regions diverged by the insertion or deletion of units of 9 bp — the basic (Gly-X-Y) repeat of collagen. Boedtker and colleagues (Harvard University) have analysed the codon usage for the amino acids in the α_1(I) and α_2(I) chains of Type I collagen and find that the usage differs significantly between the chains. Genomic clones of the sheep proα_2(I) have also been isolated (Schafer *et al. Nucleic Acids Res* **8**, 2241; 1980, and show at least 17 intervening sequences in 60% of the 3′ portion of the gene. Non-coding sequences are 300 to 1,600 bp, while the coding regions are 250 bp or less. Somatic cell genetic studies using species-specific DNA probes should soon clarify the location of some of the collagen genes and their possible synteney, if not linkage.

Haemoglobins (Weissman, Yale University), histones (Zweidler, Institute for Cancer Research, Philadelphia) and heat shock proteins (McCarthy, University of California, San Francisco) were discussed as representatives of rather different types of gene families, in regard to linkage and co-ordinate expression. Until the genetic map of the collagen genes is known it is obviously not possible to know if, as a family, it resembles any of these others. By analogy with the non-linked α and β genes, and the linked $\beta\cdot\delta\cdot\gamma$ genes of haemoglobin, will the proα_1(I) and proα_2(I) genes of collagen be unlinked and the proα_2(I,II,III,IV,) linked? Alternatively, will all the "collagenes" form a linked cluster as with the histones, or be scattered throughout the genome as with the actin, ubulin, and heat shock genes of Drosophila? As yet there is no information to whether any of the collagen genes exist in multiple copies.

There [illegible] inherited connective tissue diseases are likely to involve defects in col[illegible]es, such as Marfan's Synd[illegible]eogenesis imperfecta and [illegible]ards their understanding ap[illegible] these diseases have eluded definition at the molecular level, largely because of the extreme difficulty of the protein chemistry. It was agreed that current DNA technology should be applied to defining these diseases, bearing in mind that in most cases there is no direct evidence for collagen gene involvement. It is not reasonable to clone collagen genes from individuals with connective tissue disorders without direct evidence that these genes are actually involved as the primary defect. A more general approach is needed whereby collagen gene mutations can be detected. One suggestion was to screen as many different patients as possible, with different diseases, by restriction mapping and Southern blots using collagen probes, and where appropriate tissue biopsies are available, by S1 mapping. Using these two techniques some types of mutations in the collagen genes could be detected. For results from either of these techniques to be meaningful, however, a great deal of data is needed regarding the degree of variation in these genes in the normal population. A second approach discussed at length was that of linkage analysis within families using the collagen gene probes and restriction site polymorphisms, as done by Kan and Dozy, for sickle cell anaemia (*Lancet* ii 910; 1978). The collagen diseases are rare, extremely heterogeneous, both clinically and genetically, and probably often represent new mutations. They are unlikely to have evolved by selection, as have some of the haemoglobinopathies, and it was therefore emphasised that each family would have to be screened with a set of restriction enzymes to find an appropriate polymorphism. The purpose of this type of analysis would be both to identify affected fetuses by prenatal diagnosis, and also to indicate the involvement of a collagen gene defect in those diseases.

Also discussed was the complexity of the genetics of a protein with as many enzymatic post-translational modifications as collagen. For example, mutations in different modification enzymes could lead to the same disease phenotype, and different mutations in the same enzyme could give dominant or recessive modes of inheritance.

The extensive post-translational modifications of collagen and proteoglycans, including removal of signal sequences, hydroxylation, glycosylation, disulfide bond formation, triple helix formation, and procollagen to collagen conversion was an important topic. Different types of collagen are modified to different extents and individual types of collagen show a degree of heterogeneity in their particular modification. Among the questions regarding modification, therefore, is to what degree individual primary amino acid sequences determine the position and extent of, say hydroxylation

---

A conference on 'Gene families of collagens and other proteins' was held from April 27-May 2, 1980 at CMDNJ — Rutgers Medical School. The organisers were D. J. Prockop and P. C. Champe.

Ellen Solomon is Head of the Somatic Cell Genetics Laboratory at the Imperial Cancer Research Fund Laboratories, London.

and glycosylation, and whether there are tissue-specific enzymes for each of the different types of collagen. As yet there is no direct evidence for such enzymes (Kivirikko, University of Oulu, Finland). This may well be due to the difficulty in assaying many of these enzymes. The need exists for more rapid and specific assays for each enzyme including electrophoretic separation techniques, and immunological or colourometric detection. The questions of tissue-specific forms of the enzymes, genetic map location, possible linkage of groups of these enzymes, linkage to the collagen genes, and control of expression could be approached if less cumbersome assays could be developed.

A final major topic was the extracellular matrix (collagen, fibronectin, proteoglycans, fibrin) and the cytoskeleton (actin, microtubules, intermediate filaments). Through much information exists on structural differences between individual members of the gene families (collagen, actin, tubulin, keratin) the funtional significance of these differences is not at all clear. Certain common functional domains can, however, be identified. For example, the collagen cross-linking regions and collagenase cleavage site are strongly conserved in collagen Types I. II and III. Other macromolecules are associated with collagen fibres, and may have specific interactions with the collagen and each other. The most clearly defined system is that of cartelage proteoglycan, where the proteoglycan combines with hyaluronic acid and link protein to form large aggregate structures (Muir, Kennedy Institute of Rheumatology, London). It is anticipated that collagen will also be incorporated into such multimeric structures. Fibronectin has a number of separate functional domains that allow it to bind to collagen proteoglycan and the cell (Vaheri, Helsinki University). Martin (National Institutes of Health) reported that proteins analagous to fibronectin but specific for chondrocytes (chondronectin) and epithelial cell (laminin) have been discovered. These bind specifically to these cells and their collagens. Such interactions may explain the role of the tissue specific collagens. □

Assembly of immunoglobulin heavy chain genes

from H. V. Molgaard

IT has been clear ever since it became possible to compare the amino acid sequences of immunoglobulin molecules that they pose two formidable problems for genetics. The first is the extreme variability of the N terminal portions (V regions) of the chains, which make up the antigen-recognition site. The second is how one of a very large number of V regions can come to be associated with one of a very small number of the constant regions (C regions) which mediate the effector functions of the molecule in the elimination of antigen.

It was the occurrence of a very variable sequence joined to a relatively constant sequence that led Dreyer and Bennet to propose that the V and C genes are separately encoded in the genome[1] — a proposal which was confirmed by the first DNA sequence studies on mouse light chains. Those studies showed that a large but limited set of V genes exists at some distance from the C gene in the germline DNA. During the maturation of an antibody-producing B cell, one of the V genes is brought into the proximity of the C gene. As it has turned out, this translocation also provides at least a partial explanation for antibody diversity, since it has proved that the V region is itself constructed from two genes: the V gene and one of four J genes adjacent to the C gene on the germline DNA. V genes seem able to combine at random with one of the J genes, the exact site of the junction varying slightly and coinciding with hypervariable region 3 on the light chain[2].

DNA sequence analysis has now been extended to the mouse heavy chain genes, which are of particular interest because of the evidence that each V gene may be translocated more than once in the course of ontogeny. Unlike the light chains, for which there is only one C region gene for each set of V regions, each heavy chain V gene (V_H gene) may be expressed with any of eight different heavy chain constant genes (C_H genes), C_μ, C_γ, $C_{\gamma 1a}$, $C_{\gamma 2b}$, $C_{\gamma 3}$, C_α, C_ε, C_δ, which define the heavy chains as μ, γ, α etc and the different classes of antibody molecule, IgM, IgG, and so on. All V_H regions are expressed first in μ chains, but the same V_H sequence may later be expressed as part of a γ chain or an α or an ε chain. The mechanism of this phenomenon, the heavy chain switch is therefore a mystery peculiar to the heavy chain genes. DNA sequencing has shed some important light on this mystery; but it has also shown that the V regions of the heavy chain genes have a more complex structure than their light-chain partners.

The V_H region is encoded by three genes.

Hybridisation of germ line DNA with V_H probes has shown that there are at least 50 and probably many more V_H genes, arranged in tandem arrays[3–5] and separated by an unknown length of DNA from a cluster of C genes[6].

Comparison between the DNA sequence of a germ line V_H gene and the corresponding rearranged sequence expressed in a myeloma have in two different cases — a V sequence expressed in an α chain[7] and another expressed in a γ_{2b} chain[8] — shown that the germ line V_H segment ends at the sequence coding for the third hypervariable region before the end of the expressed V_H sequence. This suggested, by analogy with the light chain genes, that the missing sequences should be found in J segments near a C gene. Since $C\mu$ is the first C gene to be expressed in B-cell ontogeny, the J segments were sought and found near the $C\mu$ gene in a cluster of four, 8kb upstream from $C\mu$. However, the J segments still do not account for all of the third hypervariable region. This has lend to the suggestion that the missing residues are separately encoded in yet another set of gene segments, the 'D' or 'diversity' segments, the existence of which had already been predicted on the basis of the amino acid sequence data[9,10].

It remains controversial whether heavy chain diversity is fully accounted for by random combination of V,D and J segments and codon variation at the joins of these segments or whether further diversity arises out of point mutations at the other two hypervariable regions during the differentiation of the B lymphocyte.

Mechanism of V gene rearrangement

With the availability of data from both light and heavy chain germ line gene segments it is possible to generalise about the mechanism of V-J segment translocation. In both cases it involves deletion of the intervening DNA[4,11] and in both cases two short conserved sequences occur in the sequences 3′ to the V segment and 5′ to the J segment close to the point of recombination.

At the germ line V_H and J_H segments which are rearranged and expressed in the S107 myeloma the two conserved sequences are arranged[7] as shown below. One strand is shown folded back on itself to illustrate that the J_H segment conserved sequences are almost inverse complements of the V_H segment sequences. Comparison of these sequences at all the known light and heavy chain V segments shows that they can all be derived from the heptamer CACAGTG and the nonamer ACAAAAACC with usually only one or two base changes. Similarly the conserved sequences at all the J segments derive from CACTGTG and GGTTTTTGT.

H.V. Molgaard is in the Biophysics Department of University of London King's College

0028-0836/80/330657-03$01.00

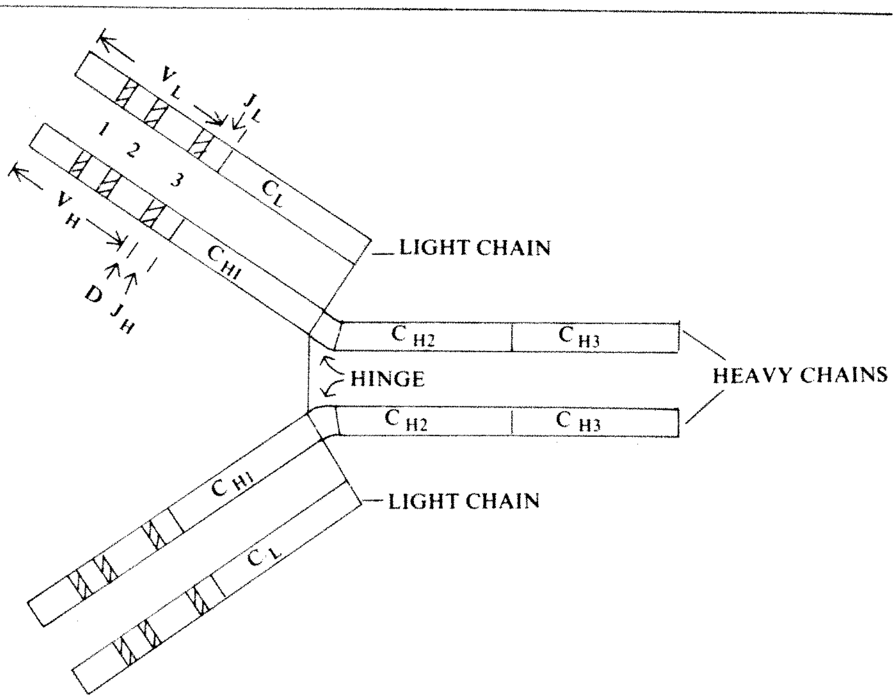

Fig. 1 Schematic diagram of an IgG antibody molecule. C_{H1}, C_{H2}, C_{H3} and C_L are the the heavy (H) and light (L) chain constant region domains — these are regions 100-125 amino acids long within the chains which show some homology with each other in amino acid sequence and secondary structure. The parts of the light chain V region coded by the V_L and J_L gene segments are shown as are the sections of the heavy chain V region coded by the V_H, D and J_H gene segments. The hypervariable regions 1,2,3 determine the antigen recognition and binding site. The C regions mediate the effector functions involved in the elimination of antigen.

conserved sequences is that the length of the random sequence separating the heptamer and nonamer is highly conserved. At the heavy chain V and J segments the separating sequences vary from 21 to 24 base pairs (bp) in length. In contrast, in the two light chain families, the κ and λ chains, the spacers at the V segments differ from those at the J segments. The spacers at the V_{κ} segments are 11 or 12 bp long while the spacers at the J_{κ} segments are 21-24 bp long. Conversely at the V_{λ} segments the spacer is 22 or 23 bp while at the J_{λ} segments a 12 bp spacer occurs.

Spacer lengths of 11-12 and 21-24 bp correspond closely to one and two turns of the double helix, and mean that the heptamer and nonamer form a nearly continuous sequence around the double helix interrupted by one or two complete turns. Since in light chain V-J recombination, a one turn spaced heptamer and nonamer and a conserved sequence interupted by two turns occur at the two recombining segments Early *et al.*[7] and Sakano *et al.*[8] propose that two different but closely related joining proteins recognise the one and two turn spaced sequences and that these proteins form a complex within which the cutting and joining of the DNA takes place. As it is likely that the heavy chain V and J segments recombine first with a D segment this model predicts that the D segments should be flanked by these conserved sequences interrupted by one turn. It would also rule out recombination within the V and J segments. Early *et al.*[7] argue against a mechanism involving the previously proposed stem structures[11,12] which can be formed between these inverse complementary sequences flanking the V and J segments on the grounds that such structures are unlikely to form spontaneously between such widely separated segments of DNA and that they do not account for the conservation of the spacer sequences.

These sequence homologies between the light and heavy chains suggest that, whatever the recombination mechanism, it is the same for both light and heavy chain genes. As the two light chain families and the heavy chain family are each on different chromosomes recombination between families is prevented.

The mechanism of the heavy chain class switch

A further important implication of the germ line organisation of the heavy chain genes can be drawn from the discovery that the J segments which are expressed in α and γ_{2b} heavy chains of myeloma proteins are next to the $C\mu$ gene in the germ line: this establishes that the translocation of V_H and C_H gene segments to give complete α and γ_{2b} chain genes must have been preceded by the recombination of a V_H segment with a J_H segment at the C_{μ} gene. The second recombination event, the heavy chain switch, occurs between a complete $V_H J_H$–C_{μ} gene and, for example, either a C_{α} or a $C_{\gamma 2}$ gene which is still in a germ line context. In addition to the recombined $V_H D J_H$ segments, a considerable portion of the J_H-C_{μ} intron is translocated, giving a new intron in the expressed α or γ gene whose sequences originate partly from the J_H-C_{μ} intron[13,14,6 & 8].

In the hope of identifying specific signals in the DNA sequence which could mediate the heavy chain switch, Sakano *et al.*[8] have identified the sites in the J_H-C_{μ} intron and in the sequences 5′ to the germ line $C_{\gamma 2b}$ gene where the recombination event which gave a complete expressed γ2b gene had occurred, and have sequenced the DNA around these sites. Two short sequences, TCCTGG and AGA, occur at equivalent positions 5′ to the two sites and could be the signals for the μ to γ2b switch. However, these sequences do not occur at the μ to α[8] and μ to γ_1[13] switch sites, both of which lie in a region of tandemly repeated sequences in the J_H-C_{μ} intron. It seems that the switch sites are different for the different class switches and may even vary within one type of class switch[15]. The recombination sites involved in the class switch need not be unique as long as they do not create signals which terminate transcription or destroy the signals required for the splicing event which removes the intron containing these sites.

It is possible that the homologies in the flanking sequences of the different C_H genes are a consequence of their evolutionary history. Each C region consists of three or four (depending on the heavy chain class) partly homologous domains thought to have evolved by tandem duplication from a common sequence coding for a single domain. Homologies in the flanking sequences might then have been conserved if they had come to acquire a role in the recombination events leading to class switches. If indeed the three domains of each C region derive from the same gene, then weaker sequence homologies might be expected in the

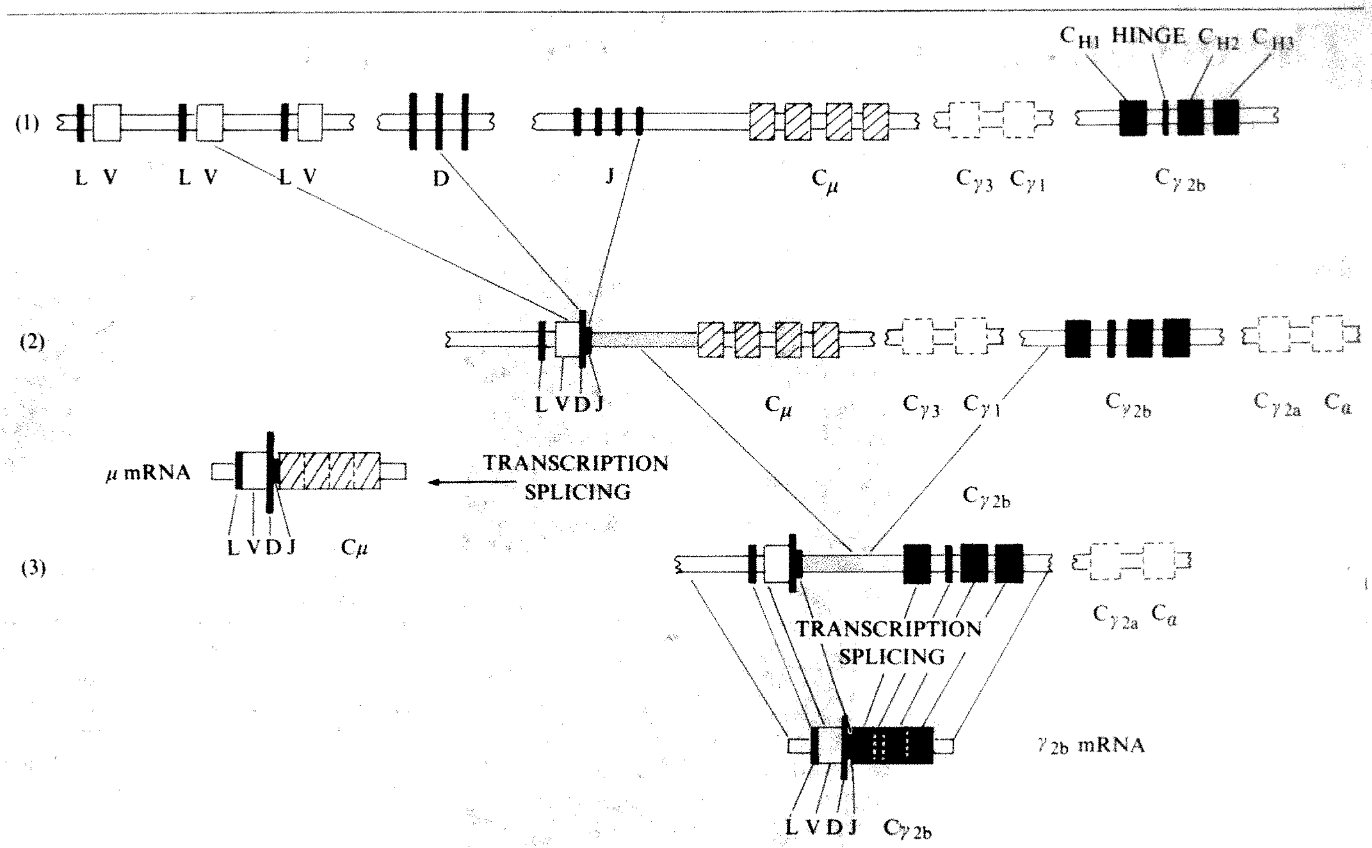

Fig. 2 Recombination events leading to a complete γ2b gene. (1) The germ line DNA before rearrangement. These is a cluster of at least 50 genes (each with a short leader sequence L) coding for part of the variable (V) region, a cluster of D gene segments coding for most of the third hypervariable region and some distance away there are 4 J segments which complete the Vregion coding sequence. The J segments lie about 8kb from the C_μ gene which lies at the start of a cluster containing all the C region genes. The C region gene sequences are interrupted by non-coding sequences to give a series of exons which coincide with the domains and the hinge region in the C region amino acid sequence (2) In the first translocation event one of each of the V, D and J segments are recombined to give a complete μ chain transcription unit. The transcript is a copy of the gene as shown but the non-coding sequences (introns) are removed by splicing events which lead to a continuous coding sequence in the μ m-RNA. (3) A second translocation event, the heavy chain switch, deletes the C_μ, $C_{\gamma 3}$ and $C_{\gamma 1}$ gene segments and places the VDJ segment and part of the J-C_μ intron near the $C_{\gamma 2b}$ gene. Following transcription the introns are removed by splicing leading to a continuous coding sequence in the γ2b mRNA.

intervening sequences that have been found between constant region domains. Such homologies have in fact been found in an investigation of a deletion mutant in a myeloma cell line. An illegitimate recombination event or class switch has led in this case to the deletion of an exon coding for the first domain in $C_{\gamma 1}$ (ref. 16). That the region of tandemly repeated sequences in and near the switch region is a particularly good site for recombination is illustrated by the spontaneous deletions which occur in this region, on cloning or propogation in *E. Coli* and which have prevented several groups from isolating complete DNA fragments containing these C_μ flanking sequences[8,14].

The heavy chain switch involves deletion of C_H gene segments.

The overwhelming evidence of a number of experiments by different groups in which cloned constant region probes have been used to probe the DNA of many different plasmacytomas is that the expression of a constant region class other than μ involves deletion of other constant region genes including C_μ in a way which is consistent with a C_H gene order μ–γ_3–γ_1–γ_{2b}–γ_{2a}–α (δ and ε have not yet been studied) and a model in which the genes preceding the expressed gene are deleted[4,16–18]. Some controversy remains however as to whether the deletions occur only on one chromosome or on both. Honjo and Kataoka[19], who were the first to find evidence for the deletion model, concluded on the basis of DNA hybridization kinetics that deletion was confined to one allele. Yaoita and Honjo[20] have now produced stronger evidence for deletion on only one allele by analysing a IgG_{2b} secreting myeloma induced in an F_1 hybrid of C57BL and BALB/c mice. A judicious choice of restriction enzymes enabled them to distinguish the two alleles and to show that the C_μ and $C_{\gamma 1}$ genes of the expressed allele are deleted and the expressed $C_{\gamma 2b}$ gene is rearranged, while the unexpressed alleles C_μ, C_{γ_1} and $C_{\gamma 2b}$ are unchanged. They did find two unexpected rearrangements in the 5′ flanking sequences of the unexpressed C_μ allele and in the 3′ flanking sequences of the unexpressed $C_{\gamma 1}$ gene.

However, in the numerous myelomas analysed by the other groups deletions and rearrangements often occur on both alleles. Unexpected rearrangements such as the rearrangement of both C_α alleles in some IgG_{2a} expressing tumours has led Coleclough *et al.*[17] to propose a stochastic model in which, after the first translocation which creates the complete μ gene, deletion events may occur within the C_H cluster on both alleles, only some of which expose a V_H gene to a second C_H gene leading to a heavy chain switch. Other deletions may have no effect on expression or may limit the options for further switching.

It should be borne in mind that all these studies have been carried out with mouse plasmacytomas which are known to show chromosomal abnormalities, are of unknown ploidy, being perhaps mostly hypo tetraploid[21] and have been maintained in culture much longer than the life time of a normal diploid B-cell. Some of the events observed in the myelomas may not occur or may be infrequent in normal cells. In an isolated study of a mixed population of normal B cells Joho and Weissman[22] produced evidence consistent with rearrangement occurring on only one C_κ allele. The question has been raised, however, of whether the technique they used has sufficient resolution to detect cells with both chromosomes rearranged if those cells are in a minority. The events on the second allele are important as only one allele is expressed (allelic exclusion).

With the question of allelic exclusion, molecular immunologists are drawn into the issue of how events occurring on one chromosome might affect those occurring on another; and thus into fields of enquiry even thornier than those they have so successfully tackled in the last five years. □

The origins of marine bioluminescence

from Frank McCapra and Russell Hart

THE astonishment of seeing bright light issuing from living organisms is sometimes reflected in the view that the light must have a unique biochemical origin. Yet a timely reminder of the wide variety of the chemical systems involved has been provided by the recent observations of Dunlap, Hastings and Shimomura (*Proc. natn. Acad. Sci. U.S.A.* **77**, 1394; 1980). They have demonstrated that although two distantly related organisms, the dinoflagellate *Pyrocystis lunula* and the euphausiid shrimp *Meganyctiphanes norvegica* have the same novel luminescent reactant or luciferin this molecule has no structural similarity to the luciferins identified in more than 20 other organisms.

The luminescent reaction in most organisms occurs by the action of a luciferase upon a luciferin. The similarities in the luciferins and luciferases in different organisms can be traced both by seeing if a light emitting cross-reaction is possible between the chemicals extracted from each of them and by elucidating the chemical structure of the luciferins themselves.

Experiments of this type have shown that although there is no simple pattern of distribution of particular luciferins and luciferases among the light emitting organisms one molecule does appear again and again. This 'coelenterate-type' luciferin (luciferin 1, see Fig. 1) either in the free state, protein-bound or as a simple derivative, has been found in a variety of coelenterates and in such unrelated animals as shrimp, squid and fish (see Table 1). This widespread distribution may best be explained if the luciferin derives from a common origin in the food chain.

A second luciferin (luciferin 2, see Fig. 1), *'Cypridina* luciferin' has a similar structure to coelenterate luciferin sharing the same imidazopyrazine nucleus and producing light by an identical chemical mechanism (McCapra *Accounts Chem. Res.* **9**, 206; 1976) but it has no amino acids in common with luciferin 1 and must have a separate origin. No single food source could be responsible for the appearance of both luciferins in higher organisms. Luciferin 2 is also widely distributed in a variety of organisms (see Table 2), again suggesting a food chain origin. This is supported by the finding that several luminescent fish, e.g. *Apogon* and *Parapriacanthus* (Johnson *et.al. Proc. natn. Acad. Sci. U.S.A.* **47**, 486; 1961) have been caught with large numbers of *Cypridina* in the gut and the luciferin of these predators is identical to that of the food organism.

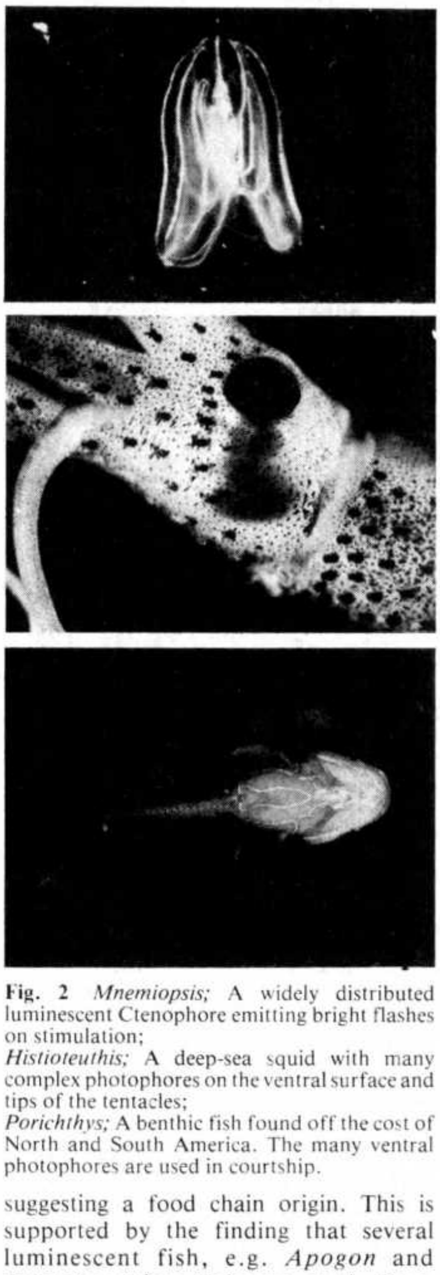

Fig. 2 *Mnemiopsis;* A widely distributed luminescent Ctenophore emitting bright flashes on stimulation;
Histioteuthis; A deep-sea squid with many complex photophores on the ventral surface and tips of the tentacles;
Porichthys; A benthic fish found off the cost of North and South America. The many ventral photophores are used in courtship.

More direct evidence that the *Cypridina* luciferin is derived from *Cypridina* comes from the work done by Tsuji and his collaborators (*Mol. Cell. Biochem.*, **9**, 3; 1975) with the midshipman fish *Poricthys notatus* collected in two separate locations off the western coast of the US. The fish collected in Puget Sound are 'dark' although possessing the large number of highly developed photophores of the southern (Californian) luminescent fish. The only way in which luminescence could be induced in the 'dark' fish was either by injection or ingestion of *Cypridina* luciferin, demonstrating a direct link between food source and light emission.

It may be that the Puget Sound area merely lacks the required, as yet unidentified, food organism containing the luciferin or a precursor. The complexity of the photophores, the nature of the transport involved and the response to administered luciferin nevertheless suggest caution in accepting this simple view. For example it is extremely unlikely that the ingested enzyme (luciferase) could survive proteolysis in the gut. In addition the endogenous luciferase in either the dark or luminous fish differs in several significant aspects from *Cypridina* luciferase.

Doubts about a food source as the sole origin of luciferin do indeed arise. For example luciferin is notoriously unstable with a lifetime in solution of a few days at most. Yet *Poricthys* luminescence, once developed by administration of small amounts of luciferin persists for up to seven months. It should be noted however that coelenterate-type luciferin is often found as a sulphate derivative, which is considerably more stable (Hori, Nakano & Cormier *Biochim. Biophys. Acta* **256**, 638; 1972). If a similar derivative exists for *Cypridina* luciferin then this would reduce the force of this objection.

Other luminous organisms (Table 3) have luciferins and bioluminescent systems with nothing in common with each other or the coelenterates.

Frank McCapra and Russell Hart are in the School of Molecular Sciences, University of Sussex.

1 2 3 4

0028-0836/80/330660-02$01.00

There is no doubt that bioluminescence arose anew many times in evolutionary history. This is shown by the markedly different structures found for the luciferins. The ubiquity of coelenterate-type luciferin does suggest a single source in this case, but may obscure several instances of *de novo* synthesis. No direct experiments have been done to settle the matter, nor do we know very much about the genetic mechanisms controlling the generation of luciferin and luciferase. Some problems are already raised by the need to explain (in genetic terms) the simultaneous appearance of luciferin and luciferase in the same organism. These will be compounded if it is necessary to account for their separate appearance in unrelated organisms.

A possibility is that food sources contain peptide material capable of elaboration by the luminescent organisms. Such sources may or may not be luminescent. By analogy with the firefly, it may be that degradation of the product of the reaction or of the less stable luciferin gives rise to the amino pyrazine which may then condense with p-hydroxyphenylpyruvic acid (see Fig. 1) following a known synthesis. It is clear that no single origin can be demonstrated, and establishing the actual blend of mechanisms will require both direct feeding experiments using labelled precursors, and some insight into the genetic mechanisms controlling the whole phenomenon. □

A new dimension for particle detectors

from David J. Miller

THE trouble with modern particle physics experiments is that you need to detect all kinds of particles at the same time. Not so long ago there were groups of ten or so physicists who did important programmes of research with nothing much more than a dozen neutron counters, or five spark chambers and a magnet. But storage-ring physics is different. As Cashmore (Oxford) told us on the first day of the Uppsala meeting*, the PETRA e^+e^- collider at Hamburg only produces 20 collisions per intersection region per day with strongly interacting particles (hadrons) in the final state. At such rates each event must be made to give up every scrap of information that can be measured. We don't want to see just the charged tracks. We want to see which of them are pions, kaons, protons, muons or electrons. All of the γ-rays must be converted. Neutrons and long lived K^0 must be made to interact. Neutrinos will escape, of course, but it is very important that they should be the only particles to escape so that their missing energy and momentum can be inferred from the measured particles.

The new director designate of CERN, Schopper (Hamburg), told us about the plans to build a first stage 'stripped down' LEP (large electron-positron) machine in Geneva by 1986. If this goes ahead, the first proposals for detectors will be asked for in 1981.

The detectors now working at other storage-ring machines provide prototypes for many of the ideas presented at the meeting. They are constructed like Russian babuschka dolls. Around the beam-pipe is nested a sequence of different devices, each fitted tightly over the next with the minimum of lost volume and without any chinks for particles to escape. Closest to the pipe there is often a multiwire proportional chamber and usually a cylinder of scintillation-counters. These establish the position of charged tracks coming out into the detector and, even more important, they establish the starting time. The time of flight of a particle from the pipe to an outer ring of counters, one or two metres away, is measurably different for pions, kaons and protons below about 2 GeV/c. At present, times can be measured to about 200 picoseconds, though considerably better particle identification could be made if 50 picosecond resolution were possible. Schemes for doing this were presented, but it was not obvious that any marked improvement can be made which will be as reliable, compact and robust as scintillators. Strand (Brookhaven, US) reported an elegant technique for making hodoscopes of 1 mm scintillating fibres, though this offers the advantage of good resolution at high particle fluxes rather than an improvement in timing.

The next shell of the detector is usually a tracking-chamber. At LEP it will have to be able to resolve up to 50 charged particles, many of them bunched in 'jets'. The present chambers working at PETRA (Hamburg) seem only just good enough for the job, though one of them, in the JADE detector, is more ambitious than the others. It uses fewer drift-cells and lets the electrons from a track drift further than in the conventional chambers. This, or the even more ambitious TPC (the time-projection-chamber at Stanford, built by a Berkeley group and reported at the meeting by Nygren), seemed to be the model people were taking for the LEP detector. Position resolution of 100 microns should be possible — though present detectors only achieve around 200 microns — and tracks only 5 mm apart will need to be resolved. Separating close tracks is where TPC and JADE win over the conventional chambers. But these two 'pictorial drift chamber' techniques also give many more samplings of the ionisation on a track and that can also be used to provide π/K/proton identification below 1.5 GeV/c and, in principle, from 3.5 to about 40 GeV/c by measuring the 'relativistic rise' in ionisation. There was more controversy over the measurement of the

---

*An international meeting on experimentation at LEP was held in Uppsala, Sweden from the 16th to the 20th of June 1980.

0028-0836/80/330661-02$01.00

relativistic rise than over any other topic. Allison (Oxford) claims that the ISIS device is now achieving the predicted resolution in ionisation measurement, but there were many others who have made similar measurements and, as Lehraus (CERN) has observed, can only come within a factor of $\sqrt{2}$ of the goal. Such a factor is crucial when the effect is only a 10% change is energy-loss and one expects around ± 4% uncertainty in measurements.

An alternative to relativistic-rise measurements is to use c̄erenkov radiation to separate π, K and proton. TASSO at PETRA, as described by Leconte, has two large slices of c̄erenkov counters which penetrate through the outer part of the detector and cover 20% of 4π solid-angle. There is a layer of aerogel counters with refractive index 1.023 and outside it two layers of atmospheric-pressure gas counters. This is an impressive and complex piece of instrumentation, yet it still leaves gaps — momenta at which π, K and proton cannot be separated. A recurrent call from speakers was for even lighter aerogel — a gossamer-like clear plastic — and groups at Saclay and Lund claimed that they will get the refractive index of aerogel down to 1.006 well before LEP is built. The disadvantage of the c̄erenkov approach to particle identification is that it seriously impedes the other kinds of measurement which, in a general purpose detector, come outside the tracking chamber. A radical idea from Ypsilantis (Ecole Polytechnique) may overcome this by using concentric spherical c̄erenkov detectors in which particles would produce ring images whose size would give the particle type and whose position would give the direction. Successful tests have been made on the detection of c̄erenkov light by large-area gas counters, but a list of formidable technical problems still has to be solved before a ring-imaging central detector can be proposed for LEP.

In the central region only charged tracks are measured. But a great deal of energy goes into the neutrals; π^0s and γ-rays or neutrons and long-lived K^0s. To catch the neutrals 'calorimeters' are used. These are dense arrays of heavy material and counters in which a fraction of the energy from an interacting neutral particle is converted into analogue signals which are summed to give a measurement of the energy. For electromagnetic showers the requirement is a high value of the atomic number Z, since γ-ray conversion and electron bremsstrahlung are proportional to Z^2. The most precise energy measurements are those made with sodium iodide crystals and a number of specialised detectors ('crystal balls') have been used for γ-ray spectroscopy with a small tracking chamber surrounded by hundreds of closely packed crystals. One such device may be needed at LEP because there are a number of very important single-γ decays which should be looked for, such as $e^+e^- \rightarrow$ (Higgs + γ) at the Z^0 peak, or the cascading γ decays of the "toponium" family — an expected heavy analogue of the well-established ψ/J "charmonium" family in which the $\psi\ (3.7) \rightarrow \gamma\chi$ processes have given useful information on quark binding. Less-specialised electromagnetic calorimeters will need similar energy resolution to the present lead plus liquid argon or lead scintillator systems, and better spatial resolution than all but the best of present detectors. Lots of new ideas for electromagnetic calorimetry were presented, including a plea by the author for the merits of solid argon, based on work by an École Polytechnique-UCL collaboration. The new suggestion which was best received was the 'Time Projection Quantameter' — a drift-chamber filled with perforated lead sheets. It could not — nor could other gas-filled calorimeters — match the energy-precision of lead-glass or lead plus argon but it has good spatial resolution and may be easier to run than some of the other devices. For neutrons and long-lived kaons a much thicker and coarser calorimeter is needed because the absorption length for strongly interacting particles (hadrons) is much longer than for electrons and γ-rays. Some of the present detectors incorporate hadron calorimeters outside the electromagnetic calorimeter and there was considerable discussion of these techniques. The best material to use is probably uranium, which amplifies and feeds back the energy normally lost as slow neutrons, but in many cases people are happy to use the segmented iron return yoke of the track-chamber magnet. It was surprising to many of us that with a conventional solenoid around the central detector and with a hadron calorimeter of uranium plus scintillator, charged hadron energies above 10 GeV/c might be better measured in the calorimeter than in the tracking chamber.

Solenoid magnets remain popular. There is a strong school of thought which advocates conventional, large-radius, low-field solenoids, rather than small superconducting ones. For specialised detectors the 'open solenoid', as used by the DELCO detector at Stanford, can allow particles out into c̄erenkov counters without interacting, but experience with the PETRA detectors shows that one radiation-length of coil does not interfere too badly with the performance of a subsequent electromagnetic calorimeter.

One intriguing development reported at the meeting may turn out to be important in many other fields as well as in high energy physics. Kunz (Stanford University) described his 'emulating processor', a small cheap home-made microprocessor which has similar internal architecture to Stanford's large IBM computer. This allows it to execute programs which have been compiled on the IBM and so take away a large part of the 'number crunching' load from the central laboratory machine. One Stanford experiment now claims to have more computing power than two or three of the major international laboratories put together. Among other powerful electronic techniques which can now be considered there was considerable interest in 'flash analogue to digital converters' — devices developed for television purposes which sample an analogue level at a rate of more than 40 MHZ. They are expensive at the moment and, as an alternative, the TPC group made a strong defence of their charge-coupled shift-register technique for doing the same kind of job. They claim it costs only $30 per channel including the analogue to digital converter. When the data has been digitised it must be checked. Do all these 'hits' constitute a track? How much energy did the calorimeter catch? It may be that the advances in hard-wired or field-programmable microprocessor logic will play a larger part in improvements of the instrumentation at LEP, compared with PETRA, than any advances in the detectors themselves. LEP will have 25 microseconds between bunch-crossings so it will be possible, according to Waloschek (Hamburg), to apply ~ 50,000 separate series and parallel tests on the data from one event before deciding whether to record it; and if there is a bank of emulating processors standing by it could then be possible to run through the complete analysis on the spot. A totally different approach to decision-making logic was suggested by Julia Thompson (Pittsburg) who has been experimenting with a holographic technique which might go well with fibre-optic data transmission.

Techniques already exist for doing many of the things that need doing at LEP and there is a community of high energy physicists from all over the world who are eager to get started. The teams are likely to be of a hundred or so per experiment. There will not be much that a ten-man-team could do by themselves, but since the equipment is so modular it is clear that small groups from many separate institutions will contribute their own pieces to the whole and, with the spread of remote-access computer systems, much of the analysis will still be done in universities hundreds of miles away from LEP itself. ☐

100 years ago

In a recent paper to the Belgian Academy (*Bull.*, No. 5) Abbé Spée contends that the spectral line D3, with wave-length about 588, observed in the chromosphere and protuberances, and assigned to a hypothetical body, helium, which some suppose to have a still more simple molecular constitution than hydrogen, probably belongs in reality to this gas. As to its non-reversibility, he considers that at a very small distance from the chromosphere the solar hydrogen may be so far cooled as to be comparable to that which we manipulate, and so, unable to extinguish waves which it can no longer produce, just as a stretched cord loses the property of vibrating in sympathy if its tension have been altered.

REVIEW ARTICLE

The ontogeny of the neural crest in avian embryo chimaeras

Nicole M. Le Douarin

Institut d'Embryologie du CNRS et du Collège de France, 49bis, avenue de la Belle-Gabrielle, 94130 Nogent-sur-Marne, France

The migration and subsequent development of autonomic ganglion cell precursors can be followed in suitably constructed chimaeric quail–chick embryos, thanks to the distinctive structures of quail and chick interphase nuclei. The decisive role of environmental factors arising from non-neuronal tissues on the chemical differentiation of neurones was demonstrated together with the lability of their phenotype during ontogeny.

EMBRYONIC development involves extensive movements of cells to achieve histogenesis and modelling of the body. With a few exceptions, such movements are extremely difficult to follow precisely by classical embryological methods. In fixed tissues, migrating cells, if they can be identified at all, can usually only be recognized in favourable situations, as for example when they are just leaving their site of origin. Since the expression of a particular differentiated phenotype generally occurs only after cell migration has taken place, the cells rapidly become indistinguishable from the equally undifferentiated surrounding tissues. The construction of embryonic 'fate maps' thus involves marking presumptive migrating cells so that their movements can be followed during ontogeny. This type of study, from which fundamental data on the formation and the fate of the germ layers have been obtained[1,2], entails differential labelling of relatively large tissue areas with rather crude methods, such as the application of vital dyes or small marking particles to specified embryonic regions. To investigate the migratory behaviour of individual cells, more precise means had to be found. One important way of achieving such refinement has been the use of techniques for combining early embryonic cells of different genotype. Such chimaeras develop normally and can be used to trace cell lineages through characteristic genetic markers.

In recent years, cell migration, cell derivation and cell–cell interactions during ontogeny of the avian embryo have become better understood, through the development of such a marking technique based on differences of the nuclear structure in two species of birds—the chick (*Gallus gallus*) and the quail (*Coturnix coturnix japonica*).

The quail–chick marking technique

The presence in all embryonic and adult cell types of the quail of a large amount of heterochromatin associated with the nucleolus was first described in 1969, and this characteristic was proposed as a cell-marking technique in combinations of embryonic cells from the quail and the chick[3]. Taxonomically, the two birds are closely related, but they differ significantly in the duration of their incubation period (16 days for the quail, 21 days for the chick) and their size at birth: the newly hatched chick weighs about three times as much as the quail. However, as shown by the tables of development of the two species[4,5], the chronology of development and also the size of the embryo differ only slightly during the first half of the incubation period, when the most decisive events of embryogenesis occur. Quail and chick cells can readily be recognized in sectioned material with the Feulgen–Rossenbeck stain or in the electron microscope after the routine uranyl acetate-lead citrate staining procedure. In undifferentiated cells, characterized by a high proliferation rate, the nucleolus is enlarged and made up of intimately associated DNA- and RNA-containing structures[6]. In most differentiated cell types, the nucleolus is formed of a compact mass (sometimes 2 or 3) of heterochromatin, distinct from the nucleolar RNP, which occur as 'satellites' in contact with the heterochromatin. The structure of the nucleolus thus varies somewhat according to the cell type considered and the degree of differentiation reached. Nevertheless, the differences in their structures in quail and chicken cells are always conspicuous enough to make them easy to identify[6].

Quail–chick chimaeras can be constructed either *in vivo* or in culture. In the latter case, interactions between cell types from each species can be analysed in the course of a definite histogenetic process. Organotypic culture *in vitro* or grafting of the combined tissues on the avian chorioallantoic membrane (CAM) provides suitable conditions for these kinds of experiment[7,8]. The quail–chick system has also been applied to cell culture for recognition of nuclei in heterokaryons after acridine-orange staining[9]. However the domain in which it has so far been the most profitable is in the analysis of chimaeric embryos constructed *in ovo* by implanting quail cells into chick, or vice versa.

This method has been applied in my laboratory to study the ontogeny of two systems that involve extensive cell migrations in the embryo, the neural crest and the haemopoietic organs.

Migration pattern and fate of neural crest cells

The neural crest is a transitory structure of the vertebrate embryo arising from the lateral ridges of the nervous primordium and giving rise, among other cell types, to the neurones and supporting cells of the peripheral nervous system (sensory ganglia of the head and the rachis and autonomic sympathetic and parasympathetic ganglia), to the melanocytes and to mesenchymal derivatives in the head. As the elements derived from the neural crest are dispersed in various locations, the neural crest cells have to migrate throughout the developing body before reaching the embryonic rudiment in which they differentiate. This structure is, in many ways, an attractive model for the study of certain developmental problems and the fate of its cells has been widely investigated. Although they yielded much important information, the experimental techniques used by earlier workers for investigating differentiating capabilities of crest cells (excision and electrocauterization of the neural anlage, and various cell labelling techniques: see refs 6, 10, 11) did not provide a complete and detailed picture of the migration pattern and the developmental fate of the whole population derived from the crest. The application of the quail–chick marker to this problem brought additional information on the role of the neural crest in the construction of the head in higher

0028-0836/80/330663—07$01.00

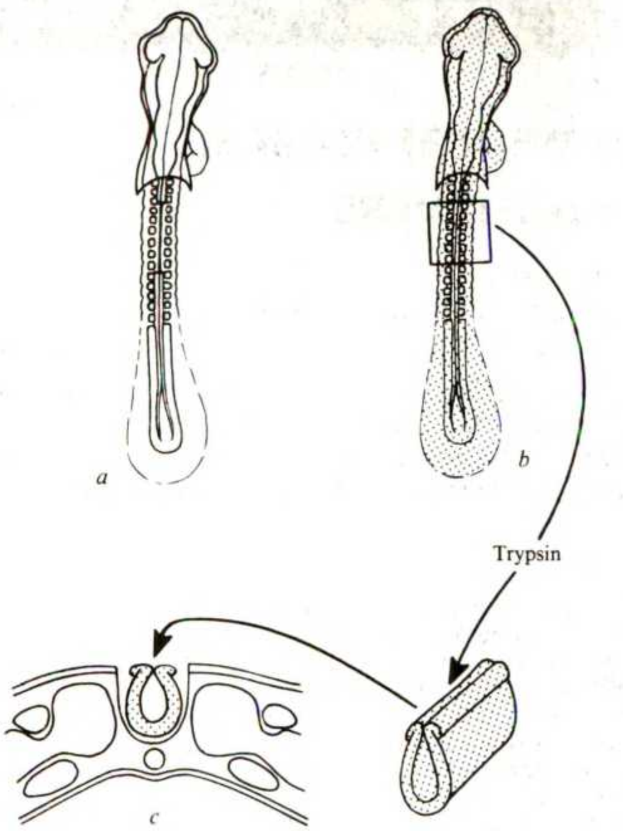

Fig. 1 Schematic representation of the isotopic-isochronic grafting technique of neural primordium between quail and chick embryos. *a*, Chick host embryo following the removal of the neural anlage from somite 4 to somite 10. *b*, Quail donor embryo from which the corresponding fragment of the neural tube + neural fold is isolated by enzymatic digestion. *c*, Graft of the quail neural primordium into the chick embryo.

vertebrates[12-16] and allowed new crest derivatives to be identified[17-19]. The method used, derived from that described by Weston[20], involved (1) surgical removal of a defined region of the neural primordium in a host embryo before the onset of crest cell migration at this level; and (2) its replacement by the strictly equivalent neural area originating from a donor embryo of the alternative species, at the same developmental stage (that is, isotopic and isochronic grafts) (Fig. 1). Since the graft is correctly positioned in the host, it develops normally in the chimaera (Fig. 2). Furthermore, the regulation processes that often follow extirpation of embryonic territories do not take place in the chimaera since the empty space is occupied by an equivalent structure originating from the donor embryo. Immunological mechanisms do not function during embryonic life and tissues of the two species are thus tolerated by each other. In the cephalic region, where the neural fold is larger than in the trunk, selective substitution of pieces of the neural crest alone can be carried out[12,13]. Migration of crest cells is followed on serial sections of the host embryos at various developmental stages. Recognition of the phenotype displayed by the grafted cells requires identification of both nuclear characteristics and an appropriate differentiation marker in the same cell. Electron microscopy can sometimes do this but, more often, the successive application of a cytochemical method (for example Falck's technique to evidence catecholamines[21]) and the Feulgen–Rossenbeck stain on the same section, have to be used.

Differentiation of the peripheral nervous system

Cells originating from the neural crest differentiate into constituents of two major neuronal systems: the sensory and the autonomic. Considerable interest has been focused in recent years on the development of autonomic nerve cells and particularly on their chemical differentiation in terms of neurotransmitter synthesis. In complementary approaches the migratory behaviour and capabilities for differentiation of the presumptive autonomic neuroblasts have been studied by means of transplantation experiments *in vivo*, and the stability of neurotransmitter synthesis in developing autonomic neurones has been examined *in vitro*.

Although the ganglia of the autonomic nervous system and the adrenomedullary cells have long been recognized to be of neural crest origin, the migration pathways followed by their precursor cells were controversial (see ref. 22). By using the quail–chick chimaera system, we investigated their origin in normal development in the avian embryo. Isotopic and isochronic grafts of small fragments (corresponding to a length of 4–6 somites) of quail neural primordium into chick embryos (and vice versa) were systematically carried out along the whole length of the neural axis. The migrating neural crest cells were thereafter observed on serial sections of the host trunk (in the sympathetic chain and the adrenal medulla) and digestive tract (in the enteric and intravisceral ganglia). A correspondence could be established between the level of the graft and the definitive location of ganglion cells. In this way, the fate map of the autonomic cell precursors could be established (Fig. 3).

One of the striking observations made during these experiments was the finding that in the cervico-dorsal region (between somites 7 and 28) neural crest cell migration was strictly confined to the dorsal mesenchyme derived from the somites and the intermediate cell mass. Except for the melanocytes and for the Schwann cells that followed the nerve bundles to the periphery, neural crest derivatives were restricted to the sensory and sympathetic chain ganglia, the aortic and adrenal plexuses and the adrenomedullary paraganglia. No ganglion cell precursors penetrated the dorsal mesentery to contribute to either the ganglion of Remak or the enteric plexuses. In contrast, isotopic grafts carried out at the vagal (from somites 1 to 7) and lumbosacral (behind the 28th somite pair) levels of the neural primordium resulted in colonization of both the dorsal mesenchyme and the splanchnopleure. The myenteric plexuses are derived mainly from the crest at the level of somites 1–7; the contribution of the lumbosacral crest is restricted to the ganglion of Remak and to some ganglion cells of the post-umbilical gut. Crest cells continue to migrate ventrally from the vagal region between the 7- and 14-somite stages (approximately) and become incorporated into the mesodermal wall of the fore-gut, where they subsequently undergo a long cranio-caudal migration. Penetration of the hind-gut by either vagal or lumbo-sacral crest cells does not occur before days 7 to 8 of incubation[22,23].

The neural crest can therefore be divided into several different axial regions with respect to the development of the autonomic nervous system. One (level of somites 1–7) gives rise

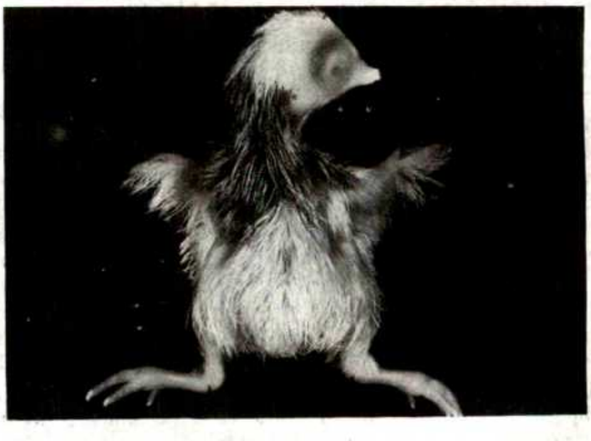

Fig. 2 Transverse pigmented stripe resulting when a fragment of a quail neural tube was grafted into a White Leghorn chick embryo.

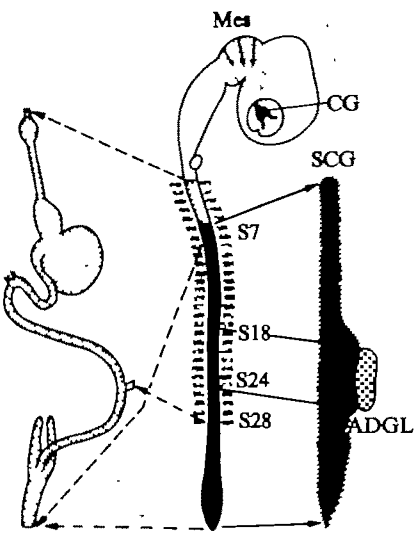

Fig. 3 Diagram showing the origin of adrenomedullary cells and autonomic ganglion cells. The spinal neural crest caudal to the level of the fifth somite gives rise to the ganglia of the orthosympathetic chain. The adrenomedullary cells originate from the spinal neural crest between the level of somites 18–24. The vagal neural crest (somites 1–7) gives rise to the parasympathetic enteric ganglia of the pre-umbilical region, the ganglia of the post-umbilical gut originating from both the vagal and lumbosacral neural crest. The ganglion of Remak is derived from the lumbosacral neural crest (posterior to the 28th somite level). Ciliary ganglion (CG) is derived from the mesencephalic neural crest. ADGL, adrenal gland; Mes., mesencephalon; SCG, superior cervical ganglion.

to the enteric ganglia of the gut. Another (somites 7–28) is the precursor of sympathoblasts of the trunk (within this area, the 'adrenomedullary' level of the crest contributes to the adrenal glands) and, finally, there are two regions from which both enteric and sympathetic ganglion cells arise (somites 5–7 and behind the 28th pair of somites). Next, neural primordia were transplanted heterotopically between quail and chick embryos, as shown in Fig. 4. This was to find out whether the migratory behaviour and phenotypic expression of crest cells from these regions were irreversibly fixed before migration and if experimental rearrangement of the axial levels of the neural crest would lead to developmental disturbances in the distribution and development of crest cell derivatives. Analysis of the resulting chimaeras showed that the neural crest cells of the adrenomedullary region, grafted at the vagal level, were able to colonize the gut (which they never do in normal development) and give rise to functional cholinergic enteric ganglia; second, neural crest cells from the quail mesencephalon or rhombencephalon, grafted at the chick adrenomedullary level, produced adrenergic sympathetic ganglia, populated the adrenal gland and differentiated into adrenomedullary-like cells[24,25]. This indicated that the migratory behaviour of the crest cells depends on the pathways available when they leave the neural primordium rather than on some specificity related to their origin in the neural axis. The vagal and the adrenomedullary regions of the embryo provide preferential pathways leading crest cells to the gut and to the suprarenal gland, respectively. In addition, the phenotypic expression of the crest cell population is regulated by environmental factors which elicit either cholinergic or adrenergic cell differentiation, irrespective of their fate in normal development. Furthermore, the potentialities for giving rise to cholinergic parasympathetic cells, adrenergic sympathetic ganglia and adrenomedullary paraganglia are not restricted to the areas identified in the isotopic-isochronic experiments, but are present in the entire crest.

Two questions thus arise. First, do the environmental signals for differentiation act on neural crest cells during their migration or after they have reached their definitive location? And second, when do the developing autonomic neurones become irreversibly differentiated into adrenergic or cholinergic cells?

When is the chemical differentiation of the autonomic neurone precursor determined?

To determine if chemical differentiation occurs before migration, we investigated the kind of transmitter synthesized by neurones when their extraintestinal migratory phase was eliminated. Since neural crest cells reach the hind gut only at 7 to 8 days of incubation, the colorectum remains totally aneural if it is removed from the embryo before this stage and grown on the CAM. When such an aneural rectum was associated with trunk neural crest for 10 to 12 days on the CAM, the crest cells migrated into it and differentiated into Auerbach's and Meissner's plexuses, in which catecholamine (CA)-containing cells were never observed. In contrast, significant levels of choline acetyltransferase (CAT) and acetylcholinesterase (AchE) activities were present in the explants[7,26]. Thus the induction of cholinergic metabolism does not depend on environmental signals received by autonomic neurone precursor cells during migration.

In contrast, the expression of the adrenergic phenotype in sympathoblasts does seem to be influenced by developmental cues during the dorso-ventral migration of the neural crest cells. By associating the neural crest with various trunk structures, Cohen[27] and Norr[28] reached the conclusion that the crest cells receive differentiating signals on their route and that the notochord, ventral neural tube and somitic mesenchyme are of decisive importance in promoting CA-synthesis in crest neuroblasts.

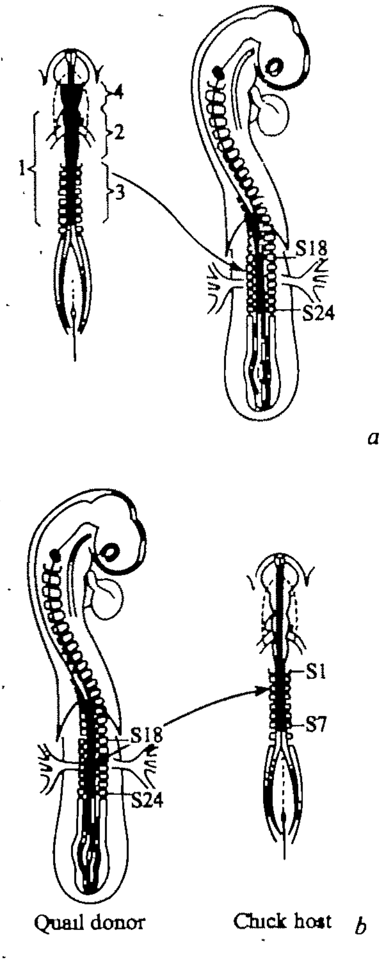

Fig. 4 Heterotopic grafts of quail neural primordium into the chick embryo. *a*, The quail primordium is removed from the mesencephalon; the anterior rhombencephalon or at the vagal level and grafted into the adrenomedullary region. *b*, The neural tissue is taken at the adrenomedullary level and grafted at the vagal level.

	Enteric ganglia	CAT activity	Adrenergic ganglia
Quail NC 1  Chick intestine	+	+	–
Quail NC+NT 2  Chick intestine	+	Not determined /	–
Quail NC+NT 3  Chick notocord Chick intestine	+	Not determined /	+

Fig. 5 Association of the aneural colorectum of a 5-day chick embryo with various dorsal trunk structures of 2-day embryos: (1) chick intestine + quail neural crest (NC). (2) chick intestine + quail neural crest and neural tube (NT). (3) chick intestine + quail neural crest/neural tube and chick notochord. CAT, choline acetyltransferase. Cholinergic ganglia develop in all cases. Adrenergic ganglia differentiate only in explants containing the notochord.

It is striking that the first CA-containing neuroblasts appear in the somitic mesenchyme (in fact in the sclerotomal part of the somite) in the immediate vicinity of the notochord and of the dorsal aorta. We therefore decided to reinvestigate the respective roles of each of these dorsal trunk structures (neural tube, notochord and somitic mesenchyme) in sympathoblast differentiation. When trunk neural primordium was isolated and inserted in aneural gut wall mesenchyme (Fig. 5), the neural crest gave rise to enteric plexuses; but in spite of the presence of the neural tube in the explants, no CA-containing cells could be detected in the ganglia. The result was therefore similar to the differentiation observed when the neural crest alone was associated with the gut[26]. In contrast, the inclusion of the notochord in the tissue associations resulted in the development of cholinergic myenteric plexuses and also in the formation of a series of adrenergic ganglia, located in the wall of the gut and characterized by the greenish fluorescence of CA. It is therefore clear that among the dorsal trunk structures, the notochord is of decisive importance in eliciting adrenergic differentiation in sympathoblasts, since, in its presence, adrenergic cells develop in the splanchnopleural gut mesenchyme, which normally supports only cholinergic differentiation. Moreover, this finding is in contradiction with the conclusions previously reached by Cohen[27] that the somite was the only structure of the embryo able to provide a convenient mesenchymal environment for adrenergic differentiation of crest-derived neuroblasts. In fact, culture experiments (unpublished) show that both the notochord and the sclerotomal part of the somitic mesenchyme are equally able to induce CA metabolism in the crest neuroblasts. This accounts perfectly for the distribution of the adrenergic cells in the trunk structures of the early embryo.

A recent observation made by Cochard *et al.*[29] in the rat embryo supports the notion that notochord induces the adrenergic phenotype. Both tyrosine hydroxylase and CA first appear at 11.5 days of gestation in the sympathetic ganglia of the trunk. But, in addition, cells with an adrenergic phenotype are transiently detectable in the gut wall from day 11.5 to about day 14.5. Thus CA differentiation in these cells may have been induced by interactions with the somite-notochord-neural tube environment during their dorso-ventral migration towards the gut. The resulting adrenergic phenotype is expressed for a time after cells have left the dorsal trunk structures and while they are pursuing their migration in the gut, but it cannot be maintained in the gut, either because of the lack of appropriate stimulation, or because other factors intervene.

Lability of transmitter phenotype in developing autonomic neurones

If the neurotransmitter phenotype of neural crest cells is selected by the tissue environment during early development what is the stability of the chemical differentiation in the developing autonomic neurones? We have investigated this by attempting to change the fate of already differentiating ganglion cells.

Cholinergic ciliary ganglion from 4.5–6 day quail embryos were incubated and implanted into the dorsal trunk environment of a 2-day chick host at the level of somites 18 to 24, the idea being to subject the maturing cholinergic cells to the adrenergic signals normally operating from day 3 to 4 on the precursors of sympathoblasts and adrenomedullary cells (Fig. 6). The ciliary ganglion, which normally never contains adrenergic cells at any stage, exhibited cholinergic activity at the time of grafting[30–33]. Examination of the host embryos at 8 to 10 days showed that, irrespective of its age when grafted, the ciliary ganglion never remained intact at the site of implantation. Quail cells were found dispersed in the host trunk structures, but not randomly: they were always localized exclusively in normal sites of neural crest cell arrest and participated in the formation of various host crest derivatives, that is sympathetic ganglia, aortic and adrenal plexuses, adrenomedullary cords, ganglion of Remak and enteric plexuses. However, quail cells were virtually never found in the host sensory ganglia; in contrast, the Schwann cells of the rachidian nerve were mostly of the quail type at the site of the graft.

The ability of cells of a differentiating ganglion to migrate anew when grafted into the microenvironment which normally sustains crest cell migration is remarkable enough. However, the result obtained by treating the sections with the combined FIF–Feulgen–Rossenbeck techniques was even more striking: the quail cells which had homed to the sympathetic ganglia, the aortic and adrenal plexuses and the suprarenal gland exhibited the bright greenish fluorescence of CA (Fig. 7). In electron microscopy, most of the quail cells of the suprarenal gland, recognizable by their large DNA-rich nucleolus, were also seen to contain the electron-dense secretory granules characteristic of adrenomedullary cells.

Although in some cases sympathetic chain ganglia in the host were found to be totally (or mainly) made up of quail cells, grafted and host cells were usually intermingled. The possibility that the fluorescence observed in the quail cells resulted merely from an uptake of CA released by host sympathoblasts was ruled out by experiments in which the host neural crest was removed before the graft of the quail parasympathetic ganglion. In this case, adrenergic nervous structures entirely made up of quail cells developed at the site of the operation and showed the same CA fluorescence as in the previous series[33].

The cells of the ciliary ganglion which colonized the splanchnopleure and became localized in the host Remak and enteric ganglia were not CA-positive after FIF treatment, and presumably developed as cholinergic cells.

In recent (unpublished) experiments, pieces of ciliary ganglia taken from quail embryos as old as 9 days of incubation were similarly grafted into 2-day chick embryos. Quail cells were found in the same locations in the host structures as in the previously described experiments except that their migration was practically restricted to the dorsal trunk and generally did not penetrate the dorsal mesentery. Many quail cells were found with CA fluorescence in the sympathetic host ganglia in the adrenal gland and in the aortic plexuses.

We are currently examining in detail the ability of the grafted cells to proliferate in a young host. Merely from the extent of quail cell distribution in the 8-day host following the graft of a 4.5-to 6-day-old ciliary ganglion, it is clear that their number is higher than the total number of neurones of the mature ciliary ganglion. Detailed counts of the number of quail cells labelled one hour after ^{3}H-thymidine injection at various intervals after grafting, show that many mitoses occur both during the migration of ciliary ganglion cells and after their stabilization in host structures. Numerous quail neurones and adrenomedullary cells are labelled with ^{3}H-thymidine at all stages up to 9 days of incubation of the host. These observations are in agreement with the recent findings[34] that developing sympathoblasts, actually synthesizing CA, divide until late in development.

Such proliferative potential is not maintained as long in the cholinergic ciliary ganglion since, according to the work of Landmesser and Pilar[31], mitotic activity has virtually stopped in chick neuroblasts at stage 25 (4.5 to 5 days of incubation), while the definitive number of neurones, after physiological cell death has occurred, is reached around day 12. Therefore, transplantation of a cholinergic ganglion into a younger host changes its developmental program profoundly enough to modify not only its chemical differentiation but also the number of cell cycles that the neuroblasts undergo before reaching maturity.

In summary, our results demonstrate that CA synthetic ability exists in cells of developing cholinergic ganglia; although not expressed in normal development, it can be elicited by the dorsal trunk structures and the adrenal gland environment.

Since all our experiments deal with the transplantation, not of single cells but of a population, our results do not allow us to state that the appearance of CA-producing cells results from the conversion of initially cholinergic cells. It may well be that the ciliary ganglion, even as late as 9 days of incubation, contains a pool of still undifferentiated neuroblasts which may be destined to disappear later on in normal development. It should nevertheless be emphasized that the capacity for a developing autonomic neurone to change its transmitter metabolism in response to environmental influences has been indisputably demonstrated by experiments *in vitro*[35–38].

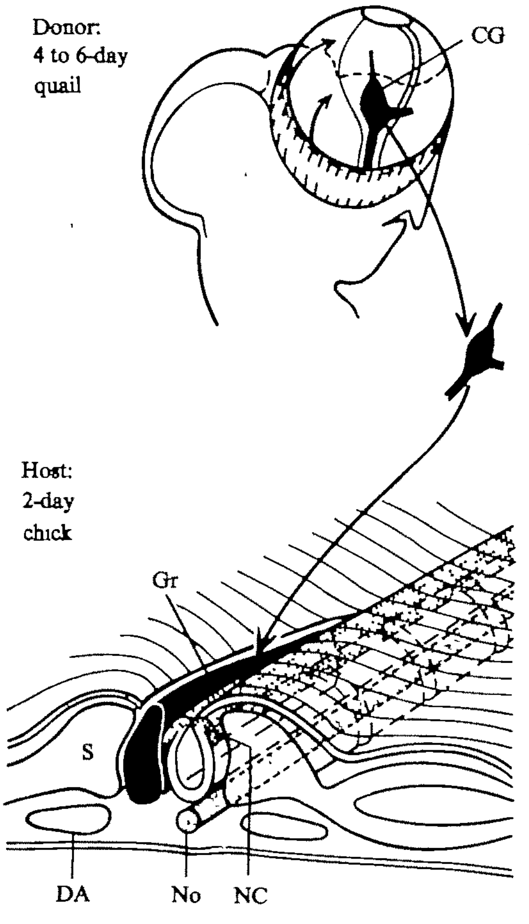

Fig. 6 Experimental design for back-transplantation of differentiating cholinergic ganglia from 4- to 6-day quail donor embryos into 2-day chick hosts. The ciliary ganglion (CG) is dissected and inserted either whole or in pieces into a slit made between the neural primordium and the somites (S). DA, dorsal aorta; Gr, graft; NC, neural crest; No, notochord.

Manipulation of the fluid environment in which dissociated post-mitotic neurones from the newborn rat superior cervical ganglion are growing has been shown to influence the choice of transmitters and the type of synapse they make. These elegant experiments (reviewed by Patterson[39]) have revealed the existence of a soluble factor mediating the conversion of an adrenergic to a cholinergic phenotype Moreover, during the switch in transmitter metabolism in culture, neurones with both adrenergic and cholinergic functions have been identified in single-cell cultures[40,41].

Although cell physiology may be profoundly altered by culture conditions, the results obtained *in vitro* are important in defining the mechanisms regulating autonomic nervous system development *in vivo*, particularly in two respects. First, the discovery that a change in transmitter synthesis can occur in post-mitotic nerve cells and the demonstration of dual-function neurones in culture strengthen the view that in the transplantation experiments *in vivo*, the environment imposes the choice of phenotypic expression on bipotential neuroblasts. The alternative hypothesis, that the microenvironment merely selects from a mixed population of committed adrenergic and cholinergic neuroblasts, becomes more unlikely. If the dual-function neurones detected in culture represent a transitional state between the adrenergic and the cholinergic condition, it seems probable that a similar process takes place in reverse when the cholinergic ciliary ganglion cells become adrenergic after back-transplantation into a younger host. Second, the demonstration that cholinergic differentiation can be triggered *in vitro* by a factor of non-neuronal cell origin suggests that an analogous mechanism might operate *in vivo*. In particular our experiments suggest that adrenergic differentiation is regulated by 'factors' produced by cells of the notochord or by the sclerotomal part of the somite and released into the extracellular matrix. Alternatively, an integral membrane component of the somitic mesenchyme might influence crest cell differentiation through intimate cell–cell contacts. The developmental relationships between sclerotomal and neural crest cells during ontogenesis support such a hypothesis but, experiments involving cultures of neural crest *in vitro*, to be described below, show that such cell–cell contacts are not necessary for eliciting CA metabolism in the developing sympathoblasts.

Developmental capabilities of neural crest cells *in vitro*

From their study of the *in vitro* differentiation of crest cells in the absence of any other tissue of the embryo, Greenberg and Schrier[42] reported CAT activity in mesencephalic neural crest cells after 7 days in culture and Cohen[43] described the appearance of adrenergic cells in trunk crest cultures. In both cases, the total neural anlage was explanted for 48 hours and, after the migration of crest cells had taken place, the neural tube was mechanically removed. This technique cannot avoid possible contamination of the crest cultures by central neurones or possible influence of the neural tube itself on peripheral neuroblast differentiation[44]. Therefore our approach has been to excise neural crest from quail embryos, at both mesencephalic and truncal levels, by a microsurgical procedure that leaves the neural tube in place. Cultures of pure crest explants from each region underwent morphological differentiation and were able to synthesize both ACh and CA. Although the amount of neurotransmitter synthesized could be increased by co-culturing with a variety of embryonic tissues, the ratio of ACh to CA formed in a given culture was markedly dependent on the composition of the liquid medium. In particular, horse serum was found to favour ACh synthesis, whilst fetal calf serum preferentially enhanced CA production. These studies, together with those of other workers[42,43], strongly suggest that direct intercellular contact with non-neural tissue is not essential for inducing neurotransmitter synthesis.

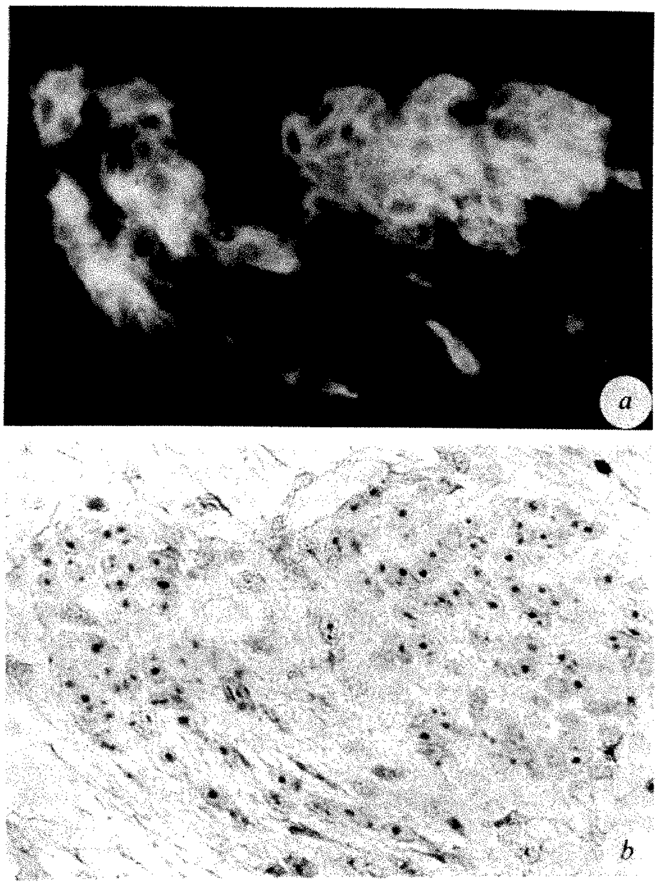

Fig. 7 Result of the experiment of back-transplantation of a quail autonomic ganglion into a 2-day chick embryo (as represented in Fig. 6). Transverse section of the host at 7 days of incubation at the level of the sympathetic ganglia. *a*, CA-containing cells shown after application of Falck's technique. *b*, Post-staining of the same section with the Feulgen reaction shows that the fluorescent cells originate from the grafted ciliary ganglion since they have the nuclear marker. ×460.

The choice between the cholinergic and the adrenergic pathways made *in vivo* by future neuroblasts could thus be the result of selective induction by soluble factors encountered at the opportune moment. If such an interpretation is correct, one has to assume that differentiating factors for both ACh and CA synthesis are present in the culture medium. They might be provided by the serum and/or by the embryo extract. Another possibility is that neuroblast precursors have the ability to synthesize neurotransmitters while still in the neural primordium; the role of environmental cues would then be limited to stabilizing and enhancing the appropriate phenotype.

As far as the adrenergic system is concerned, a number of histochemical studies have shown that the earliest detectable appearance of tyrosine hydroxylase and of CA synthesis in presumptive sympathoblasts coincides with their aggregation into the primary sympathetic chain[29,45,46]. This suggests that the first of the above mentioned alternatives is correct and that an inductive event occurs during the crest cells' dorso-ventral migration which gives them a bias towards the adrenergic pathway. On the other hand, recent results from our laboratory cast serious doubt on the applicability of this hypothesis to cholinergic differentiation[47]. We were, in fact, able to show that mesencephalic crest, excised from quail embryos of 8–12 somites (when the crest appears as an actively migrating sheet of cells under the ectoderm[44]) is able to convert ^{3}H-choline to ^{3}H-ACh and that this transformation is due to CAT. Furthermore, this activity can also be detected at an even earlier stage (5–7 somites), when migration is just beginning. In other words, mesencephalic crest cells already contain a cholinergic system when they start to migrate. We cannot yet say whether all or only some of the crest cells are involved. However, if we assume that the early cholinergic differentiation concerns the presumptive parasympathetic neuroblast (the ciliary ganglion is derived from the mesencephalic crest[13,48]), the obvious implication is that no inductive stimulus is necessary once the latter have reached their definitive site, and cholinergic maturation involves consolidation and augmentation of already acquired properties. There is one clear case in which external cues have been shown to stabilize synthesis of a particular kind of transmitter and decrease the lability of neuronal chemical differentiation: Walicke *et al.*[49] have shown that the chemical differentiation of sympathetic neurones is stabilized by neuronal activity itself.

Conclusions

In our laboratory and elsewhere quail–chick chimaeras have proved most useful in the investigation of the early stages of the differentiation of the nervous system[48,50,51]. We have already identified some new derivatives of the neural crest and analysed certain aspects of the development of the autonomic nervous system; comparison of the *in vivo* transplantation and *in vitro* culture experiments has been particularly fruitful.

Future experiments will explore the developmental relationships which may exist between the neuroblasts that give rise to the sensory neurones of the dorsal root ganglia and those which become autonomic cells. It would be of great interest to know when the commitment of these different cell types occurs and whether the choice in this case also, remains labile for a while. The relationships between the glial satellite cells of the ganglia and the neural cell lines will also be examined. Furthermore the chemical differentiation of the peripheral neurones needs to be reconsidered in terms of neurotransmitters other than just ACh and CA and including neuropeptides.

Note that the chimaeric cell labelling technique has also been of great value in analysing many other aspects of embryonic development such as the ontogeny of the haemopoietic system[52–59], the development of the kidney[60,61] and limb[62–67] and the early movements of cells in gastrulation[68,69].

An immunoglobulin deletion mutant with implications for the heavy-chain switch and RNA splicing

W. Dunnick, T. H. Rabbitts & C. Milstein

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

The IF2 immunoglobulin mutant is a DNA deletion of one coding segment and large sections of the flanking intervening sequences. The deletion results in a new splicing pattern and starts in a DNA region containing tandemly repeated sequences which may carry heavy-chain class switch signals.

IF2 WAS the first structurally defined deletion mutant of eukaryotic cells growing in tissue culture[1]. It was isolated as a spontaneous mutant secreting an immunoglobulin of altered isoelectric point[2]. Its phenotype was defined by sequence analysis[1], mRNA size[3] and mRNA sequence[4] as due to an internal deletion of the $\gamma 1$ heavy chain of the parental myeloma protein secreted by the cell line P3 (a line of the tumour MOPC 21 (ref. 5) adapted to tissue culture[6]). Internal deletions of immunoglobulin heavy chains are characteristic of a myeloma-like disease, the human heavy-chain disease (HCD)[7,8], and IF2 represents an analogous example in the mouse. We show here that the genetic origin of the protein deletion is a large deletion at the DNA level. The deletion involves at least 5.5 kilobases, including an entire segment of coding sequence (exon) and parts of the intervening sequences (introns). The consequence is a new phenotype resulting from the splicing of two exons not normally ligated together, demonstrating the importance of colinearity of splicing points.

The segments of DNA at which the deletion begins and ends have been studied in detail. The present study leads us to conclude that those points are relevant to an important event taking place during maturation of the immune response, the heavy-chain switch. For this reason, experiments are also described to explore further the correlation between the IF2 deletion and the class switch.

The IF2 mutation is a DNA deletion in the heavy-chain gene

The constant (C) region of the $\gamma 1$ heavy chain (the subclass secreted by P3 and its mutant IF2) is divided into three domains of primary and tertiary structure homology, designated CH1, CH2 and CH3 from the amino- to the carboxy-terminal end. Between the CH1 and the CH2 domains there is a segment, the hinge region, of about 13 amino acids, which includes all the inter-chain disulphide bridges. The IF2 protein deletion encompasses exactly the CH1 domain. The gene for the Cγ1 region contains four segments of DNA coding for each of the domains and the hinge (exons) separated by intervening sequences (introns)[9,10]. As the exons are spliced together, the CH1 protein deletion could be the result of either a DNA deletion of part or all of the CH1 exon, or the result of another

Fig. 1 Isolation of a recombinant DNA clone containing γ1 coding sequences from IF2 cells. *a*, Identification of *Eco*RI fragments containing γ1 sequences. High molecular weight DNA from P3-X63 cells (left) or IF2 cells (right) was digested with *Eco*RI, using as an internal control the digestion pattern of phage λ DNA. The digested mouse DNAs were fractionated on a 0.8% agarose gel and transferred by blotting onto nitrocellulose filters[40]. The filters were pretreated and hybridized in 1×SSC, 0.9% dextran sulphate to nick-translated pγ1/A5 (ref. 4) DNA as previously described[11,41,42]. The filters were washed[11] and autoradiographed for 14 days at −70 °C, using preflashed film and tungstate intensifying screens[43]. *b*, Partial purification and cloning of the IF2 mutant gene. High molecular weight DNA (600 μg) from IF2 cells was digested with *Eco*RI, extracted with phenol and precipitated with ethanol. The sample, dissolved in 0.25 ml 50 mM NaCl, 20 mM EDTA, was fractionated on a 10–30% sucrose gradient containing 1 M NaCl, 1 mM EDTA, 10 mM Tris (*p*H 7.5) in the SW27 rotor (25,000 r.p.m., 23 h, 20 °C). The gradient was fractionated into 39 fractions, and aliquots of fractions 13–28 were analysed on a 0.8% agarose gel, using *Eco*RI-digested λ DNA (M) as size markers. Also present on the gel was *Eco*-RI-digested IF2 DNA which had not been fractionated on a sucrose gradient (Tot). The DNA was visualized by ethidium bromide staining. Charon 4A DNA[12] was digested with *Eco*RI and the left- and right-hand fragments (19.8 and 10.8 kilobases) were purified on sucrose gradients as described above. About 4 μg of these Charon 4A 'arms' were ligated to 4 μg of fraction 22 of the *Eco*RI-digested, fractionated IF2 DNA (above), and the resulting DNA was packaged into phage particles *in vitro*[44–46]. The packaged DNA was used to transfect *E. coli* strain 803 suII⁺suIII⁺; about 200,000 plaques were generated. The top agar containing these plaques was scraped into culture media, and a phage stock was prepared[44]. After this amplification process, about 400,000 plaques were screened by the Benton–Davis procedure[47]. Hybridization to nick-translated pγ1/A5 was in 6×SSC (no dextran sulphate). Positively hybridizing plaques were repurified twice as individual plaques. Three resulting plaques which hybridized to pγ1/A5 were designated γM1, γM5 and γM14.

event leading to the incorrect splicing of the V-region exon to the hinge exon. To investigate these two alternatives, we have studied the structure of the IF2 DNA.

The γ1 genes of IF2 cells and of the clone P3-X63 from the parental cell line were compared by the Southern filter hybridization technique, using as a probe the cloned IF2 heavy-chain cDNA[4]. Two fragments hybridize to the cDNA probe in *Eco*RI-digested P3-X63 DNA: a 6.8-kilobase fragment which contains the γ1 wild-type constant-region coding sequences[9,10], and a 20-kilobase fragment which has been assigned to the γ2a coding sequences[11] (Fig. 1*a*). In addition to these fragments, the cDNA clone hybridizes to more fragments in *Eco*RI-digested IF2 DNA, a 15-kilobase fragment and weakly to a 6-kilobase fragment (which we designate the 6.0 RI fragment). We have partially purified the 15-kilobase fragment by sucrose gradient fractionation after *Eco*RI digestion (Fig. 1*b*). The enriched fraction was ligated into the λ vector Charon 4A (ref. 12) and packaged *in vitro*, and about 200,000 plaques were amplified and 400,000 plaques screened. Three clones which hybridized to the cDNA clone were purified and grown in bulk for analysis. The three clones seemed to be similar, in that their restriction patterns after *Eco*RI digestion were identical (not shown). One (γM14) was analysed extensively.

A restriction map of γM14 was constructed using single and double digests with *Eco*RI, *Bam*HI, *Hin*dIII, *Xba*I and *Kpn*I (Fig. 2*a*). The IF2 DNA insert includes four *Eco*RI fragments. Therefore, the γM14 clone seems to be a product of partial *Eco*RI digestion, in spite of the fact that the IF2 DNA was apparently digested to completion, as shown by the digestion of an internal control phage λ DNA. We have isolated an independent, but identical clone by a second *Eco*RI digestion of IF2 DNA and screening of Charon 4A clones prepared from unfractionated IF2 DNA. Thus, it is very unlikely that the four *Eco*RI fragments came together by random re-ligation.

Southern hybridization analysis showed that the IF2 heavy-chain cDNA hybridized to the 6.0 RI fragment and to two *Pst*I fragments of about 1.8 and 1.6 kilobases from γM14 DNA. More extensive restriction enzyme and Southern hybridization analysis (which will be discussed below) located the two *Pst*I fragments within the 6.0 RI fragment (Fig. 2*b*). These two *Pst*I fragments were isolated and partially sequenced by a combination of the dideoxy method on phage M13 subclones[13,14] and the Maxam–Gilbert method on a pBR322 subclone[15] (see Fig. 2*b* legend). These sequences demonstrated that the two *Pst*I fragments contained the γ1 hinge, CH2 and CH3 coding sequences and appropriate introns arranged as shown in Fig. 2*b*. Part of these sequences, including the hinge exon and about 80 nucleotides to the left of the hinge exon (that is, in the intervening sequence towards the V region), are shown in Fig. 2*c*. The sequence derived from the γM14 clone agrees with that of the Cγ1 gene[9,10] throughout the hinge exon and for the first 46 nucleotides to the left of the hinge coding sequence (with a single A for G discrepancy). Forty-six nucleotides into the intervening sequence, the two sequences diverge completely.

The nucleotide sequences presented in Fig. 2*c* and others we have completed (Fig. 2*b*) demonstrate that the γM14 recombinant clone contains γ1 coding sequences. They also indicate that the γ1 gene included in γM14, when compared with the parental γ1 gene, has been altered in the intervening sequence between the CH1 and hinge exons. To determine the extent of this change, we have constructed a detailed restriction map of the IF2 γ1 gene and compared this with the published restriction sites in the normal γ1 gene[9,10]. As expected from the sequences described above, the restriction sites (compare Fig. 3*a* and *b*) lying to the right of the hinge correspond to those previously mapped in the wild-type gene[9,10]. On the other hand, those to the left do not correspond at all to the sites to the left of the hinge in the γ1 gene. In particular, the enzyme sites for *Bam*HI, *Xba*I, *Sac*I and *Hin*cII, which cut in the γ1 CH1 exon, or just to its left, are missing or altered. These differences correlate with the loss of CH1 from the IF2 heavy chain[1]. The restriction mapping data indicate that a deletion removes the whole of the CH1 exon, at least 3 kilobases of the intron to its left, and 0.3 (85%) of the intron to its right.

The V region of P3 cells and IF2 cells are identical[1]. Therefore, the IF2 deletion must begin in the V–CH1 intervening sequence (after the V-region exon). The deletion results in the direct splicing of the V exon to the hinge exon. Insofar as can be estimated by gross yields of mRNA[3], the IF2 cell splices the V exon to the hinge exon as efficiently as P3 cells splice V to CH1 and CH1 to the hinge. Thus, only the linear order of exons seems to determine which exons are joined together, as has been suggested by the sequences of junction regions. These results argue against a multiplicity of splicing enzymes, for the splicing machinery seems to be able to join any exon–intron boundary to any intron–exon boundary. As the same V region can be spliced with different C regions (the class switch), the argument of a single enzyme specificity applies to all heavy chains.

The fact that 85% of the CH1-hinge intron and at least 5 kilobases (see below) of the V–CH1 intron have been deleted without affecting splicing capability provides evidence against the importance of internal intron sequences in splicing. This also

Fig. 2 Restriction analyses and sequencing of the recombinant clone γM14 *a*, **Restriction map of γM14.** This map was constructed from the restriction pattern of single and double digests of γM14 DNA, and single digests of *Eco*RI fragments eluted from agarose gels. The 0 7-kilobase *Eco*RI fragment could not be unambiguously placed, although partial *Eco*RI digestion of γM14 DNA suggested its position to be between the 3 0- and 6.8-kilobase *Eco*RI fragments. The 6.0-kilobase *Eco*RI fragment (hereafter referred to as '6 0 RI fragment') hybridized to the pγ1/A5 probe. The γM14 clone is a product of partial *Eco*RI digestion of IF2 DNA; a small amount of the 6.0 RI fragment (total digestion product) can be seen in Southern hybridization filters (Fig. 1*a*) R, *Eco*RI; K, *Kpn*I; B, *Bam*HI; X, *Xba*I, H, *Hin*dIII. *b*, **Sequencing strategy.** Two *Pst*I fragments from γM14 (about 1 8 and 1.6 kilobases) hybridized to pγ1/A5 in a Southern filter hybridization experiment (not shown). These fragments were prepared by electrophoresis in a 6% acrylamide gel (400×200×0.4 mm, 7 mA, 28 h) and eluted by soaking the gel slices in 0.3 ml 0.2 M sodium acetate, 0.5% SDS and 0.1 mM EDTA three times for 24 h each. The DNA was precipitated with the addition of 20 µg yeast tRNA and ethanol. The 1.8-kilobase fragment, hereafter referred to as the '1.8 *Pst* fragment' was subcloned in the *Pst*I site of pBR322 (ref 48); propagation was carried out in the disabled *E. coli* strain MRC-1 (GMAG issue number 2–5). Some *Hph*I fragments were prepared from this plasmid (designated pγ1/IF2P.1.8) and sequenced by the method of Maxam and Gilbert[15]. Strand separation was accomplished by hybridization to appropriate single-stranded M13 DNA (see below and ref. 49). The 1.8- and 1 6-kilobase *Pst*I fragments were cut with *Sau*3A, and the subfragments were ligated into the *Bam*HI site of a derivative of M13mp2 containing a single *Bam*HI site[30] and an amber mutation (G. Winter, unpublished). The ligated DNAs were used to transform *E. coli* JM101 (ref 50) and DNA samples from white plaques were sequenced using the dideoxy method[13,14] The fragments sequenced are shown in the lower part of Fig 2*a* Each arrow represents sequences obtained from an independent clone. A 1,200-base pair *Hae*III fragment from pγ1/IF2P.1.8 was purified on a 6% acrylamide gel, and about 0.5 µg of this fragment was cloned in the *Eco*RI site of M13mp2 using synthetic *Eco*RI linkers[14]. DNA from a white plaque was sequenced by the dideoxy method[13,14] Note the break in the 1.8 *Pst* fragment, which we estimate to be 400 base pairs. The sequence derived is shown fully in Fig. 4. *c*, **Sequences near the hinge coding region.** The sequence of the hinge coding region (with amino acid sequence) and of the adjacent intervening sequence is shown. The intron between the hinge and CH2, the CH2 exon and part of the 3′-untranslated region of γM14 have also been sequenced and correspond to the published γ1 sequences from newborn mouse DNA[10] and from the MOPC 21 myeloma DNA[9]. The following differences were noted (using the numbering system of Honjo *et al.*[10]): residues 800–801, we find three Ts rather than two[10]; residues 804–805, we find three Cs rather than two[10]; residues 809–811, we find four Cs rather than three[10], residue 828, we find C rather than A[10], residues 843–844, we find three Cs rather than two[10], residue 1,754, we find T rather than C[10], residue 1,821, we find G rather than C[10] *d*, **The sequence of the γ1 germ-line gene[9] near the hinge coding region.** The line indicates concordance with the γM14 sequence.

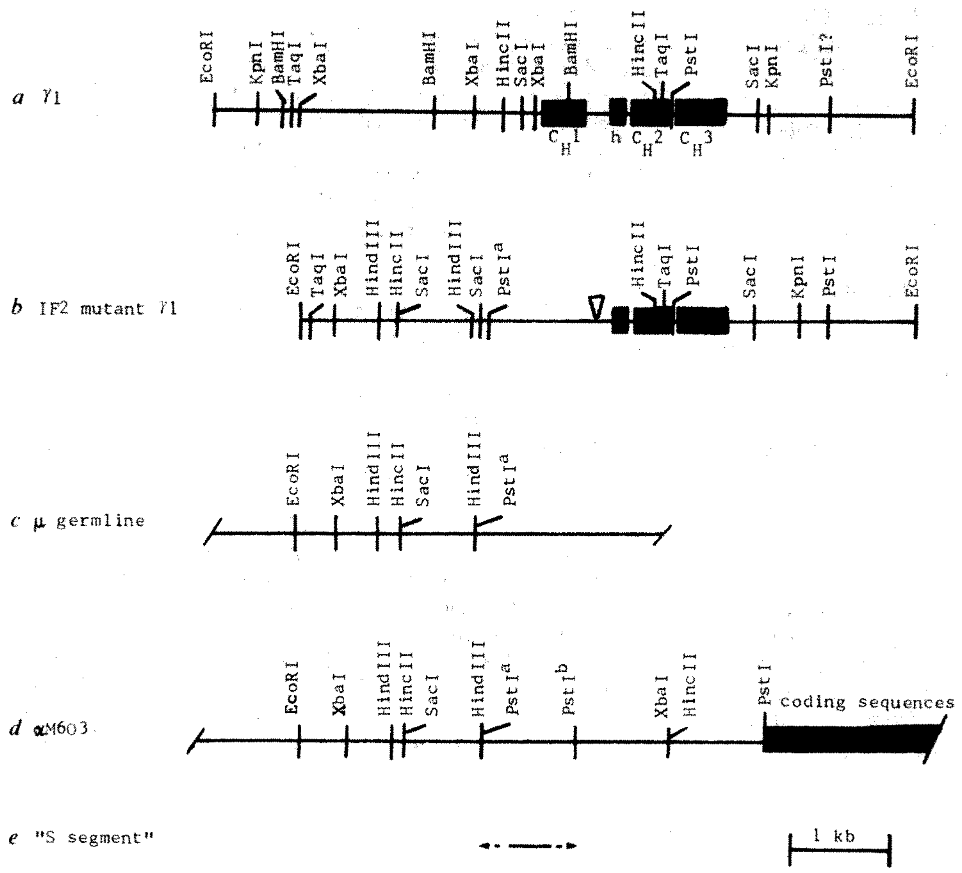

Fig. 3 Restriction maps of various DNA segments associated with mouse heavy-chain genes. The restriction maps shown are the wild-type P3 γ1 gene[9,10] (*a*), the IF2 mutant γ1 gene (*b*), a segment of the Cμ gene[24,30] (*c*) and the α gene of M603 myeloma cells[24] (*d*). The restriction map of the IF2 γ1 gene was constructed from Southern filter hybridization data of digests of γM14 DNA, and from restriction analysis of the isolated 6.0 RI fragment. The α gene from M603 cells is known to have introns; we do not show them in *d*. *e* Shows the region in which the switch leading to the M603 α gene took place (the S segment).

introduces severe constraints on models implicating secondary structure of introns in splicing events, and highlights the importance of intron sequences near the splicing points[16–18].

The IF2 deletion and human HCD proteins

IF2 is analogous to HCD proteins where the deletion involves a single exon[7,8]. In other HCD proteins, deletions involve part or all of the V region in addition to the CH1 domain[7]. The amino terminus of HCD proteins may or may not be recognizable as V region. Still other HCD protein deletions do not involve the V–C junction at all; in some cases, only the hinge is deleted, in others CH3 is apparently missing[7]. The HCD proteins are thus a heterogeneous group, and are probably the result of several different types of mutation. Some are likely to be the result of nonsense mutations[1,7], and mutations in RNA splicing signals have been hypothesized to be involved in HCD protein variants[19]. We have shown that one such protein, the IF2 heavy chain, is the result of a DNA deletion. Below we propose that others, especially those centering on the V–C junction, will also reflect deletions at the gene level. Many of these deletions may result from errors in the recognition of class switch signals.

The heavy-chain switch

Early in the immune response, the dominant heavy-chain class is μ; later the dominant class becomes γ or perhaps α. This switch pattern in whole animals can also be demonstrated in single cells or in clones of single cells, although the exact sequence and restrictions of the class switch are somewhat controversial[20–23]. It is now believed that the molecular events in commitment to a single VH gene and in the class switch are as follows: a single VH gene is first expressed by an integration event to a putative JH fragment associated with Cμ (ref. 24), an event analogous to the one observed in the joining of VL and JL in light chains[25–28], for the putative signal sequences adjacent to VH genes are homologous to those in VL genes[29]. This leads to VHCμ expression. The class switch requires a second, different form of rearrangement, involving a different segment of DNA believed to lie in the intervening sequence between VH and Cμ (refs 11, 24, 30). Recent hybridization analysis of DNA from cells making various classes of heavy chains[11,31,32] support the hypothesis proposed by Honjo and Kataoka[33] that the class switch occurs by deletion events involving the exons and introns of all CH genes between the expressed V region and the new CH gene to be expressed.

Davis and colleagues[24] have presented evidence that in an α myeloma about half of the intron between VH and Cα is derived from the germ-line μ gene; the other half is derived from the germ-line Cα gene. The position of this sequence change occurs between the sites labelled *Pst*I^a and *Pst*I^b in Fig. 3*c*, *d*, as *Pst*I^a and all sites to the left are found in the Cμ gene, whereas *Pst*I^b and all sites to the right of *Pst*I^b are found in the germ-line Cα gene[24]. A similar situation has been described in an expressed γ1 gene[30]. In both cases, the switch seems to have taken place within the DNA segment designated S in Fig. 3*e*. It is reasonable to suggest this region as being crucial in the heavy-chain switch.

The S segment in γM14 DNA

The restriction map of the IF2 gene to the left of the deletion boundary (Fig. 3*b*) corresponds to a part of the germ-line Cμ gene and the homologous part of the expressed α M603 gene (Fig. 3*c*, *d*). In other words, the intron fragment of the Cμ germ-line gene which is retained during the deletion leading to the class switch is part of the γM14 DNA we have cloned. We were therefore in a position to study the sequences which may be involved in the heavy-chain switch.

Part of the γM14 sequence which contains the 'S segment' is shown in Fig. 4. Immediately at the site of the IF2 deletion (at the bottom of Fig. 4), tandemly repeated homologous sequences begin. The repeat unit is 49 base pairs long and is repeated

10 1/3 times. No two of the repeated sequences are identical, varying from each other by 1 to 14 residues. This set is preceded by 11 unrelated nucleotides and then by a second set of repeats of a basic unit beginning with GGGGT followed by two to four GAGCT pentanucleotides. Towards the left (the V region), the repeat drifts away from the basic unit and the number of GAGCT subunits becomes more variable. There is a total of about 38 repeats of such elements with an average content of two to three GAGCT subunits. The divergence is such that no significant homology is retained within 100 bases of *Pst*I*.

In a general sense, tandemly repeated sequences would be ideal for promotion of DNA deletions like those that take place in the heavy-chain switch. A simple hypothesis could then be that each heavy-chain C gene is preceded by homologous S segments containing tandemly repeated units. Recombination by pairing between the repeats (for example, from a μ gene and a γ gene) would result in deletion of all the sequences between them. This hypothesis predicts (1) the presence of at least one S segment for each C region in the germ line, and (2) the loss of one germ-line S segment for each CH gene lost during a switching event. To test this hypothesis we have used the 1.8 *Pst* fragment, which also contains the γ1 hinge and CH2 coding sequences, as a probe for the S segment in *Eco*RI-digested kidney and myeloma DNAs (Fig. 5). The *Eco*RI fragments containing the γ2a (ref. 11), γ2b (ref. 34) and γ1 (refs 9, 10) coding sequences, which hybridize to the γ1 coding sequences in 1.8 *Pst*, are detected in kidney DNA (slot 6). In addition, at least five *Eco*RI fragments from kidney DNA hybridize to the 1.8 *Pst* fragment (bands a, b, d, e, f) but not to the γ1 coding sequences (results not shown, see also ref. 9). This result agrees with prediction (1) of multiple germ-line S segments. In agreement with prediction (2), at least three of these fragments are lost as one follows the expression of heavy chains These are b, a and d as one follows the expected progression kidney-μ-γ1-γ2b-γ2a-α

Fig. 4 Tandemly repeated sequences near the site of the IF2 deletion. The numbers indicate the distance in base pairs from *Pst*I* (Figs 2*b*, 3) In residues 70–401, the underlined nucleotides show homology (80% or more) to the pentanucleotide GAGCT In residues 402–511, there is a repetitive pattern beginning with GGGGT followed by one to five GAGCTs, or some close derivative of it These patterns can be seen on the upper half of sequencing gels; we estimate that this pattern is repeated 24 more times (residues 511–850). In residues 850–1,029, this repetitive unit has become more or less exact, except for variations in the number of GAGCT pentanucleotides To emphasize the more exact repeat unit, residues 850–1,029 are enclosed by dotted lines, and solid lines indicate concordance with the sequence at the top line of the box After a short sequence (residues 1,030–1,040), a new tandem repeat appears, extending from residues 1,041 to 1,545 (the site of the IF2 deletion). Again, the repeated sequences are enclosed within dotted lines and solid lines indicate concordance with the sequence at the top line of the box. The repeated units in residues 402–1,040 and those in residues 1,041–1,545 are apparently unrelated. These sequences were determined as described in Fig. 2. As the sequence from residues 444 to 1,040 was determined on one DNA strand only, we judge it to be 95% accurate

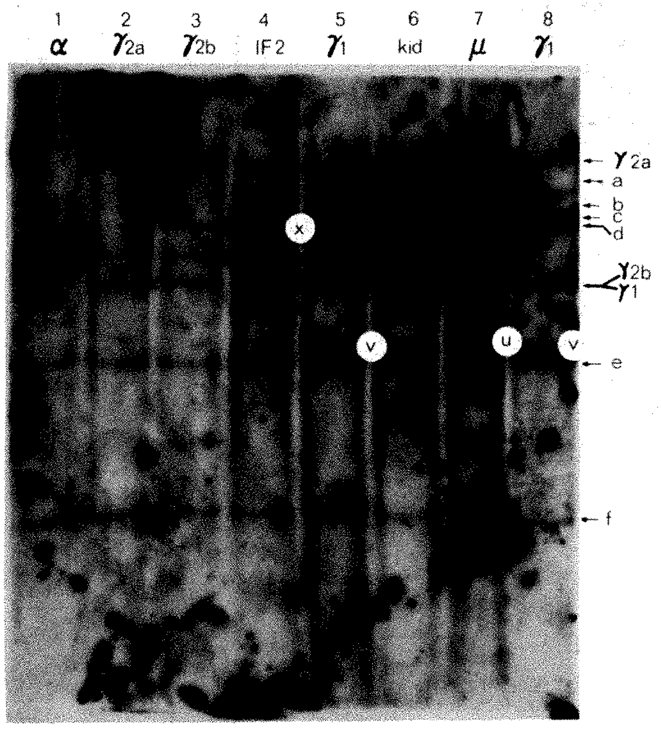

Fig. 5 Arrangement and rearrangement of tandemly repeated and associated sequences in DNA from myelomas secreting various classes of immunoglobulin. DNAs from kidney cells and various myelomas were digested with *Eco*RI and analysed by the Southern filter hybridization technique[11]. Hybridization to pγ1/IF2P.1.8 was in 6×SSC (no dextran sulphate). Slot 1, MOPC 315 DNA (α heavy-chain producer); slot 2, P1 DNA (γ2a heavy-chain producer); slot 3, MPC 11 DNA (γ2b heavy-chain producer); slot 4, IF2 DNA (γ1 mutant heavy-chain producer); slot 5, X63 DNA (γ1 heavy-chain producer); slot 6, kidney DNA; slot 7, MOPC 104E DNA (μ heavy-chain producer); slot 8, NSII/1 DNA (γ1 heavy-chain producer; the NSII/1 heavy chain is smaller than the parental X63 γ1 heavy chain; the nature of the defect is not known[35]. All DNAs were prepared from tissue culture cells except for 104E (slot 7) which was from ascites cells. Infiltration by lymphoid and non-lymphoid tissue could account for minor contaminants. Bands labelled γ1, γ2b and γ2a contain coding sequences which cross-hybridize to the cDNA clone pγ/A5 (see also ref. 11).

Note that in the γ2b producer (slot 3), the γ2b band has, albeit slightly, shifted position. The switch to γ2b production deletes theγ1 gene[11,31–33]. The γ2b sequences may be rearranged to give an *Eco*RI fragment of a slightly different size. This band and all others in the γ2b/γ1 position are different from band z present in the γ2a producer (slot 2). Band z does not hybridize to the γ1 cDNA sequences (data not shown); we presume that this contains the rearranged S segment.

(refs 11, 30–32). In addition, for most of the myelomas tested, new fragments hybridizing to the noncoding part of the 1.8 *Pst* probe can be identified (bands u, v, y and z). This is presumably the result of sequence rearrangement in the environment of S segments during the switch. To describe it schematically, let us take the sequence A-B-C-B-D-B-E. Deletion of B-C would yield A-B-D-B-E, and would involve a change in two fragments containing B. A-B-C and C-B-D are lost, D-B-E is retained, and a new fragment, A-B-D, is formed. Specifically, we suggest that bands u, v, y and z are the rearranged forms of S present when μ, γ1, γ2b and γ2a (respectively) are expressed. We have not rigorously shown that u and v are different, but we have shown that the z component of γ2a and γ2b are indeed different. The latter cross-hybridizes with the γ1 coding sequences whereas the former does not (results not shown, see also ref. 9). This highlights the shortcomings of this type of analysis. Fragments may exist which are not detected (too large or too small) or are hidden under other hybridizing fragments. For example, we have no good candidates for the Cγ3 and Cα germ-line S

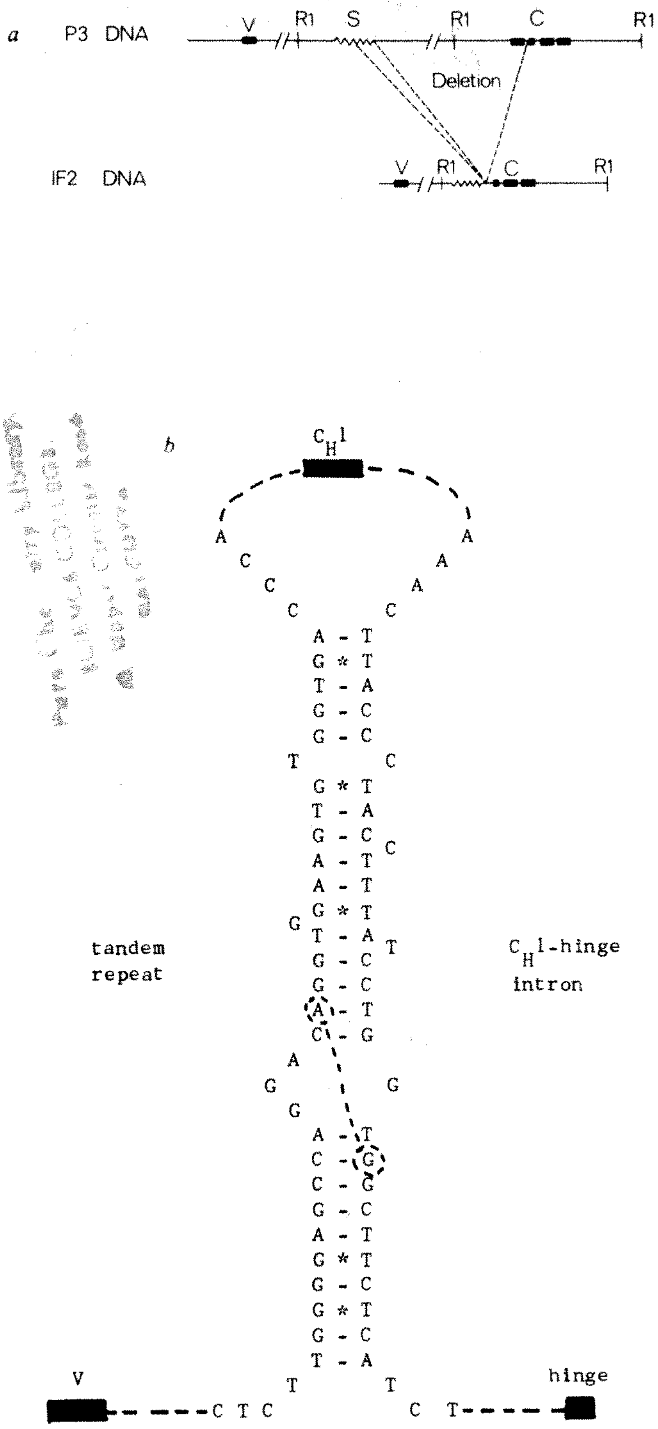

Fig. 6 *a*, Generation of the IF2 mutant. The hypothesized structures of P3 γ1 gene and of IF2 γ1 gene are shown, with coding sequences in darkened boxes and the S segment in a zig-zag line. The dotted lines denote the extent of the IF2 deletion, which could begin in the S segment or at its right end. *b*, A putative hairpin loop at the site of the IF2 deletion. The left-hand side of this structure below the circled A was constructed using the sequence of the IF2 gene to the left of the deletion (Fig. 4, residues 1,525–1,543). The left-hand side above the circled A was constructed from the consensus sequence of the 49-base tandem repeat (which is represented by residues 1,054–1,073, Fig. 4). The right-hand side comes from the Cγ1 sequence[10] near the site of the IF2 deletion (see also Fig. 2*d*). Ligation of the circled A and G would result in the sequence at the site of the deletion in the IF2 gene (Fig. 2) and deletion of the sequences above these two residues. G+T base pairs are shown by an asterisk; in the other DNA strand (not shown) these would be unpaired A+C.

segments. On the other hand, there are other components (for example, band c) for which we find no good explanation. Two germ-line fragments (e and f) hybridizing to the 1.8 *Pst* fragment, but not to the $\gamma 1$ cDNA clone, persist even in the α producer. These fragments may correspond to the other heavy chains ε and/or δ, to a hitherto unidentified heavy chain, or to repeats of a similar sequence unrelated to immunoglobulins.

From the experiment shown in Fig. 5, the minimium size of the IF2 deletion can be calculated. IF2 DNA (slot 4) shows two new bands, x and w, and lacks the rearranged band v. Band x is the product of partial *Eco*RI digestion we have cloned. Presumably, the IF2 deletion resulted in fusion of band v and the $\gamma 1$ coding sequences to yield band w (the 6.0 RI fragment). Thus, the size of the IF2 deletion is 5.5 kilobases [6.8 kilobases ($\gamma 1$ coding sequences) + 4.7 kilobases (band v) − 6.0 kilobases (band w)], asssuming no *Eco*RI fragments between band v and the fragment containing the $\gamma 1$ coding sequences.

We would like to argue that the signals for the class switch are based on the tandem repeats described above. As we have discussed, the switch occurs in or near the S fragment, which is mostly composed of these tandem repeats. Further evidence for involvement of the tandem repeats is provided by a comparison of the work of Kataoka *et al.*[30] and the one described here. Based on the restriction maps shown in Fig. 3, one can locate in their work an S segment which included the putative switch point. A close inspection of their sequence shows the presence of four sequential pseudo-repeats homologous to the 49-base pair repeat shown in Fig. 4 (starting 14 residues from the putative switch point). Preceding these sequences is a long sequence about 10% of which is GAGCT.

The difference between the sequences described by us and those described by Katoaka *et al.*[30] could have trivial sources, such as drift during tumour propagation. The difference could be a consequence of the deletion which gave rise to IF2. We prefer a third alternative, which is that these differences are a consequence of the switch process itself. The precise point of the switch could vary along the extended tandemly repeated sequences in both the donor gene (for example, μ) and the acceptor gene (for example, γ)[24,30]. Therefore, two rearranged $\gamma 1$ genes could have different S sequences, depending on how the donor and acceptor S sequences aligned, and where the recombinational event took place. Also, the S sequences in $\gamma 1$ genes might vary depending on whether or not the V regions went through a VH–C$\gamma 3$ intermediate.

HCD proteins in general, and IF2 in particular, have been implicated with DNA rearrangements for several years. Specifically, it has been proposed that signals for DNA rearrangements were duplicated along with primordial CH domains during the evolution of modern CH genes[35]. The signals preceding each CH gene retained their function while those between CH domains drifted. Some HCD deletions could result from the illegitimate use of the ancestral homologue within a single CH gene, as opposed to legitimate use of switch signals between CH genes.

With this in mind, we searched for homology between S-segment sequences, which we believe to be the switch signals, and sequences in the normal $\gamma 1$ gene[9,10]. This search resulted in a hairpin loop structure at the site of the deletion (Fig. 6). This hypothetical structure was formed between a consensus sequence of the 49-base repeat and the sequence of the $\gamma 1$ germ-line gene at the site of the deletion. The sequence of the IF2 $\gamma 1$ gene at the deletion results from the ligation of the circled A and G (see also Fig. 2*c*). The sequences above these two residues would represent the deletion. Such hairpin loop structures can only be speculative. The free energy of the structure shown in Fig. 6*b* is +3.4 kcal mol^{-1} (refs 36, 37), corresponding to a melting temperature of 30 °C. This value can be compared with those of similar structures. For example, the proposed hairpin structure for κ V–J joining[27,28] has a free energy of about −19 kcal mol^{-1} ($T_m = 67$ °C). Obviously, for a low frequency event such as a mutation, one expects relatively unstable structures.

In conclusion, we suggest that the deletion which gave rise to the IF2 mutant, and also the deletions for similar HCD proteins[5], were the result of illegitimate use of switch signals. Whether the proposed hairpin loop formation, or other mechanisms such as sister chromatid exchange[38], represent a model for the physiological switch remains to be seen.

We thank A. R. MacLeod for DNA ligase, G. Winter for the M13mp2 vector containing the *Bam*HI site and amber mutation, F. Blattner for phage Charon 4A, and S. Brenner for the bacterial strain MRC-1. W.D. was a fellow of the Jane Coffin Childs Memorial Fund, and this work was supported in part by a grant from that fund.

After submission of our article, we received a copy of manuscript by Sakano *et al.* (see accompanying article[39]). Our sequence (Fig. 4) up to residue 448 is identical (except for nine bases) to their sequence of the germ-line Cμ gene between residues 1,114 and 1,490. After residue 448, however, the two sequences differ drastically. It seems, therefore, that in the P3 lineage the switch from the Cμ gene occurred to the right of this point. Apparently, in the three cases so far described, the switch has taken place at three different sites. Furthermore, tandemly repeated units in the sequences of Sakano *et al.*, Kataoka *et al.* and ourselves are in the same polarity, implicating homologous pairing rather than hairpin loop formation in the DNA exchange mechanism associated with the switch.

Two types of somatic recombination are necessary for the generation of complete immunoglobulin heavy-chain genes

Hitoshi Sakano, Richard Maki, Yoshikazu Kurosawa, William Roeder & Susumu Tonegawa

Basel Institute for Immunology, 487 Grenzacherstrasse, Postfach CH 4005, Basel 5, Switzerland

At least two types of somatic recombination are necessary for the generation of a complete immunoglobulin γ2b gene from germ-line DNA sequences. The first type of recombination consists of the assembly of three separate DNA segments, each encoding a different part of the variable region. The second type of recombination replaces the exons coding for the constant region of the μ chain with those coding for the same region of the γ2b chain. The DNA sequencing studies suggest that the two types of recombination operate by different mechanisms.

COMPLETE, active immunoglobulin genes are created by somatic recombination that occurs during the differentiation of lymphocyte precursor cells[1–3]. The organization of the gene sequences before and after somatic recombination has been studied extensively for both λ- and κ-type light chains in the mouse[4–10]. These studies established that in the embryonic genome, the major portion of the conventionally defined variable (V) region is encoded in a DNA segment (V DNA) that is located some distance away from a DNA segment (J DNA) coding for the rest of the V region. The J DNA segment has been mapped a few kilobases upstream of (that is, 5′ side, with respect to the direction of transcription) the single-copy DNA segment (C DNA) coding for the constant (C) region. In the myeloma cells in which the light-chain gene in question is active, the V DNA segment and the J DNA segment are contiguous as a consequence of a recombination that apparently accompanies deletion of the DNA sequence occurring between the V and J DNA segments in the germ-line genome[7]. The entire region of the chromosome containing the V DNA segment, J DNA segment, J–C intron and C DNA segment is transcribed into a single RNA molecule from which a mature messenger RNA is generated by RNA splicing[11,12]. The V–J joining step is considered to be a key event in the activation of the immunoglobulin gene. It may also contribute to the increase of the organism's capacity to synthesize a large number of different antibodies[7,13–15].

As the heavy-chain polypeptide is also composed of a V and C region, one might assume that what has been established at the DNA level for the light chains would also be true for heavy chains. However, the expression of heavy chains has some features which make it considerably more complex than that of light chains. For instance, unlike the light chains, there are in the mouse at least eight different C regions, each of which seems to share the same set of V regions, that is, a given V gene can be expressed with more than one heavy-chain class or subclass. In addition, it seems that, as the lymphocytes differentiate, the C region of the heavy chain synthesized switches from one class to another without alteration of the V region[16–18].

Recently, we reported on the structure of the complete γ2b gene isolated from a myeloma, MOPC141, an IgG2b secretor[19]. These studies showed that, unlike the light-chain genes, at least two recombinations are necessary to generate the heavy-chain gene. One of them occurs at or near the 3′ end of the V DNA segment and in the vicinity of the J DNA segment. In contrast to the light-chain genes, where the J DNA segments are located in the 5′-flanking regions of their respective C genes, in the heavy-chain gene system the J DNA used for the MOPC141 γ2b gene does not lie in the 5′-flanking region of the germ-line Cγ2b gene, but is located in the 5′-flanking region of the germ-line Cμ gene. This recombination between V DNA and J DNA near the Cμ gene probably allowed the μ gene to be activated in the precursor B cells to MOPC141 myeloma. The second recombination occurs between a pair of sites, one located between the J DNA segment and the Cμ gene and the other in the 5′-flanking sequence of the Cγ2b gene, and replaces the Cμ-coding exons with the Cγ2b exons. This recombination is referred to as 'switch recombination', for it seems to be a key event preceding the heavy-chain switch. A similar gene structure was also observed for a complete α-chain gene[20] and for a γ1-chain gene[21].

We report here on the two types of recombination, studied by DNA sequencing. The sequences around the V–J joining and the switch recombination sites have different features, suggesting that at least two distinct enzyme systems are involved in the generation of the active immunoglobulin γ2b gene. In addition, sequence analysis of the V DNA of MOPC141 and its germ-line components, the embryonic V DNA and J DNA, revealed that the third hypervariable region is encoded in a separate DNA segment(s) in the germ-line genome.

Mouse DNA inserts in the DNA clones used in this study are listed in Fig. 1. The homology among these DNA fragments has been determined by heteroduplex analysis and restriction enzyme mapping. The coding regions were mapped by R-loop analysis using mRNAs from MOPC141 (γ2b) or MOPC104E (μ). Isolation and electron microscopic characterization of clones M141–P21 (complete γ2b), MEP203 (embryonic J plus Cμ) and MEP3 (embryonic Cγ2b) have been described elsewhere[19]. The isolation of the embryonic V-gene clone, PJ14, is described below.

Identification of J DNA for MOPC141

We have previously identified the putative V–J joining site on the complete γ2b gene clone (M141–P21) and on an embryonic Cμ gene clone (MEP203) by heteroduplex analysis and R-loop mapping[19]. The electron microscopic studies indicated that the putative J DNA for the MOPC141 heavy-chain gene lies 3.6 kilobases 5′ to the Cγ2b gene on M141–P21 and 5 kilobases 5′ to the Cμ gene on MEP203. To analyse the structural features of heavy-chain V–J joining sites, we determined the nucleotide sequences of the appropriate regions of M141–P21 and MEP203. Although the amino acid sequence of the MOPC141 heavy chain is unknown, identification of the J DNA segment coding for this chain was possible because J-peptide sequences are highly conserved. As shown in Fig. 2, M141–P21 carries a DNA sequence in the vicinity of the putative V–J joining sites which can encode a peptide that is identical to the J peptides of

0028-0836/80/330676—08$01.00

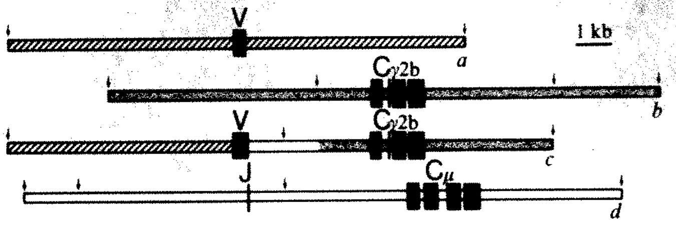

Fig. 1 Mouse DNA inserts in the clones used in the study. Embryonic V_{M141} gene clone PJ14 (*a*), embryonic Cγ2b gene clone MEP3 (*b*), complete γ2b gene clone M141–P21 (abbreviated to M141) (*c*) and embryonic Cμ gene clone MEP203 (*d*) are shown. Arrows indicate *Eco*RI cleavage sites. Filled boxes are exons identified by R-loop mapping. The regions of homology among the four DNA clones as determined by heteroduplex analysis are indicated by bars of different types of shading.

MOPC21 and MOPC173 heavy chains (see Table 1). We also analysed the MEP203 insert to determine whether the same J DNA segment is present in the expected position. Our previous study on clones MEP203 and M141–P21 suggested that the J_{M141} DNA segment and the sequence that follows this segment are derived from a region 5′ to the Cμ gene. In fact, the sequence of MEP203 showed that the J DNA segment and its 3′ noncoding sequence found on M141–P21 are also present in the region about 5 kilobases 5′ to the Cμ gene on MEP203 (Fig. 2). Comparison of these two J_{M141} DNA sequences, one on M141–P21 and the other on MEP203, indicates that the germ-line J_{M141} DNA can encode the M141 J peptide starting with the second nucleotide of the Leu codon at position 112.

In γ2b heavy-chain peptides, the boundary of V and C regions has been thought to be around Ala 126 (ref. 22). The J_{M141} DNA segment can fully encode Ser 125, but only partially Ala 126. We found a triplet, GGT, instead of the Ala codon GCN. Because, in almost all cases studied thus far, an intron starts with the doublet GT (ref. 23), we tentatively conclude that the coding of the J_{M141} DNA ends with the first letter G in the triplet GGT.

Four heavy-chain J DNA segments around 8 kilobases 5′ to the germ-line Cμ gene

Previous studies showed that most, if not all, κ-light-chain J DNAs are tightly linked[7,13]. To examine whether the same applies to the heavy-chain J DNA segments, we isolated DNA clones containing the rearranged V gene from myelomas MOPC603, MOPC315, HOPC8 and MOPC173 and analysed the heteroduplexes formed between each of these DNA clones and the embryonic μ DNA clone MEP203. It is expected that the divergency point observed on a Y-shaped heteroduplex molecule corresponds to the J DNA segment used for expression in the respective myeloma cells. In this way, we mapped four different J DNA segments in the region 5′ to the Cμ gene, at 1.1 (MOPC173-II J), 1.6 (HOPC8-II J), 1.9 (MOPC315 J) and 2.2 (MOPC603 J) kilobases, 5′ to the *Eco*RI site located 3.5 kilobases from Cμ DNA on MEP203. As MEP203 carries a 3-kilobase deletion at 1.5 kilobases 5′ to the Cμ gene (see below), the *Eco*RI site is 6.5 kilobases from the Cμ gene on the mouse chromosome. Using μ-chain mRNA from MOPC104E in R-loop analysis, we also identified the J_{M104E} DNA segment at 2.3 kilobases 5′ to the *Eco*RI site (data not shown). As the MOPC104E μ chain and the MOPC603 α chain seem to have the same J peptide (Table 1), this J DNA segment is probably the same as that detected by heteroduplex analysis using the MOPC603-derived V-gene clone.

Figures 3*Aa* and 4 show the restriction map and the DNA sequence of the 1.5-kilobase J-rich region, respectively. So far, 22 heavy chains have been sequenced in the J-peptide regions. They can be classified into four different groups according to the amino acid sequences of the J peptides (Table 1). Comparison of these J-peptide sequences with the DNA sequence allowed identification of the corresponding four J DNA segments. These four segments can account for all heavy-chain J peptides sequenced so far (see Table 1) and, therefore, seem to encode the J peptides of all different classes or subclasses. We designate these J DNAs as J_{H1}, J_{H2}, J_{H3} and J_{H4} from 5′ towards 3′. No additional J-like DNA sequence has been observed in the 1.5-kilobase region sequenced thus far. There is one unexpressed J DNA, Jκ3 (ref. 7), in a κ-light-chain gene, and there may also be some in the heavy-chain gene.

Isolation of the germ-line V-gene clone for the MOPC141 heavy chain

To determine the recombination site on the germ-line V gene, we attempted to identify and clone the *Eco*RI DNA fragment carrying the germ-line V gene for the MOPC141 heavy chain. First, we analysed embryonic DNA by Southern hybridization using the V DNA probe purified from M141–P21. This probe is a 257-base pair *Ava*II–*Hga*I fragment encoding residues 9–94 of the M141 heavy chain (Fig. 3*Ab*). In the *Eco*RI digest of mouse embryo DNA, about 10 hybridizable bands were detected (data not shown). Detection of 5–10 bands by a single V-gene probe has previously been reported for both κ light chains[5,9] and heavy chains[24–26]. This is due to cross-hybridization among a subset of germ-line V genes that have presumably diverged more recently. As the length of the 5′-noncoding region of the V_H gene on M141–P21 is 6.5 kilobases, the size of the *Eco*RI fragment carrying the germ-line V_H DNA for the M141 heavy chain should be larger than 6.5 kilobases. We separated the *Eco*RI digest of embryonic DNA on a preparative agarose gel, eluted the DNA from the 6.5–23-kilobase region and used it for DNA cloning. Using the V-region probe, we isolated some 30 clones from 2 separate experiments and classified them into 5 different types according to the size of the *Eco*RI insert. Heteroduplex molecules formed between the clones of each type and M141–P21, a complete γ2b gene clone, were examined by electron microscopy.

Although the *Eco*RI inserts of these clones were all hybridizable with the V-gene probe, only the clones containing a 14-kilobase insert formed Y-shaped heteroduplex molecules with M141–P21, in which the homology extended from the 5′ *Eco*RI end to a site 6.9 kilobases away from it. R-loop analysis using the MOPC141 γ2b mRNA indicated that the V-coding DNA segments map at or around the heteroduplex fork point. We further analysed one of these 14-kilobase clones, PJ14, by restriction mapping and DNA sequencing. Evidence that the 14-kilobase clone contains the germ-line V gene for the MOPC141 γ2b chain is obtained from restriction enzyme maps. The cleavage sites for *Bam*HI, *Kpn*I, *Xba*I, *Sac*I and *Hin*dIII in the 5′-flanking region of the V gene on M141–P21 were all found at the corresponding positions on the embryonic V-gene clone, PJ14 (data not shown).

The third hypervariable region is encoded separately

The DNA sequences around the V-coding regions of PJ14 and M141–P21 are shown in Fig. 2. The sequences include a 46-base pair exon presumably coding for the hydrophobic signal peptide, an 81-base pair intron, the entire V-gene exon and the 3′-flanking regions. As in all κ- and λ-chain genes studied so far (refs 4, 6, 8 and G. Heinrich, unpublished results), the V coding begins with the residue at position −4 within the signal peptide. Also, as in the light-chain genes, the coding by the embryonic clone PJ14 ends prematurely with Ser 97, whereas that of the myeloma clone, as mentioned above, continues up to Ser 125. In the 0.6-kilobase stretch of DNA starting with the *Hin*dIII site in the 5′-noncoding region and ending with the Ser 97 codon, the

Amino acid sequences of 22 mouse heavy chains[27,32,34–40] for residues 90–113 (numbering is after Kabat *et al.*[22]) are shown by one-letter codes[41]. According to the J-region peptides, the chains are classified into four groups. The amino acid sequence of the MOPC141 γ2b chain was deduced from the nucleotide sequences determined in this study. The first amino acid residues in the J peptides are shown in small letters whenever the first letters of their codons are not included in the corresponding J DNA segments.

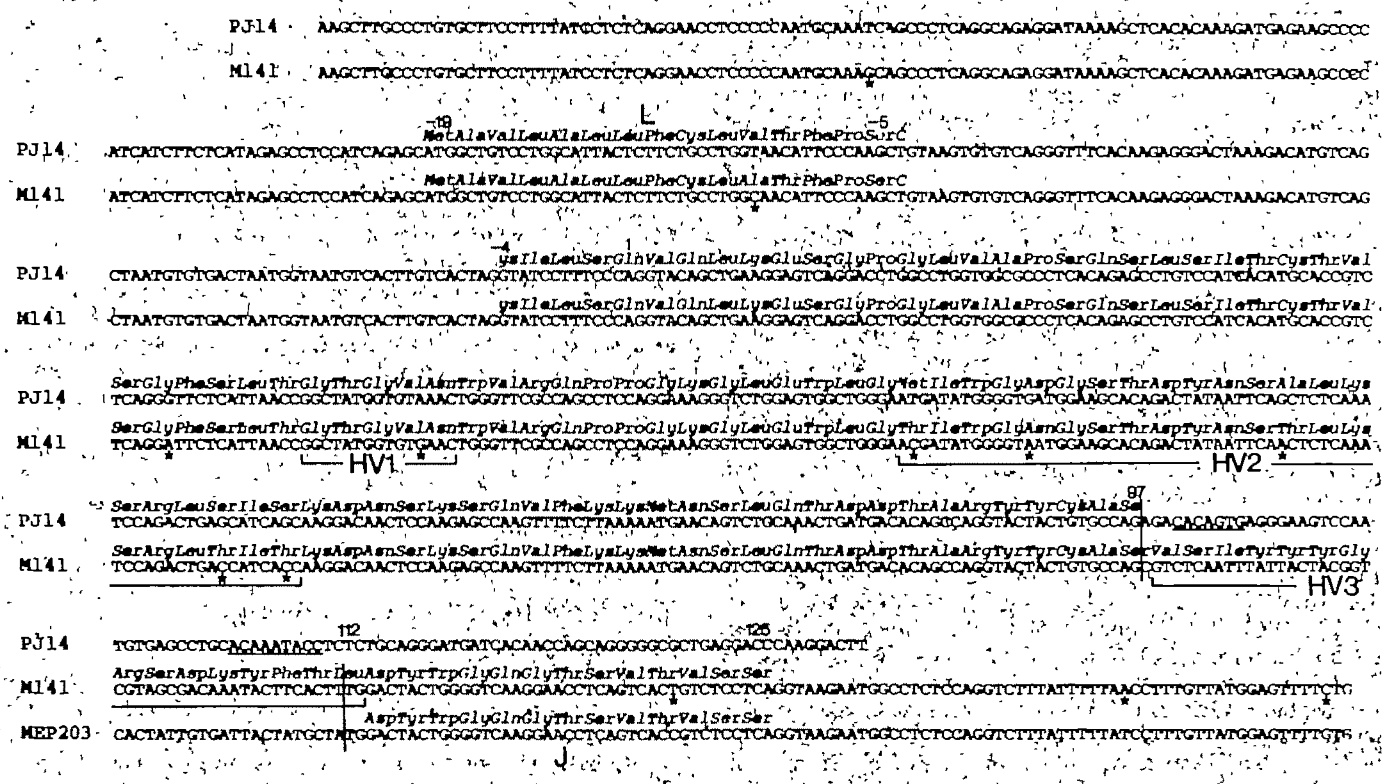

Fig. 2 Nucleotide sequences of MOPC141 V_H DNA (M141), its embryonic V_H DNA (PJ14) and the embryonic J DNA (J_4) coding for the J peptide of the MOPC141 γ2b chain (MEP203). Sequencing strategy is shown in Fig. 3A. Sequence determination was carried out according to the method of Maxam and Gilbert[43]. The amino acid sequence of the complete MOPC141 V region predicted by the nucleotide sequence of clone M141 is shown in italics. The amino acid sequences predicted by the germ-line V DNA segment in clone PJ14 and the J_4 DNA segment in clone MEP203 are also shown. The nucleotide differences observed between the two clones, M141 and PJ14, are shown by asterisks. Vertical lines indicate the possible recombination sites. The two conserved sequences in the 3′-flanking region of the embryonic V DNA are underlined. HV1, HV2 and HV3 designate the three hypervariable regions.

sequences of the two DNA clones differ in 9 base pairs. Of these differences, 6 are within the first and the second hypervariable (HV) regions. Similar, limited, single-base differences have previously been observed in the hypervariable regions of a germ-line V gene and its somatic variants for the light chains of both λ and κ types and were taken as direct evidence for somatic diversification of antibody genes[6]. Three other differences may be a consequence of the similar somatic mechanism or may have occurred during the propagation of the myeloma cells.

Figure 2 also shows the DNA sequence around the J_{M141} DNA segment of the embryonic clone MEP203. As described before, coding begins within the Leu 112 triplet and ends with the Ser 125 triplet. It thus seems that the 14-residue peptide comprising the third hypervariable region (HV3) beginning with Val 98 and ending with Thr 111 is encoded in neither the germ-line V gene nor the J DNA segment. This situation is in contrast to that of light-chain genes previously studied[6–8], in which no such coding gap was observed. We suggest that the third hypervariable region of this heavy chain is encoded in one or more discrete DNA segments (D DNA segments for 'diversity'[27]) that lie elsewhere in the germ-line genome. The V, D and J DNA segments must be assembled by recombination to generate the complete V gene present in the myeloma cells.

The exact joining ends of V and J DNA segments are unfixed

Close examination of the amino acid sequences around the third hypervariable region and the nucleotide sequences around the 3′ end of the germ-line V_H gene and around the 5′ end of the J_H DNA segments suggest several interesting features of the DNA joining events. As previously suggested for the light-chain J DNA segments[7,13–15], the exact 5′ boundary of J_H DNA segments seems to be unfixed (Table 1). For instance, in the case of J_{H4}, the coding of the MOPC141 γ2b chain begins with the second base of the Leu 112 triplet UUG as indicated in Fig. 2. In contrast, coding of the MOPC21 γ1 chain and the MOPC173 γ2a chain by the same J_{H4} DNA segment seems to start with a Tyr triplet UAU and another Tyr triplet UAC, respectively. The first letters of the two Tyr triplets are 7 and 10 bases ahead (5′ side) of the first base used for the coding of the MOPC141 J region. Similar examples for J_{H1}, J_{H2} and J_{H3} are indicated in Fig. 4 and Table 1.

The DNA sequence of the clone PJ14 demonstrated that coding by the germ-line V_{M141} gene ends with the second letter of the Ser 97 codon AGC (Fig. 2). As shown in Table 1, the amino acid sequences immediately preceding Ser 97 are highly conserved among various V regions. Particularly noteworthy is

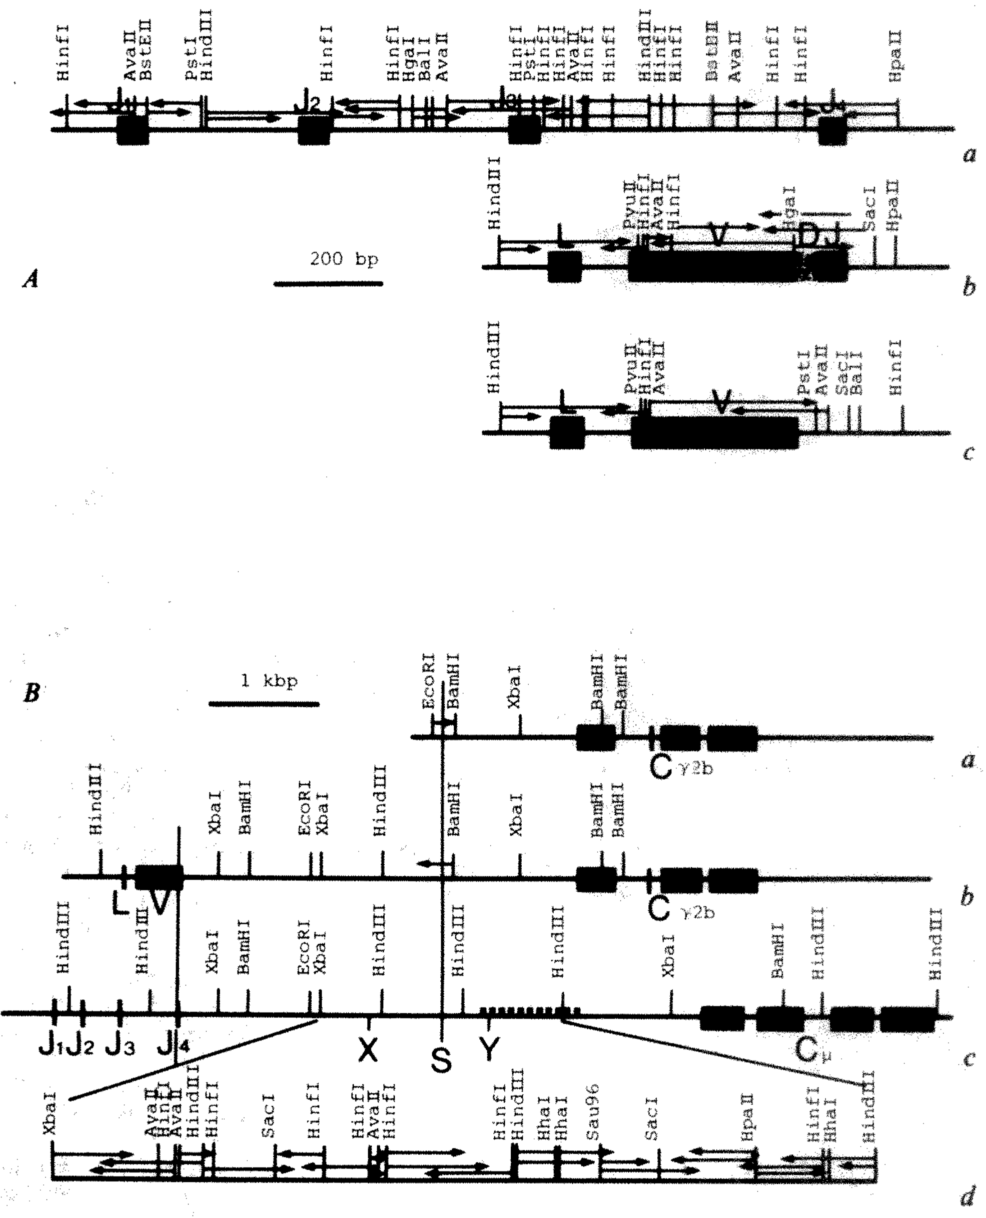

Fig. 3 Restriction enzyme cleavage maps of part of the mouse DNA inserts in clones MEP 203 (*Aa*, *Bc*, *Bd*), MEP3 (*Ba*), M141–P21 (*Ab*, *Bb*) and PJ14 (*Ac*). Cleavage sites were determined by the end-labelling method of Smith and Birnstiel[42], by the separation of single and double digests of DNA fragments by various restriction enzymes, and/or by DNA sequence determination. Horizontal arrows indicate the extent and direction of sequence determination. The filled boxes are exons identified by R-loop mapping and/or DNA sequencing. Vertical line S in *B* indicates the switch recombination sites for MOPC141 heavy-chain genes. X and Y in *Bc* are sequences similar to the Sμ(γ2b) sequence. Four J DNA segments, J_1, J_2, J_3 and J_4, were identified by heteroduplex analysis of rearranged V-gene clones isolated from MOPC603, MOPC315, HOPC8 and MOPC173, respectively. The J DNA segment for MOPC104E was identified as J_1 by R-loop mapping with μmRNA of MOPC104E. The region of clone MEP203, composed of repetitions of CTGAG or sequences closely related to it, is indicated by a broken line in *Bc*. bp, base pairs; kbp, kilobase pairs.

Fig. 4 Nucleotide sequence of the 1.4-kilobase region of the embryonic clone MEP203 containing four J_H DNA segments. The sequencing strategy is shown in Fig. 3*Aa*. The J_H DNA segments are referred to as J_1, J_2, J_3 and J_4 from 5′ to 3′. The amino acid sequences encoded by these J DNA segments are shown in italics. The sequences closely related to the palindromic heptamer, CACTGTG, and present in front of every J DNA segment, are underlined. The vertical lines indicate determined (solid lines) or predicted (broken lines) sites where coding by the J DNA segments begin in the various heavy-chain genes present in the indicated myelomas. The sites were determined by comparing the J DNA sequences with the sequences of the rearranged V DNA cloned from the respective myeloma. (See Fig. 2 for the M141 γ2b chain gene. The others are based on unpublished sequence data.) We have identified, isolated and sequenced two rearranged V genes, one from HOPC8 and the other from MOPC173. The V regions encoded by these rearranged V genes are different from the published ones, and are therefore referred to as H8-II and M173-II. It is not clear whether these V genes are part of the active heavy-chain genes of the respective myelomas. The putative sites for the heavy-chain genes of S107, M167, M315, A4, J539, M173 and M21 were deduced by comparing the J-peptide amino acid sequence of each heavy chain with the DNA sequence of the corresponding J DNA segment (Table 1).

the universal Cys at position 95. Tyr 93, Tyr 94, Ala 96 and Arg 97 are also well conserved. We therefore believe that the coding by most, if not all, germ-line V genes ends in the immediate vicinity of the 97th triplet. If so, coding gaps of various lengths exist in the majority of the cases listed in Table 1. As suggested above, these residues must be encoded elsewhere in the genome. The gaps in the heavy chains of four myelomas, A4, E109, U61 and A47N, are the shortest: only the first letter of Gly 98 is unaccounted for. Similarly, only several more bases are necessary to code for the HV3 of the J558 α chain. Previous studies on κ-chain genes indicated that the 3′ end of a given germ-line V gene may not be precisely fixed and could shift within a range of several nucleotides[7]. If the same applies to the heavy-chain genes, the heavy chains with shorter HV3, such as those of A4, E109, U61 and J558, could be fully encoded by the respective germ-line V gene and the J DNA segment. It thus seems that in some cases the germ-line V DNA segment directly joins with the J DNA segment, as is the case in the light-chain genes. However, it is also possible that the assembly of the V_H always occurs in two steps, but that in some cases the D segments are very short or do not even contribute to protein encoding at all.

In either case, by modulation of the joining sites and by various combinations of these DNA segments, diversity could be generated in the third hypervariable region of heavy-chain molecules. However, the location and number of the D DNA segments in the germ-line genome are unknown. They may be at the 3′ end of each of the multiple germ-line V genes or clustered between the V DNA segments and the J DNA segments. In either case we assume that the order of the V, D and J DNA segments in the germ-line genome is the same as in the completely assembled V genes, so that successive joining of the three types of DNA segments is possible by the looping-out of the intervening spacers.

Sequence characteristics around the V and J joining sites

We have previously reported that the five Jκ DNA segments and the one Jλ DNA segment are preceded by two blocks of short, conserved sequences: a palindromic hexamer interrupted by an AT base pair at the centre of symmetry, CACTGTG, and a nanomer, GGTTTTTGT (ref. 7). Similar sequences are also present 5′ to all four J_H DNA segments, although deviation from the basic sequences seems to be slightly higher for the J_H segments than for the J_L segments (Table 2). We also reported previously that germ-line Vκ and Vλ DNA clones contain inverted complements of the nanomer and heptamer in the 3′-noncoding regions. As shown in Fig. 2 and summarized in Table 2, the same or similar sequences are also present in the equivalent positions of the germ-line V_{H141} gene clone. Based on the fact that these sequences are highly conserved, we propose that they constitute recognition signals for the putative recombinase. The finding of similar sequences near the heavy-chain gene DNA segments strengthens the validity of this hypothesis.

In the case of J_{H3}, two sequences, CACAATG and CAATGTG, are closely related to the basic heptamer sequence, CACTGTG. Similarly, two sequences, TATTGTG and TACTATG, are present near the 5′ end of J_{H4} (Fig. 4). In these cases it is not clear which of the two sequences constitutes part of the proposed recognition signal.

The presence of the closely related conserved sequences in the corresponding positions of both light- and heavy-chain germ-line V genes and their J DNA segments suggests that all recombination events necessary for the generation of complete, somatic V genes are carried out by the same or a similar mechanism. We predict that the similar recognition sequences are also present on both sides of the D DNA segments.

An additional feature of the conserved signal sequences is the striking regularity in the length of the spacer between the heptamer and the nanomer. As summarized in Table 2, in almost all cases the spacers are 12 or 23 base pairs long. One exception is one of the two alternative cases of J_{H4}, where the spacer is 31 base pairs long. As a DNA double helix completes a turn every 10.4 base pairs[21], the above indicates that the internal boundaries of the heptamer and the nanomer of a given DNA segment are orientated in nearly the same direction relative to the axis of the helix, regardless of the length of the spacer. The spacers of all $V\kappa$ segments correspond to one turn, and those of $V\lambda_I$ and $V\lambda_{II}$ to two turns. The spacer of V_{M141} is two turns long. All $J\kappa$ spacers are two turns whereas the $J\lambda_I$ spacer is one turn. All spacers of the four J_H segments are two turns. The 31-base pair spacer, one of the two alternative spacers of J_{H4}, could be considered as an exceptional three turns. It should be emphasized that although the lengths of the spacers are conserved in a given type of gene segment, their sequences have diverged widely.

A model of the joining enzymes

The above mentioned features around the joining sites suggest some predictions about the nature of the recombinases. In both λ and κ light-chain V–J joinings, one partner in the recombination displays the heptamer and nanomer one turn of the helix apart from the recombinase, and the other displays these sequences two turns apart. We predict that the recombinase contains two DNA-binding proteins: one recognizing the heptamer and nanomer one turn apart, and the other recognizing them two turns apart. As the two partners carry essentially identical recognition sequences, the two DNA-binding proteins would be structurally closely related.

The germ-line V_{M141} gene and all J_H segments show the recognition sequences separated by two-turn spacers. If the D segment contains recognition sequences with one-turn spacers on each side, then V–D and D–J joinings would be mediated by recombinases having components equivalent to those acting on the light-chain genes. In this way, all recombinations leading to the assembly of immunoglobulin V genes would follow a one-turn/two-turn spacer rule.

The two recombinase components hold the two recombining partners together and cut and rejoin the strands in the vicinity of the heptamers. As the recognition sequences of one partner are complementary to those of the other, it is possible that intrastrand base pairing occurs, however transiently, in the enzyme–DNA complex and facilitates the ligation reaction.

This rule prohibits some unwanted recombinations, such as those between $V\lambda$ and $J\kappa$, and $V\kappa$ and $J\lambda$. However, some other unwanted recombinations, such as those between V_H and $J\lambda$, D and $J\kappa$, and $V\lambda$ and $V\kappa$, could occur. This may be the reason that the three gene families are distributed in three different chromosomes.

Table 2 The two conserved blocks of sequences near the V–J or V–D–J joining sites

Two blocks of conserved sequences found in the 5′-flanking region of J DNA segments and in the 3′-flanking region of embryonic V DNA segments are compared. The numbers between the two types of sequences indicate the distance between them in base pairs. The bases different from those of the basic sequences in the corresponding positions are underlined. The refs from which the sequences were taken are listed (* this paper; † G. Heinrich, personal communication).

The switch recombination sites for the complete γ2b gene of MOPC141

Our previous electron microscopic studies[19] demonstrated that the complete γ2b gene clone M141–P21 shows some homology to the germ-line Cμ gene clone MEP203 and some to the germ-line Cγ2b gene clone MEP3. As shown in Fig. 1, the homology between clone M141–P21 and MEP203 is 2.4 kilobases long and extends, on M141–P21, from the 3′ end of the V DNA segment to a site 1.2 kilobases 5′ to the Cγ2b gene, and, on MEP203, from the J_4 DNA segment to a site 2.5 kilobases 5′ to the Cμ gene. The remaining part of the 3.6-kilobase V–Cγ2b intron of the complete γ2b gene and the sequence that follows this part are entirely homologous to the germ-line Cγ2b gene clone. The restriction enzyme maps of the three DNA clones shown in Fig. 3*B* confirm the results of the electron microscopic studies. Thus, the cleavage sites present in the first 2.2-kilobase portion of the V–Cγ2b intron are also present at the corresponding positions of the germ-line Cμ gene clone, whereas the cleavage sites located in the rest of the intron and the DNA stretch that follows are also found in the corresponding regions of the germ-line Cγ2b gene clone. The maps show that switch recombination occurs between a pair of sites, one located within the 750-base pair *Hin*dIII–*Hin*dIII segment of the germ-line Cμ gene clone and the other within the 200-base pair *Eco*RI–*Bam*HI segment of the germ-line $C\gamma_{2b}$ gene clone, and generates the 650-base pair *Hin*dIII–*Bam*HI segment present in the complete γ2b gene clone (see Fig. 3*B*).

To understand this novel somatic event better, we determined the nucleotide sequences around the switch recombination sites (Fig. 5*a*). As expected, the 5′ portion of the M141–P21 sequence is the same as the sequence of the germ-line Cμ gene clone, MEP203, whereas the 3′ portion is identical to the sequence of the germ-line Cγ2b gene clone, MEP3. The exact μ–γ2b switch recombination sites are indicated by a vertical line in Fig. 5*a*. We propose to refer to the μ–γ2b switch sites on the germ-line Cμ gene and the germ-line Cγ2b gene as Sμ(γ2b) and Sγ2b(μ), respectively.

Sequences around the μ–γ2b switch sites

Are there any characteristic sequences around the μ–γ2b switch sites that might be considered as part of the recognition signal for the recombinase? As shown in Fig. 5*a*, two short blocks of sequences, $\begin{matrix}\text{TCCTGG}\\ \text{AGGACC}\end{matrix}$ and $\begin{matrix}\text{AGA}\\ \text{TCT}\end{matrix}$, present in front of (towards the 5′ side of) Sμ(γ2b) are also present near the Sγ2b(μ) site in the equivalent positions. The two sets of sequences are in the same orientation relative to the direction of transcription, and thus, differ from those sequences conserved near the V–J joining sites not only in the sequence content but also in the relative

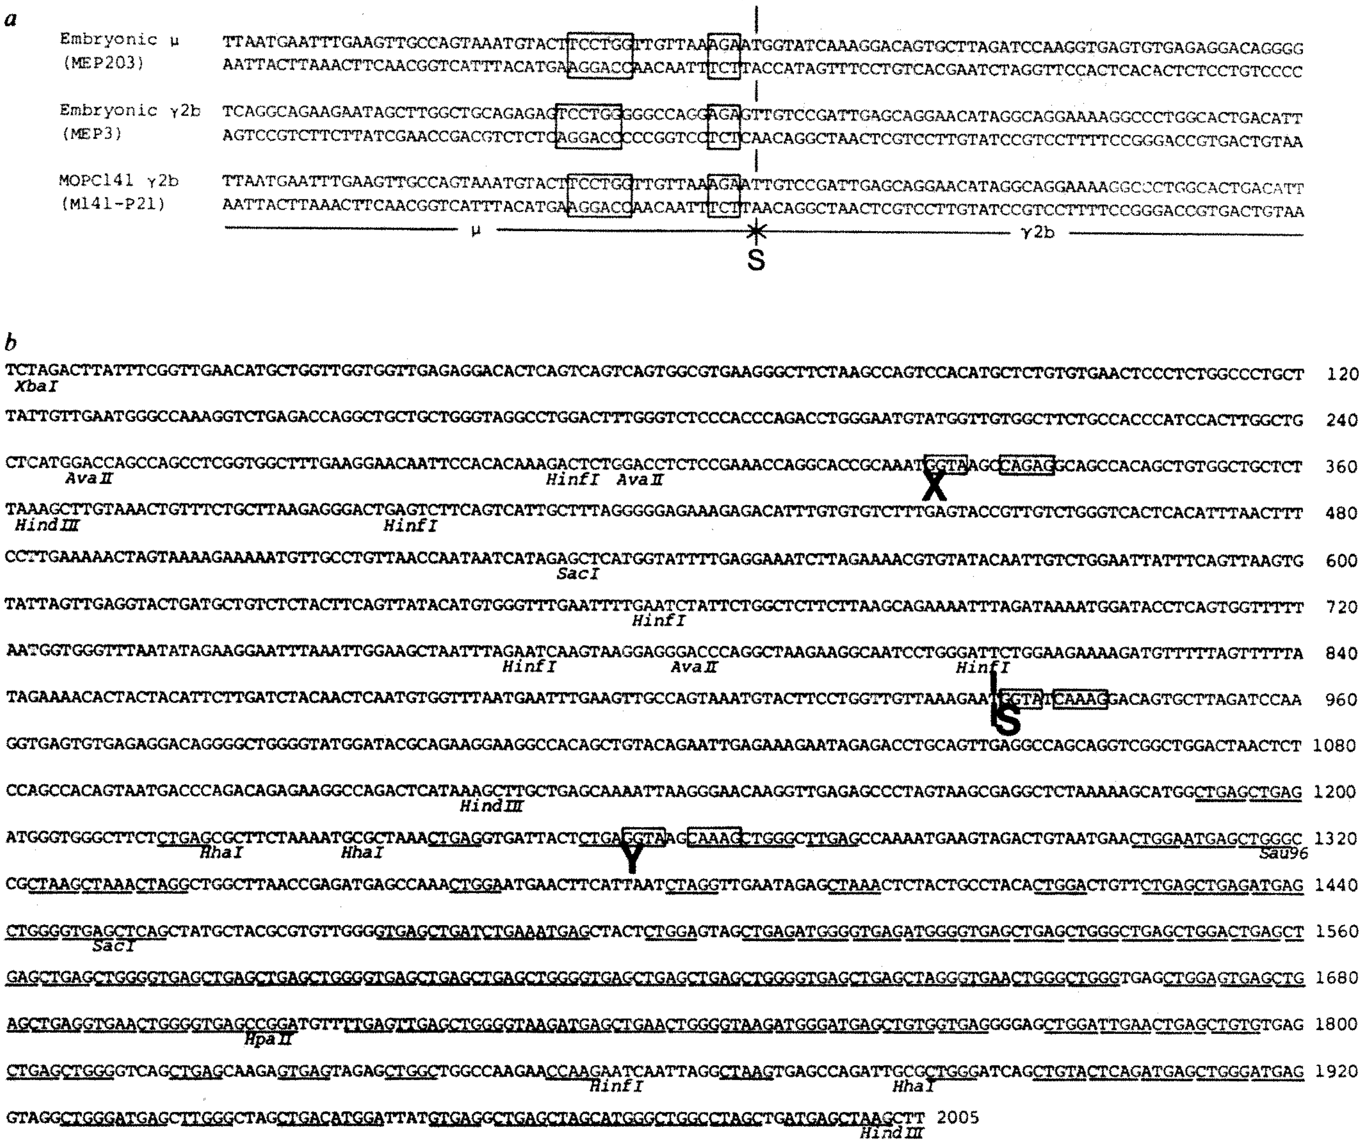

Fig. 5 *a*, Nucleotide sequences around the μ(γ2b) switch recombination sites in clones MEP203, MEP3 and M141–P21. Sequencing strategy is shown in Fig. 3*B*. The recombination sites are indicated by the vertical line designated by S. The two blocks of sequences commonly present in the 5′ side of the recombination sites of the embryonic μ and γ2b gene clones are in boxes. *b*, The nucleotide sequence of 5′-flanking region of Cμ DNA surrounding the switch recombination site for M141 γ2b gene. The 1.8-kilobase *Xba*I–*Hin*dIII segment (Fig. 3*Bd*) was sequenced according to the strategy shown in Fig. 3*Bd*. Two regions (X and Y) homologous to the M141 γ2b switch site (S) are indicated and common sequences GGTA and CAPuG are in boxes. Pentameric sequence CTGAG or its related sequences are underlined.

orientation. Although it is not clear whether these sequences are indeed recognized by the recombinase, the results suggest that the enzymatic mechanism for the μ–γ2b switch recombination is quite different from that for V–J joining.

Sequences of the 5′-flanking region of the germ-line Cμ gene

Recently, Davis *et al.*[20] isolated a complete α heavy-chain gene clone from MOPC603 that carries both V_H and Cα genes. Heteroduplex analysis of this clone against the germ-line Cα and Cμ gene clones suggested that the complete α heavy-chain gene is also generated by a switch recombination that involves the 5′-flanking region of the germ-line Cμ gene. The Sμ(α) site was mapped between the two *Hin*dIII sites at 2.2 and 1.3 kilobases, respectively, from the Cμ gene (see Fig. 3*Bc*). Thus, the μ–α and μ–γ2b switch recombinations seem to use different sites in the 5′-flanking region of the germ-line Cμ gene. This suggests that there may be several different switch sites in this region, possibly one at least for each of the six heavy-chain classes or subclasses, with the possible exception of the δ chain. (The behaviour of B cells suggests that μ–δ switches probably do not occur[29,30].)

We therefore extensively sequenced the 5′-noncoding region of the germ-line Cμ gene clone, MEP203. Fig. 3*Bd* shows the restriction map of the 2.2-kilobase region preceding the Cμ gene, and its complete nucleotide sequence is shown in Fig. 5*b*. We searched for sequences that had a resemblance to those found near the Sμ(γ2b) site and found two, which are referred to as X and Y and are located, respectively, around 0.6 kilobases upstream and 0.3 kilobases downstream of the Sμ(γ2b) site (Fig 5*b*). All three sequences share a tetranucleotide, GGTA, and a pentanucleotide, CAPuAG. However, the two sequences, TCCTGG and AGA, commonly present in the regions 5′ to the Sμ(γ2b) and Sγ2b(μ) sites, are absent in the vicinities of X and Y. It is premature to predict that X and Y are indicative of switch recombination sites. Cloning and sequence analysis of complete heavy-chain genes of various classes and subclasses will clarify the matter. (Recently, we learned that the Y sequence is indeed used for the recombination of the γ1 gene sequenced by Kataoka *et al.*[21] (N. Takahashi and T. Honjo, personal communication).)

In the 0.8-kilobase region extending from the 5′ side of the Y sequence to the *Hin*dIII site, a pentameric sequence, CTGAG, or its close variants are repeated in tandem. As the Sμ(α) site reported by Davis *et al.*[20] falls within this region, involvement of the repeated sequence in the μ–α switch recombination can be invoked. Indeed, our recent DNA sequencing study on the germ-line Cα gene clone indicates that the same pentameric sequences are prominent in the region where the Cα(μ) site had been mapped by Davis *et al.* (H.S., unpublished observations).

Clone MEP203 carries a deletion of about 3 kilobases which seems to have occurred during the cloning or subsequent propagation of the clone in *Escherichia coli.* Restriction enzyme maps of several independent Cμ gene clones isolated by our laboratory and another laboratory[20] suggest that most clones carry deletions of various lengths that map between the two *Hin*dIII sites surrounding the Y sequence. As shown in Fig. 5*b*, this is the region where the pentameric sequences are repeated. Our recent DNA sequencing studies on two independent Cμ gene clones carrying different deletions confirmed that these deletions occur within the pentamer-rich regions.

The two types of somatic recombination

The present studies deal with two types of somatic recombination required for the generation of complete heavy-chain genes, namely V–D–J or V–J joining and switch recombination. The two types of recombination are clearly different in several aspects, although they both occur somatically during lymphocyte differentiation. Although V–D–J or V–J joining should precede the synthesis of the free μ chain detected in pre-B cells[31], switch recombination almost certainly occurs after these cells mature to small B cells bearing complete IgM molecules on the cell surface. V–D–J or V–J joining takes place at the margins of two protein-encoding DNA segments and generates complete V genes. In contrast, switch recombination occurs in the sequences located away from the protein-encoding DNA segments and in effect replaces the Cμ exons of the complete μ-chain gene with exons coding for the C regions of other heavy-chain classes or sub-classes, except, perhaps, for the δ class.

In V–D–J or V–J joining, the recombinant DNAs are to be translated in the recombined regions. This imposes certain restrictions on the precise cutting and joining sites because the encoded polypeptide chains would have to fold properly to be able to function as immunoglobulin subunits. Indeed, this type of recombination seems to occur within a short (several base pairs) region adjacent to the conserved palindromic heptamer present at the margin of every V and J DNA segment studied to date. However, the recombination site does not seem to be unique in a given gene segment and this flexibility, however limited, seems to have been exploited during evolution to increase the genetic capacity of the organism's antibody repertoire. Switch recombination can *a priori* occur anywhere within the 7.5-kilobase intron separating the J DNA segments and the Cμ exons, and anywhere within a several-kilobase region located 5′ to the respective C exon of other classes, as long as the transcription unit on the recombined DNA can encompass the V and C exons and the transcript can be processed properly to the mature mRNA. This suggests that switch recombination sites may be scattered widely in these regions. Indeed, the Sμ(γ2b) site for the MOPC141 γ2b chain and the Sμ(α) site for the MOPC603 α chain are at least 500 base pairs apart. Furthermore, our recent studies demonstrated that in the *Eco*RI digests of various myeloma DNA, the sizes of the DNA fragments detected by the 3-kilobase *Xba*I–*Xba*I fragment carrying the switch region (see Fig. 3*Bc*) are diverse, even among those myelomas secreting the heavy chains of the same class or subclass (R.M., unpublished observations). This suggests that one or both switch recombination sites are not class or subclass specific.

We previously proposed that the V–J joining can be considered as a reversal of an ancient, accidental insertion of an IS-like DNA element carrying invertedly repeated sequences at the margins[7]. In contrast, the evolution of immunoglobulin chains suggests that the C exons of various heavy-chain classes or subclasses arose by duplication of ancient Cμ exons and their flanking sequences[44]. The switch recombination sites have probably arisen from these duplicated flanking sequences by making use of the sequence homology among them. Whether the switch to various classes or subclasses is actively controlled at the level of the DNA recombinations remains to be determined.

Early *et al.*[33] have independently reported the analysis of M603 α heavy-chain V DNA and its germ-line V DNA and J DNA. They found that the 18-base pair D DNA segment in M603 V DNA is not accounted for by either germ-line V DNA or J DNA. They also identified two heavy-chain J DNAs by nucleotide sequencing that correspond to our J_{H1} and J_{H2}. Our determined or predicted joining sites on J_{H1} DNA for M603, M167 and S107 heavy-chain genes are in agreement with their direct sequencing of cDNAs for heavy-chain mRNAs prepared from respective myelomas.

We thank Dr Michael Potter for myelomas and Ms L. Sultzman, Mr G. Dastoornikoo, Ms L. Gibson, Mrs P. Riegert and Mr A. Traunecker for technical assistance.

The cDNA for the β-subunit of human chorionic gonadotropin suggests evolution of a gene by readthrough into the 3′-untranslated region

John C. Fiddes & Howard M. Goodman

Howard Hughes Medical Institute Laboratory, Department of Biochemistry and Biophysics,
University of California, San Francisco, California 94143

A 579-base pair approximately full-length cDNA which codes for the 145-amino acid long β-subunit of human chorionic gonadotropin (HCG) has been cloned in the plasmid vector pBR322 and its complete nucleotide sequence determined. A hydrophobic presequence of 20 amino acids can be identified from the nucleotide sequence. The amino acid sequence of the β-subunit is known to be related to those of the β-subunits of the other glycoprotein hormones LH, FSH and TSH, but the β-subunit of HCG is unique in that it contains a C-terminal extension of about 30 amino acids which has no homologous counterpart in the other three hormones. Analysis of the βHCG cDNA nucleotide sequence suggests that this extension may have arisen by the loss of the termination codon of an ancestral β-like gene so that most of what was previously the 3′-untranslated region now codes for protein. The β-subunit of HCG terminates with the codon UAA located 16 bases before the poly(A) in the sequence AAUAAA. This sequence is believed to be a recognition signal involved in either polyadenylation or processing and therefore has a dual role in this gene, serving both a coding and a regulatory function.

HUMAN chorionic gonadotropin (HCG) is a member of a group of four glycoprotein hormones which are functionally and structurally related. The other three hormones in the group, luteinizing hormone (LH), follicle-stimulating hormone (FSH) and thyroid-stimulating hormone (TSH), are synthesized in the anterior pituitary, whereas chorionic gonadotropin is synthesized in large amounts by the placenta. The level of HCG reaches a maximum about 10–12 weeks after conception and declines towards the end of pregnancy. The hormone functions to stimulate the corpus luteum to produce steroid hormones which are essential for the maintenance of pregnancy (for reviews see refs 1, 2). An antigen which is immunologically similar to HCG is also produced by many tumour tissues and transformed cell lines[3] as well as by certain bacterial strains[4].

All four hormones are glycosylated and consist of an α- and a β-subunit[5]. The same α-subunit is common to all four hormones and in the case of humans is 92 amino acids long[6–11], whereas the β-subunits have sequences unique to each hormone and confer biological specificity.

Comparison of the β-subunits reveals that they are all related. In the human the β-subunits of HCG, LH, FSH and TSH are 145, 115, 118 and 112 amino acids long, respectively[7,12–16]. The β-subunit of HCG is thus about 30 amino acids longer than those of the other three hormones. The highest level of homology observed (82%) is between the β-subunits of HCG and LH, the homologies between all other pairs of β-subunits ranging from about 30 to 40%. Alignment of the β-subunit amino acid sequences shows that the extra 30 amino acids of the HCG β-subunit form a C-terminal extension that is unique to HCG and thus has no homologous counterpart in the other three β-subunits.[7] The function of this extension is not known.

We have described previously the isolation by cloning in the plasmid vector pBR322 of a 621-base pair cDNA fragment, synthesized from first trimester placental mRNA, which codes for the entire α-subunit[17]. The results obtained when this cDNA fragment is used to hybridize to human genomic DNA digested with various restriction enzymes imply that the α-subunit is coded for by a single gene (ref. 17 and unpublished results).

The present report describes the isolation, also from first trimester placental mRNA, of a 579-base pair cDNA fragment which codes for the 145 amino acids of the β-subunit of HCG and for a previously unknown 20 amino acid-long presequence. Examination of the sequence of the β HCG cDNA reveals that the C-terminal extension has probably arisen by the loss of a termination codon in an ancestral β-like gene so that the 3′-untranslated region now codes for amino acids. The sequence AAUAAA (ref. 18) in the β-subunit of HCG has the dual function of containing the termination codon (UAA) of the gene and a possible recognition site for polyadenylation or processing of the mRNA.

Cloning of the cDNA for the β-subunit of HCG

First trimester placental polyadenylated RNA has been shown previously[17,19–22] by *in vitro* translation and immunoprecipitation of the products to be an enriched source of the mRNAs coding for both subunits of HCG. However, there seems to be an excess of α over β mRNA; this finding correlates with the excess of free α-subunit polypeptide over the β-subunit in the placenta[23].

The cDNA for the α-subunit of HCG was identified previously on the basis of restriction enzyme analysis. Total first trimester placental cDNA was digested with a variety of restriction endonucleases and the products were visualized by electrophoresis on 5% polyacrylamide gels. Prominent restriction enzyme fragments were observed and it was assumed that these arose by digestion of the major cDNA species, the α-subunit of HCG. Recombinant plasmids were therefore screened by restriction enzyme digestion of their DNA and those containing fragments which corresponded in size to those observed in total cDNA were considered potential α HCG recombinants. Sequence analysis confirmed the identity of one such recombinant.

This approach, however, has the disadvantage that there is no positive correlation between prominent restriction enzyme fragments and a particular mRNA species until DNA sequences have been determined. Potential recombinants for the β HCG cDNA were, in fact, isolated in this way but were found by sequencing not to code for the β-subunit.

A more direct approach is to use the known amino acid sequence of a protein to predict the existence of a restriction enzyme site in the gene. Most restriction enzymes do not have recognition sequences which are uniquely determined by certain

0028-0836/80/330684—04$01.00

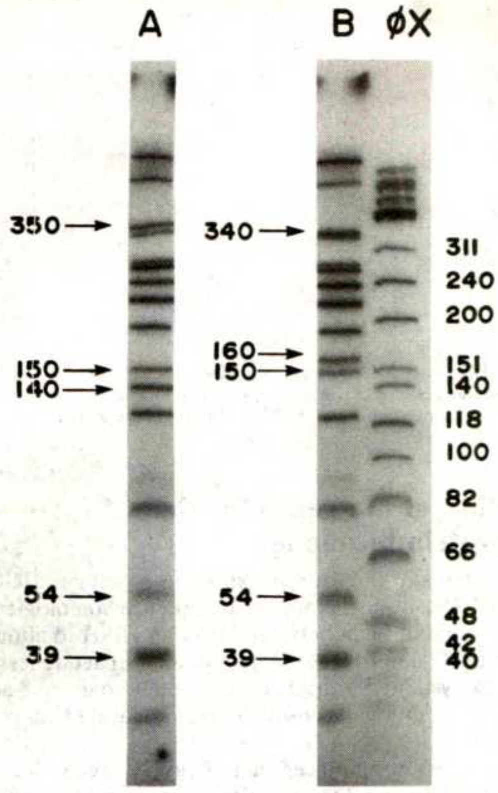

Fig. 1 Restriction enzyme analysis with *Sau*96I of the two recombinants between pBR322 and the cDNA of the β-subunit of HCG. The recombinants were obtained from first trimster placental cDNA in the size range of 500–700 base pairs using the approach of adding synthetic *Hin*dIII oligonucleotide linkers to the cDNA. Experimental details were as described previously[17] with the exception that strain RRI was used in place of χ1776. All experiments conformed with the NIH Guidelines for Recombinant DNA Research. Overnight cultures in L broth (3 ml each) were grown for 72 recombinants and the cells were pelleted. Cleared lysates were made using lysozyme, EDTA and Triton[48] and were dialysed extensively against 0.3 M NaCl, 10 mM Tris-Cl, *p*H 8.0, and 1 mM EDTA before precipation with ethanol. Each plasmid DNA preparation was then resuspended in 10 µl H_2O and 1 µl of the DNA was digested at 37 °C for 30 min with 1 unit of *Sau*96I (Biolabs) in a 5 µl reaction containing 50 mM NaCl, 6 mM Tris-Cl, *p*H 7.5, 6 mM $MgCl_2$ and 1 mM dithiothreitol. The sample was then used directly to resuspend 1 µCi of [α-^{32}P]dGTP which had been evaporated to dryness and 0.5 units of DNA polymerase I (Klenow modification) were added before incubation at room temperature for 15 min (ref. 26). The sample was then electrophoresed directly on a 0.3-mm thick 5% polyacrylamide gel until the bromphenol blue marker dye was about 5 cm from the bottom of the gel. The gel was then soaked for 15 min in 10% acetic acid to elute free [α-^{32}P]dGTP and was exposed overnight to X-omat R film at −70° C with an intensifying screen. Lanes A and B show autoradiographs of the *Sau*96I digests of the two pBR322–β HCG recombinants. The sizes of the fragments corresponding to the β HCG cDNA are indicated (see text). The third lane is a *Hin*fI digest of ΦX174 RF DNA used as size markers.

amino acid pairs, but two enzymes, *Asu*I (ref. 24) and *Sau*96I (ref. 25), are particularly useful because they recognize the sequence GGNCC. As glycine is coded for by the four codons GGN and proline by the four codons CCN, every Gly-Pro dipeptide must be represented by an *Sau*96I site in the corresponding gene. Other groups of amino acids may also be coded for by sequences containing *Sau*96I sites, as the sequence GGNCC may be translated in two other reading frames.

As there are Gly-Pro dipeptides at positions 102 and 103 and positions 136 and 137 in the β-subunit of HCG[7,12,13], the corresponding gene must have *Sau*96I sites 102 base pairs apart. Within this 102 base pairs of DNA, at amino acid positions 104–106 and 122–124, are the sequences Lys-Asp-His and Lys-Ala-Pro, respectively, which, with the appropriate codon choice, would also correspond to *Sau*96I sites. These restriction enzyme sites would result in the 102-base pair fragment being divided into pieces 9, 54 and 39 base pairs long.

Double-stranded cDNA was synthesized from first trimester placental RNA as described before (ref. 17 and Fig. 1 legend) and fragments in the size range of 500–700 base pairs were recovered from a preparative 5% polyacrylamide gel and cloned into the unique *Hin*dIII site of pBR322. Small-scale DNA preparations were made from 72 such recombinants and the DNAs digested with *Sau*96I. The resulting DNA fragments from the recombinant plasmids were labelled at their termini with [α-^{32}P]dGTP using DNA polymerase I (ref. 26 and Fig. 1) and analysed on 5% polyacrylamide gels.

Two of the recombinants were observed to have *Sau*96I fragments 54 and 39 base pairs long (Fig. 1) and were thus considered potential β HCG clones. The 9-base pair fragment would not be observed on a 5% polyacrylamide gel. In addition to these fragments, a 150-base pair fragment is common to both recombinants. A fragment of this size is compatible with the amino acid sequence for the β-subunit of HCG, as the sequence Pro-Ala-Leu at positions 50–52 could be coded for by a nucleotide sequence containing *Sau*96I site, which is about 150 bases from the *Sau*96I site corresponding to the Gly-Pro dipeptide at positions 102–103.

The other *Sau*96I fragments, 350 and 140 base pairs long in the case of A and 340 and 160 in the case of B, were shown by combined *Hin*dIII and *Sau*96I digestion (data not shown) to be terminal fragments containing pBR322 sequences in addition to cloned sequences. The two recombinants were thus considered potential candidates for containing β HCG cDNA sequences and seem to represent slightly different lengths of copying of the same mRNA species.

DNA sequence analysis of the β HCG cDNA

Both potential β HCG recombinants were positively identified by DNA sequence analysis. The plasmid DNAs were digested with *Hin*dIII, labelled with polynucleotide kinase and [γ-^{32}P]ATP, and the 5′-terminal *Hin*dIII–*Sau*96I fragments sequenced. Subsequently, the complete sequence of recombinant A, which is about 10–20 nucleotides longer than B at the 5′ end, was determined. Both the chemical method of Maxam and Gilbert[27] and the chain-termination method of Maat and Smith[28] were used, because both methods used the same 5′-terminally labelled double-stranded DNA fragments. The sequence was determined on both strands of the DNA to ensure accuracy.

The complete sequence of recombinant A, designated pBR322-cβHCG, is presented in Fig. 2. The cDNA is 579-base pairs long, of which 40 represent the poly(A) sequence. All 145 codons which correspond exactly to known amino acid sequence of β HCG can be identified[7,12,13].

A hydrophobic presequence of 18–29 amino acids, which is processed to generate the mature polypeptide, is observed in secretory proteins (see ref. 29 for a compilation of presequences). The α-subunit of HCG has a 24 amino acid-long presequence[17,30], but no information is available on the presequence of the β-subunit. If the sequence preceding the serine codon at position 1 in β HCG is read in triplets towards the 5′ end, potential ATG initiation codons are observed at positions −18 and −20 (see Fig. 2). No other ATG codons are observed between this position and the 5′ end of the cloned cDNA in this or the other two reading frames. It has been proposed, on the basis of examining the 5′-untranslated sequences of 22 eukaryotic mRNA species, that the initiator methionine codon is the AUG located closest to the 5′ end of the mRNA[31]. Two exceptions to this rule have been observed with the mRNAs for the VP1 in the virus SV40[32,33] and for bovine preproparathyroid hormone[34], but in both cases it has been proposed that the AUG triplet in the 5′-untranslated region is masked by secondary structure. The β-subunit of HCG can thus be predicted to have a presequence 20 amino acids long, but the existence of a larger presequence (greater than 28 amino acids long) cannot be definitely ruled out because there are no termination codons in phase in the part of the 5′ untranslated region which has been cloned. Characteristically, the presequence of β HCG is hydrophobic, with the somewhat unusual structure of seven consecutive leucine residues at positions −8 to −14.

The nucleotide sequence of the β HCG cDNA has a very high G+C content (G 28.0%, C 38.0%, A 16.3%, T 17.6%) when compared with total human DNA (G 19.5%, C 19.8%, A 30.9%, T 29.6%). A similar bias towards a high G + C content is also observed in the human cDNAs for insulin^{35} and chorionic somatomammotropin (ref. 36 and E. Tischer, J.C.F. and H.M.G., unpublished data), but is not so noticeable in growth hormone^{37}, the α-subunit of HCG^{17} or β-globin$^{38-40}$.

Consistent with the high G+C content of β HCG cDNA is the very considerable bias towards codons ending in G or C (G 31.9%, C 50.6%, A 7.2%, T 10.2%). A compilation of the nucleotides present in the third codon position of the known human cDNA sequences is given in Fig. 3. The high incidence of codons ending in G and C seems to be a common feature of human genes even with growth hormone, β-globin and α HCG, which do not have a marked overall high level of G and C. These data are consistent with the observation^{41} that codon choice is species specific and, if this has a role in modulating translation, may present difficulties in obtaining high levels of expression of human genes in other cell types.

Fig. 2 Nucleotide sequence of the 579-base pair cDNA fragment coding for the β-subunit of HCG. The amino acid sequence of the 145-amino acid long protein^{7,12,13} is shown as well as the 20-amino acid long presequence deduced from the nucleotide sequence. Nucleotides are numbered below the sequence and amino acids above the sequence. Only those restriction enzyme sites used in the sequence analysis are indicated. The AAUAAA sequence at the 3′ end of the coding region is marked.

cDNA	Base A	T	G	C
hαCG	25	28	29	35
hβCG	12	17	53	84
hGH	31	29	65	93
hCS	17	17	60	75
hInsulin	14	8	43	45
hβGlobin	10	40	53	45

Fig. 3 Frequency of third position codon choices in the known human cDNA sequences; β HCG, α HCG^{17}, growth hormone (HGH)^{37}, chorionic somatomammotropin (HCS)^{36}, insulin^{35} and β-globin$^{37-39}$.

Evolution of the genes for the glycoprotein hormones

The β-subunits of the four glycoprotein hormones HCG, LH, FSH and TSH all show amino acid sequence homologies which range from about 30% between HCG and FSH to about 80% between HCG and LH. Alignment of all four sequences shows that the 12 cysteine residues are completely conserved and that there is an additional conserved region located at positions 34–38 in β HCG.

A much less pronounced homology between the α- and β-subunits of bovine TSH has also been proposed by Pierce^{42}, leading to the suggestion that all glycoprotein hormones genes evolved from a common ancester which subsequently diverged to generate α and β sequences. This amino acid sequence homology can also be detected between α and β HCG and is presented in Fig. 4. The alignment used here differs somewhat in the N-terminal region from that proposed from bovine TSH and can now also be extended to include the presequences. Overall, the homology is very low (16% not including the deletions and insertions), but there is still a very noticeable conservation of the cysteine residues, with 6 of the 12 being maintained between the α and β-subunits.

Figure 4 also shows the alignment of the coding nucleotide sequences for the α- and β-subunits of HCG based on the same alignment as used with the amino acid sequences. Overall, the homology level is still very low (31%), but there are certain areas which are considerably more closely related, especially in the regions of the cysteine residues. The observed similarity between the sequences does not merely reflect a similar bias in base composition between the two species, for the base composition of the α cDNA (G 20.0%, C 24.5%, A 26.6%, T 29.0%) is very different from that of the β cDNA (G 28.0%, C 38.0%, A 16.3%, T 17.6%).

The nucleotide sequence data therefore tend to confirm the proposal that the α and β genes are related and thus probably have evolved from a common ancester, as the homology previously detected at the amino acid level is somewhat more apparent when the nucleotide sequences are considered. In this respect, therefore, the glycoprotein hormone genes may be similar to the globin genes, which are also assumed to have evolved from a common precursor^{43} into an α gene and a family of several β-like genes.

Readthrough into the 3′-untranslated region

The 3′-untranslated region of the β HCG mRNA is only 16 bases long and is thus remarkably short when compared with other eukaryotic mRNA species (see Fig. 2). The termination codon UAA is located in the sequence AAUAAA, which is found in the 3′-untranslated regions of all polyadenylated eukaryotic cellular mRNAs^{18} at about 15–20 bases from the poly(A). The lack of this sequence in some non-polyadenylated plant viral mRNAs^{44} led to the proposal that the AAUAAA is involved in the process of polyadenylation[45]. However, there is an exception to this, as the genomic RNAs of several picornoviruses are polyadenylated but do not have the AAUAAA sequence[46]. Thus, it may be that in the case of the cellular mRNAs this sequence acts as a signal in the processing of a larger precursor mRNA molecule as well as being involved in polyadenylation. In β HCG mRNA, this sequence therefore has a dual overlapping function, as it codes for the last codon, CAA (Gln), and for the terminator (UAA), in addition to the proposed regulatory function.

The alignment of the β-subunit amino acid sequences shows that the β-subunit of HCG has a C-terminal extension of about 30 amino acids which has no homologous counterpart in the other three. As the β HCG mRNA has such an unusually short 3′-untranslated region, it can be proposed that the β-subunit of HCG evolved from a common β-subunit ancester by some readthrough event so that the 3′-untranslated sequence became a coding region. This could have arisen by changes such as point or frameshift mutations or by an alteration of the splicing pattern of the precursor mRNA. Verification of this proposal will require sequence analysis of the genes for the other three β-subunits so that homologies between their 3′-untranslated regions and the C-terminal extension of β HCG can be investigated.

A similar observation has also been made with the abnormal human α-haemoglobin Constant Spring, which has a 31-amino acid C-terminal extension when compared with normal α-globin[47]. Sequence analysis of normal human α-globin cDNA showed that the carboxy-terminal amino acids of α-globin Constant Spring could be coded for by the 3′-untranslated region with a termination codon located in the same position as in β HCG[39].

The availability of cloned cDNA sequences for both subunits of HCG should facilitate further investigation of the structure and regulation of the gonadotropin genes. Hybridization probes can be generated to investigate the cellular genes to determine whether any linkage exists between the related genes and to examine the synthesis of HCG in the placenta, transformed cells and, possibly, bacteria.

J.C.F. was the recipient of a postdoctoral fellowship from the Anna Fuller Foundation. H.M.G. is an investigator of the Howard Hughes Medical Institute. The work was supported by grant (no. CA 14026) to H.M.G. We thank H. Martinez and S. Bock for the computer analysis of the DNA sequence, R.A. Hallewell for discussions, J.P. Thirion for assistance in screening some of the cDNA recombinants, members of the Department of Obstetrics and Gynecology at UCSF for assistance in obtaining placental material and B. McCabe for typing the manuscript. Avian myeloblastosis virus reverse transcriptase was from the NCI.

Fig. 4 Alignment of the amino acid and nucleotide sequences of the coding regions of the α (lower lines) and β (upper lines) subunits of HCG. To maximize the homologies, one insertion of five codons, and two deletions of one and six codons have been proposed in the α sequence. The overall sequence homologies are 16.1% and 31.0% for the amino acids and nucleotides, respectively These values do not take into account the deletions and insertions Only the region of the β HCG coding sequence which has a homologous counterpart in the α-subunit (amino acids −20 to 99) is shown

No IR burst from the X-ray rapid burster MXB1730–335

The X-ray rapid burster MXB1730–335, discovered by Lewin *et al.*[1] has been identified with a compact globular cluster embedded in the midst of the galactic plane and named[2] Liller 1. It has an extremely large interstellar extinction ($A_v = 11$ mag) from which Liller[2] and Kleinmann *et al.*[4] derived its distance as 10 kpc. Kulkarni *et al.*[3] detected IR bursts in the globular cluster, six times during their 2.5 h observing time on 4–5 April 1979 using a 1-m telescope at Kavalur[3]. The burst power emitted in *H*-band was estimated to be $1.6\text{–}2.3 \times 10^{30}$ W. Stimulated by this report, we monitored MXB1730–335 using a multi-band IR photometer for about 10 h during April and August 1979. In the latter period, although the X-ray bursts were very active, no coincident IR and X-ray burst could be detected. We show here that this conflicts with previous results by Kulkarni *et al.*[3] and Jones *et al.*[5].

The source was observed on 20–22 April 1979 at *H*-, *K*- and *L*-bands using a multi-colour photometer attached to the 1-m IR telescope at the Agematsu IR Observatory of Kyoto University. During the monitoring time, ~4 h in three days, we could not detect any change of flux exceeding the statistical fluctuations; 2.7×10^{-17} W cm^{-2} μm^{-1} at the *H*-band, 1.8×10^{-17} W cm^{-2} μm^{-1} at the *K*-band and 3×10^{-17} W cm^{-2} μm^{-1} at the *L*-band.

The X-ray satellite HAKUCHO, launched in February 1979, registered a revival of X-ray burst activity from early August 1979. We again attempted to monitor this in the near-IR using the 61-cm telescope of the University of Hawaii on Mauna Kea where we were conducting a deep IR survey in the galactic plane. The observations were performed with a multi-colour photometer built for the survey. The photometer can monitor four colours: *I*(0.82 μm), *H*(1.61 μm), *K*(2.21 μm) and *L*(3.61 μm) bands simultaneously, using beam splitters in conjunction with a Si-photodiode (*I*-band) and three independent InSb photovoltaic detectors (*H*-, *K*- and *L*-bands). The time constant of the lock-in-amplifier was set at 0.3 s. The beam was wobbled in N–S direction with a beam throw of 1.5 arc min at ~10 Hz.

Table 2 Upper limits to the IR flux changes in association with the X-ray burst event at 12 August 06.38.27 (UT)

	Upper limits	
Band	Observed (W cm^{-2} μm^{-1})	Corrected for interstellar extinction (W cm^{-2} μm^{-1})
I (0.82 μm)	1×10^{-17}	1×10^{-15}
H (1.61 μm)	1×10^{-17}	6×10^{-17}
K (2.21 μm)	4×10^{-18}	1×10^{-17}
L (3.61 μm)	2×10^{-17}	3×10^{-17}

No bursts were observed within the statistical fluctuation of the signals in any channel during the observing time of 6 h during 9, 10 and 12 August 1979. The details of the observations in April and August are summarized in Table 1; γ Sgr was chosen as a calibration star.

During the period in August, HAKUCHO was observing X-ray bursts almost every 20 or 30 min (ref. 6). From statistical considerations, therefore, it is improbable that an X-ray burst did not occur during our IR observations which lasted 6 h. However, the observations of HAKUCHO and that of the IR monitoring missed each other most of the time. Only in the following event was an X-ray burst accompanied by an IR observation.

An X-ray burst associated with IR bursts:

Onset time:	06.38.27 UT 12 August 1979
Burst duration:	126 s
X-ray burst flux:	1.3×10^{-15} W cm^{-2} (3–10 keV)

(Observation by HAKUCHO[6])

As the X-ray observation was interrupted, its end time was not observed but this is undoubtedly one of the typical X-ray bursts of the so-called 'trapezoidal' form[6]. Figure 1 shows the IR raw data in *H*- and *K*-bands recorded on strip charts in the corresponding time of the X-ray burst event. The X-ray burst profile is also shown for comparison[6].

We can find no change in the IR flux which is larger than statistical fluctuations before or after the onset of the X-ray burst. The r.m.s. fluctuations of the signals are 7×10^{-17} W cm^{-2} μm^{-1} and 2×10^{-17} W cm^{-2} μm^{-1} for *H*- and *K*-bands, respectively. Slight depressions labelled 'adj' were accidentally caused by the pointing adjustment of the telescope.

To improve the statistics, we integrated the observed fluxes of the source in its steady state before the onset of the burst and during on-burst time, from which upper limits for changes of the flux level can be estimated; the results are given in Table 2

Table 1 Journal of observations

Date (1979)	Time (UT)	Duration (min)	Bands	Beam (arc s)	Observatory

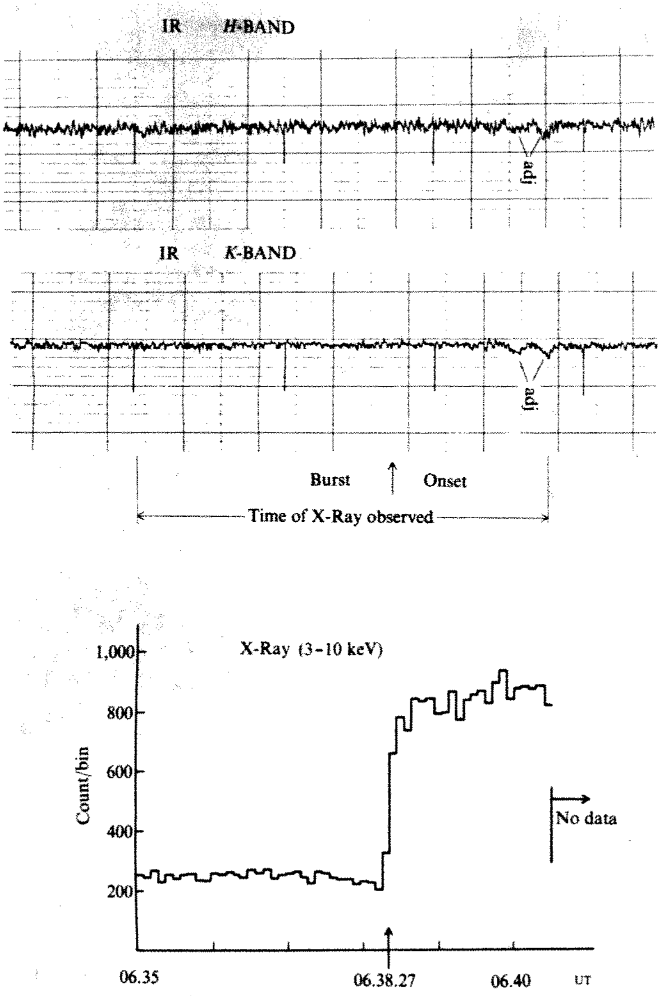

Fig. 1 IR observational data at *H*-and *K*-bands in correspondance with the X-ray burst event on 12 August 1979.

corrected for the interstellar extinction assuming $A_K = 1.1$ mag (ref. 4).

The intrinsic fluxes thus obtained for *K*- and *L*-bands are substantially smaller than the X-ray flux of 1.3×10^{-15} W cm^{-2} (3–10 keV) of the order of 10^{-2}. Assuming a distance of 10 kpc for the source, we estimate the upper limit to the energy release in the IR region to be of the order of 10^{29} W in a band width of 1 μm. This is more than one order of magnitude smaller than that detected by Kulkarni *et al.*[3]. Recently, Jones *et al.*[5] have announced another detection of IR bursts in the globular cluster on 5 September 1979, about a month later than our observations. Its energy release in *K*-band was estimated to be 2.2×10^{30} W, compatible with the previous results obtained by Kulkarni *et al.*[3].

The positive detections by Kulkarni *et al.*[3] and by Jones *et al.*[5] apparently disagree with our negative results. This may be attributable to difference in Types of the X-ray bursts. In fact Kulkarni *et al.* assumed their IR bursts to be associated with Type 1 X-ray bursts, while the X-ray bursts observed by the HAKUCHO were exclusively Type II bursts[6].

The IR bursts so far observed are not accompanied by X-ray data. We need to make simultaneous observations in the X-ray and IR regions for confirmation of their exact concurrence, or their relationship to the burst Type. If they occur simultaneously, the emission should be of nonthermal origin; which means that magnetic field would be strongly coupled with the emission mechanism. Polarimetric observations would give data about such a mechanism and about the energy spectrum.

We thank the HAKUCHO group for their encouragement and collaboration, also Dr J. T. Jefferies, director of the Mauna Kea Observatory, for permission to use the 61-cm telescope on Mauna Kea. Our work at the Mauna Kea Observatory was partly supported by the Asahi Press Science Foundation.

†Hatfield Polytechnic Observatory, Bayfordbury House, Hertford SG13 8LD, UK

We report here the results of a one-year monitoring programme of SS433 at IR and visual wavelengths. The most striking feature of these observations is the near constancy of the IR colours while the source's flux varies over a range of ~1.2 mag. There is no evidence for the 13.1-day period first reported in radial-velocity measurements by Crampton *et al.*[1]. However, it seems possible that an 11.8-day period is present.

SS433 remains an object of great interest because of the presence of enormously Doppler-shifted emission lines swinging back and forth across its spectrum[3–5]. (Suggested models are given in refs 6, 7 and comprehensive reviews of the spectroscopic data in refs 8, 9.) The work reported here is not directly connected with the emission-line phenomena but provides

additional information about the nature of the underlying binary system. The variability of the source has been studied at several wavelengths[2,10-14] and the radial velocity period of 13.1 days first reported by Crampton *et al.*[1] has now also been detected in the Hα line-to-continuum ratios[15]. A spectroscopic modulation of 13 days has also been reported by Liller *et al.*[16].

We have observed SS433 between April 1979 and May 1980 with various instruments, mostly from the Cabezon Observatory, Tenerife, using the 1.5-m IR flux collector. At Tenerife, most of the data were obtained at *VJHK* with the Leicester photometer or Hatfield polarimeter/photometer, which use the same InSb Dewar and photon counting systems. Additional *V* points were obtained at Tenerife with the RGO travelling optical polarimeter/photometer. Further *JHK* data were obtained at the AAT in Australia and at Ukirt in Hawaii. This collection of data has been supplemented with other published data[17,18].

All these data are presented in Tables 1–3 but here we mainly confine our discussion to the more abundant data in Table 1. The *JHK* measurements have been combined to produce Fig. 1 which shows the remarkable constancy of the IR colours. This is just as expected for free–free emission[18-20].

The *J* data in Table 1 have been folded at trial periods in the range 0.1–50 days using the technique of Bopp *et al.*[21] to find the most likely period. This method is appropriate to a small sample of data containing large and irregular gaps in temporal coverage.

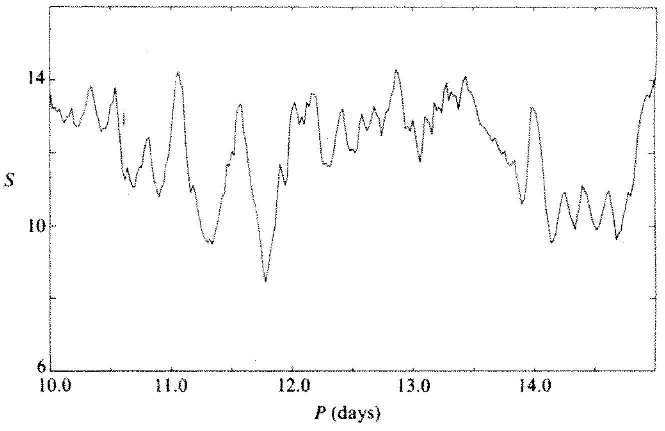

Fig. 2 An analysis of the *J* data for periodicities (Bopp *et al.*[21]). Sharp dips indicate periods of interest and the vertical scale is logarithmic ($S = \Sigma \Delta M$).

The results are shown in Fig. 2, and there is no indication of a 13.1-day period. This may be confirmed by folding the data at this period; no reasonable light curve results.

Originally Giles[22] reported smooth *JHK* light curves for a period of 11.8 ± 0.05 days, possessing two minima, the broader one being used to define the ephemeris

$$1979 \text{ August } 14.26(\pm 0.5)\ \text{UT} + 11.8E$$

This ephemeris was used to predict the occurrence of the possible narrow 'eclipse' feature[22] which was then apparently

confirmed by several subsequent observations at UKIRT in Hawaii. Further points obtained at the AAT in early 1980 also apparently confirm this feature, in phase although the width and depth are undefined and probably variable. The dip around 11.8 days from the Bopp analysis of Fig. 2 naturally produces a reasonable light curve when the data are folded at this period. Figure 3 shows the resulting *J* light curve. The apparent smoothness of this curve is somewhat less than that evident for the first attempt[22] now that more points have been added. SS433 may well have some variability over long time scales in addition to that caused by any binary period modulation.

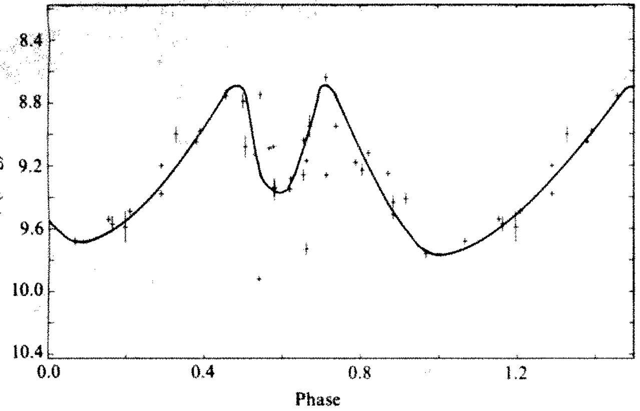

Fig. 3 *J* light curves for the data folded at 11.8 days.

We note that the photometry by Glass (personal communication) agrees with our range of intensity and colour variation but is not entirely consistent with our possible period. Such differences may prove important when a much larger data base is available if they can be related to the 164-day period. It is clearly important that the existence or otherwise of this 11.8-day period should be demonstrated over the coming summer. This will best be achieved by ~3 weeks of complete coverage rather than by folding irregularly spaced short data sets. The limited optical data we have obtained shows no periodicity so we are unable to comment on the 6.45/12.9-day period reported by Kemp *et al.*[23] or the 12.8-day period of Gladyshev *et al.*[24].

Given the unprecedented nature of SS433 it does not seem inconceivable that the source should have two periods, only one or even neither of which is a true orbital period. SS433 will clearly repay further detailed photometric study. Observations of any modulation in the X-ray flux or low-energy cutoff would be of special interest.

We thank D. J. Axon and D. A. Allen for use of their data and I. S. Glass for communicating his results and helpful discussion. We thank the SRC for funding.

Ultrasonic imaging in scanning electron microscopy

G. S. Cargill III*

Cavendish Laboratory, Madingley Road, Cambridge CB3 0HE, UK

A new type of microscopy is described here which uses a focused, modulated electron beam to generate ultrasonic waves at the front surface of a specimen and a piezoelectric transducer to detect these waves at the rear surface. The transducer output is used to form a scanned, magnified image of the specimen. A unique feature of this technique is that image contrast comes primarily from spatial variations in thermal and elastic properties. Images of integrated circuits have been obtained with ~4 μm resolution. In thin film specimens 0.1 μm resolution should be possible.

This mode of ultrasonic imaging in scanning electron microscopy is called electron-acoustic microscopy in analogy with photoacoustic microscopy[1–5] in which a laser is similarly used to generate acoustic or ultrasonic waves by thermoelastic expansion. An advantage of electron-acoustic microscopy is that the electron beam can be focused to a much smaller spot than is possible with visible light; and with proper attention to problems of electron beam spreading within the specimen, this can lead to improved spatial resolution. Although the present experiments have used 6 MHz beam chopping and 1 μm spot size, GHz chopping[6] could be used with a more finely focused electron beam to obtain ~0.1 μm resolution in thin film specimens. Only slight modifications to a commercial scanning electron microscope are needed to chop the electron beam at MHz rates. Secondary electron images can be recorded as well as electron-acoustic images, permitting easy comparisons of microscopic features revealed by the two different techniques. Electron-acoustic images can be viewed at normal SEM scan rates.

Table 1 Contributions of beam spreading d_S and of thermal diffusion d_T to the effective source diameter D*

	Au	Cu	Al	Si
d_S	0.7	1.4	4.8	5.5
d_T	2.5	2.5	2.1	1.6
D	2.8	3.0	5.3	5.8

* A 30 keV incident electron beam of diameter $d_B = 1$ μm is chopped at $\omega/2\pi = 6$MHz for thick specimens of Au, Cu, Al, and Si. All values are given in micrometres.

Major components of the electron-acoustic microscope are indicated in Fig. 1. Electrostatic deflection plates were located below the second condenser lens of a Stereoscan S4-10 SEM. Sinusoidal and d.c. voltages on the deflection plates were adjusted to produce square-wave beam current. Lenses were adjusted for maximum peak current at the specimen, typically 10 μA, with a 1.2 mm final aperture and 30 kV accelerating voltage. In most cases a 12 mm diameter, x-cut quartz 6-MHz transducer crystal was bonded with 'Durofix' cement to the bottom surface of a threaded metal plug, as in Fig. 1*b*, and the specimen to be examined was bonded onto the top of the plug and connected to earth through it. The transducer output, after amplification, rectification and black level suppression, controlled the intensity of the display cathode-ray tube.

Electron-acoustic images obtained with the beam striking either an aluminium plug (Fig. 1*b*) or the upper electrode of the transducer (Fig. 1*c*) consisted of irregular arrangements of bright and dark patches of about 0.5 mm size, which moved

---

* Present address: IBM Thomas J. Watson Research Center, Yorktown Heights, New York, 10598.

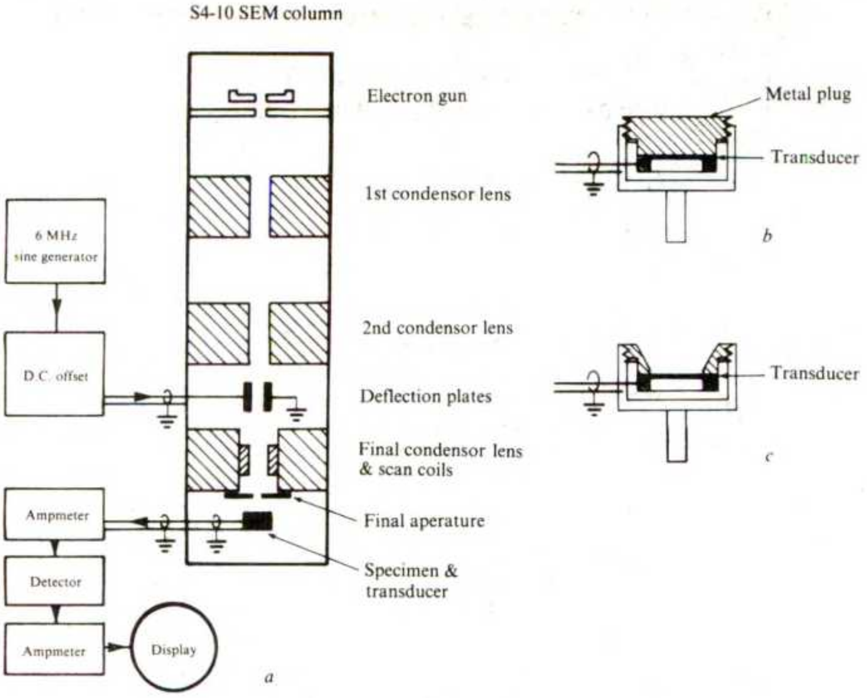

Fig. 1 Major components of the electron-acoustic microscope (*a*); and cross-section sketches of the transducer assembly, with the crystal bonded to the bottom of a metal plug (*b*), and without the metal plug (*c*).

about as the frequency was swept ±25 kHz. This contrast must have resulted from interferences involving reflected acoustic waves. Because the instantaneous transducer output is proportional to the average normal compression of the crystal, considerable cancellation is expected to occur for either of these arrangements.

Using a plug made from Invar, a low thermal expansion ($\alpha < 2 \times 10^{-6}$) alloy, instead of Al ($\alpha = 23 \times 10^{-6}$), greatly reduced the signal strength. A composite Invar-Al plug was also examined; electron-acoustic and secondary electron micrographs are shown in Fig. 2*a*. In the electron-acoustic micrograph the Invar is dark and the Al is covered with bright patches. These results are consistent with the contrast between Invar and Al being caused primarily by the larger thermal expansion of Al.

Electron-acoustic and secondary electron micrographs of Fig. 2*b* show a small area of an integrated circuit chip. In both micrographs the Al conductor lines are bright and the Si substrate, partially covered with silica, is dark. The contrast in parts of the secondary electron image is due to variations of the thickness of the silica, but this contrast is not so visible in regions covered by conductor lines. However, in the electron-acoustic image the brightness of the conductors and of the substrate is reduced over steps in the silica.

The resolution of such electron-acoustic micrographs is essentially the diameter of the region in which elastic waves are produced by periodic electron beam heating and is determined by (1) the incident beam diameter d_B, (2) the extent of beam spreading in the specimen d_S, and (3) the thermal diffusion length d_T. For the present experiments $d_B \simeq 1$ μm, including degradation caused by beam chopping. The penetration and spreading of the electron beam depend on accelerating voltage and on specimen composition and thickness. Values of d_S in Table 1 are estimates for thick specimens calculated with the simplified energy loss expression[7]

$$d_S(\mu\text{m}) = E_0^{1.43}/10\rho \tag{1}$$

where ρ is the density (g cm^{-3}) and E_0 is the incident electron energy (keV). Together, d_B and d_S determine the size of the region of energy disposition. Thermal diffusion further enlarges the source size by about the thermal diffusion length $d_T = (2K/\rho C\omega)^{1/2}$, where K is the thermal conductivity, C is the specific heat, and $\omega/2\pi$ is the frequency[8]. Values of d_T for several materials are given in Table 1, together with resulting estimates of total effective source diameters

$$D = (d_B^2 + d_S^2 + d_T^2)^{1/2} \tag{2}$$

This form of summation is commonly used in electron optics to estimate the effective beam diameter resulting from various lens aberrations (see, for example, equation 11 in ref. 9). For our

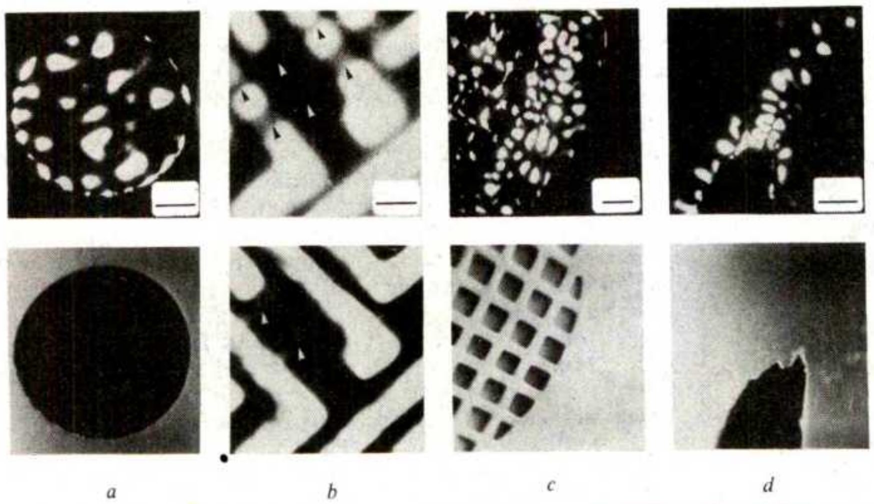

Fig. 2 Electron-acoustic (top) and secondary electron (bottom) micrographs: *a*, Al rod in Invar plug, scale bar, 0.5 mm; *b*, integrated circuit chip (arrows indicate steps in silica), scale bar, 10 μm; *c*, Cu grid on Cu plug, scale bar, 0.1 mm; *d*, hole in Al plug, scale bar, 0.5 mm.

experimental conditions, electron-acoustic micrographs are, therefore, expected to have resolutions of 3–6 μm, that is, much smaller than the wavelength $\lambda \approx 1$ mm, for longitudinal acoustic waves.

Contrast in electron-acoustic images involves both generation and propagation of ultrasonic waves. For simple cases of elastic wave generation by transient surface heating, White has shown that the stress amplitude for a given absorbed power density is proportional to $\zeta = B\alpha(K\rho C)^{-1/2}$, where B is the bulk modulus[8]. Values of ζ for Invar (<1.0), Al (3.1), and Si (1.1) (in units of 10^7 dyn s$^{1/2}$ cal^{-1}) are qualitatively consistent with contrast in electron-acoustic images of Fig. 2*a*,*b*.

Although contrast for flat, homogeneous specimens seems to depend mainly on ζ, under some circumstances other factors are also important. Thermoelastic expansions produced by the chopped electron beam are more effective in producing ultrasonic signals when they are well matched to the frequency and spatial characteristics of normal vibrational modes of the material being examined. For example, flexural modes of the 13-μm thick Cu grid in Fig. 2*c* are more efficiently excited than are vibrations in the copper plug to which the grid is glued. Although acoustic signals passing from the grid through the plug to the transducer are somewhat attenuated in the glue bond, the average signal from the grid is stronger than that from the plug. The bright spots on the electron-acoustic image are the antinodes of the 6-MHz normal mode pattern.

An example of contrast from subsurface features is shown in Fig. 2*d*. The specimen was a 6-mm high Al plug with a 1.6-mm diameter hole intersecting its upper surface at 6.5°. Only the exit hole is visible in the secondary-electron image. However, in the electron-acoustic image a collection of bright spots of high acoustic signal strength follow the course of the hole until it reaches a depth $z \approx 0.1$ mm below the surface, about 20 times the source depth $D_z = (d_S^2 + d_T^2)^{1/2}$. The magnitude of thermoelastic expansion will not be affected by subsurface features which are well below this source depth. The subsurface hole is seen in the electron-acoustic image mainly through its effect on the propagation and interference of ultrasound. However, sensitivity to subsurface features at depths $z \gg D_z$ is expected to be poor in the present experiments, because the acoustical wavelength λ is much larger than the source diameter D, producing a strongly diverging acoustic wave. Subsurface sensitivity and resolution should be improved by using a much higher frequency so that $\lambda \ll D$.

These results indicate that electron-acoustic microscopy can be used to examine some thermal and elastic properties of solids on a truly microscopic scale. This capability should be particularly useful in studies of defects and inhomogeneities in amorphous solids and in investigations of biological materials. Examination of specimens which are susceptible to electron beam damage may require using lower accelerating voltages and coating specimens with thin, electron opaque films.

Support from the SRC and from Churchill College is acknowledged. Dr W. C. Nixon provided guidance on electron beam deflection methods. Dr G. J. Curtis, AERE Harwell, provided advice and equipment for detecting ultrasonic signals. I thank Drs L. M. Brown and A. Howie for valuable suggestions.

Note added in proof: Examples of lower resolution electron-acoustic images at 100 kHz have recently been reported[10].

Attempts to polymerize hexachlorocyclotriphosphazene $(PNCl_2)_3$ by high-energy irradiation methods in the solid state have failed to give a significant amount of the polymer. We report here that $(PNCl_2)_3$ crystals can be polymerized quite easily when exposed to a low-pressure radio-frequency plasma. The polymerization takes place almost simultaneously with the plasma-exposure. The monomer conversion increases with the plasma power as well as plasma-duration. The product is a white, rubber-like material having a similar appearance to the elastomer obtained by thermal polymerization. The IR spectrum shows the same backbone structure as that obtained by thermal polymerization. It has also been found that post-polymerization takes place at elevated temperatures following a brief exposure (1–5 min) of plasma onto phosphazene crystals.

During the past decade, the chemistry of poly(phosphazene) has undergone significant development, following the demonstration that $(PNCl_2)_3$ could be polymerized thermally to a soluble high polymer[1] and the chlorine atoms substituted by various organic groups[2]. The presence of phosphorous and nitrogen in the backbone of these polymers causes the wide range of physical and chemical properties and their high temperature resistance[3].

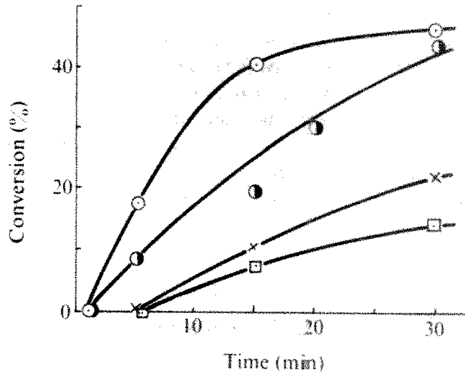

Fig. 1 Monomer conversion versus plasma duration for the polymerization of $(PNCl_2)_3$ at different power levels. Plasma power: ⊙, 110W, ◑, 90W; ×, 70W; ⊡, 50W. The plasma was sustained at 0.1 torr and room temperature.

$(PNCl_2)_3$ is usually polymerized by heating the molten monomer *in vacuo* at temperatures of 250–300 °C for 1–2 days (ref. 4). Below these temperatures, monomer conversions of only a few per cent conversion per day are observed. An attempt[5] to polymerize this cyclic compound in the solid state by γ-radiation has failed to give any significant amount of polymer at dosages, up to 10^6–10^8 rad. Irradiation by 4-MeV electrons with a dose of 10^9 rad at −70, 25 and 120 °C *in vacuo* gave only 1–2% of an insoluble product, in spite of the high dose[6]. The only example of solid-state polymerization of $(PNCl_2)_3$ is that observed using 50 keV X-ray radiation[7]. A maximum of 10% conversion of the monomer to an elastomeric polymer was

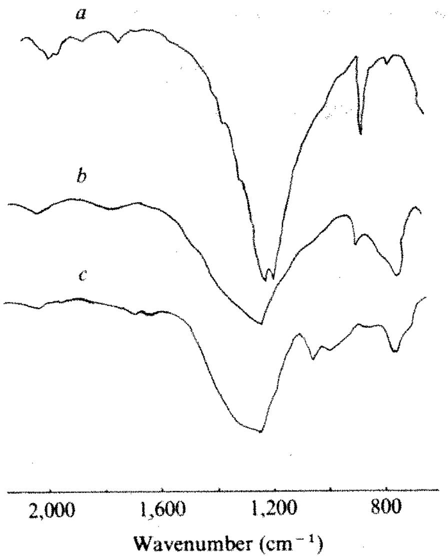

Fig. 2 IR spectra of (PNCl$_2$)$_3$ (*a*) and polymers obtained by thermal polymerization (260 °C, 15 h) (*b*), and plasma exposed polymerization (110W, 30 min) (*c*).

observed when the monomer was maintained near the melting point (114 °C) and irradiated for 40 h at a dose rate of 1.2 Mrad h^{-1}.

We have now found that (PNCl$_2$)$_3$ crystals can be polymerized quite easily when exposed to the effects of a low-pressure radio-frequency plasma. Plasma exposure was carried out on sublimed (PNCl$_2$)$_3$ crystals (Nippon Seika Chemistry Incorporated) placed in a glass ampule which was inserted between a pair of parallel-plate electrodes connected to an RFG-200 radio-frequency generator (Samco International Incorporated), operating at 13.56 MHz. The ampule was evacuated and a room temperature glow discharge was initiated in the phosphazene vapour remaining in the ampule. Following plasma-exposure, the samples were washed thoroughly with *n*-hexane to remove any unpolymerized material.

The polymerization of phosphazene takes place quite rapidly on plasma exposure, and the monomer conversion increases with the plasma power as well as the plasma-duration (Fig. 1). An oily product is formed in the very initial stage of the polymerization. The final product, however, is a white, rubber-like material having a similar appearance to the elastomer obtained by thermal polymerization. Figure 2 shows IR spectra of the phosphazene polymers obtained by plasma exposure and thermal polymerization, and demonstrates that the same backbone structure is obtained by both polymerization methods. Cross-linking might occur through labile chlorine atoms during the plasma exposure, because the observed chlorine content in the polymer decreased slightly, relative to that in the monomer, and a new absorption band attributed to P–O bond appeared near 1,040 cm^{-1}. Postpolymerization has been found to occur at elevated temperatures following a brief exposure of the phosphazene crystals. As shown in Fig. 3, (PNCl$_2$)$_3$ exposed to a plasma for 1 or 5 min undergoes postpolymerization up to certain level at 180 or 220 °C, whereas no polymerization takes place in these conditions for (PNCl$_2$)$_3$ without plasma exposure.

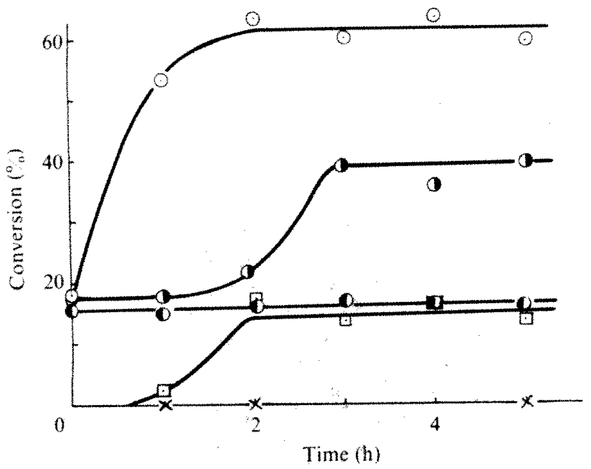

Fig. 3 The effect of time on the postpolymerization of (PNCl$_2$)$_3$. Plasma power, 110W; plasma duration and temperature of postpolymerization: ○, 5 min, 220 °C; ◑, 5 min. 180 °C; ◐, 5 min, 140°C; ⊡, 1 min, 180°C; ×, no plasma, 220 °C.

A mechanism for the polymerization of (PNCl$_2$)$_3$ under the effects of a low-pressure plasma has not yet been determined. Thermal polymerization is considered to be a minor component, however, as extensive polymerization takes place when the gas temperature in the plasma was maintained below 160 °C or the phosphazene crystals were kept at temperatures as low as −20 °C.

This research was supported in part by a Grant-in Aid from the Ministry of Education, Japan, grant 455351 (1979).

Configuration at C-24 in steranes and sterols

J. R. Maxwell, A. S. Mackenzie & J. K. Volkman

Organic Geochemistry Unit, University of Bristol, School of Chemistry, Cantock's Close, Bristol BS8 1TS, UK

Most marine and terrestrial organisms and aquatic sediments contain sterols with an alkyl group at C-24. Assignment of the configuration at this position has important biosynthetic, taxonomic and geochemical implications[1–3]; for example, it is required to elucidate biosynthetic pathways responsible for alkylation[1,2], and to reveal sources of sterols in species where there is no *de novo* synthesis[4,5] and in recent sediments[3,6]. Similarly, routine separation of the C-24 isomers of steranes in sedimentary rocks (formed from sterols present at the time of deposition) should provide information on the nature of the contributing organisms and the isomerization reactions thought to occur in steranes with increasing depth of burial and the associated temperature rise[7,8]. Using an extension of gas chromatographic (GC) methods applied previously to the separation of stereoisomers of acyclic isoprenoid acids[9] and alkanes[10], we report here (1) the complete separation of (24*R*)-24-methyl-5α-cholestane (I) from its C-24 isomer (II in Fig. 1), the partial separation of (24*R*)- and (24*S*)-24-ethyl-5α-cholestane (III and IV), (2) the application of these separations to a study of the C-24 configuration in the steranes of a sedimentary rock and a petroleum and in those from reduction of the sterols of a marine coccolithophorid, and (3) similar separations of the corresponding 3β-OH saturated C$_{28}$ and C$_{29}$ alcohols as acetates (stanol acetates).

To date, assignment of the C-24 configuration in steroidal compounds has relied on X-ray crystallography[3,6], differences in melting points[11], optical rotation measurements[12,13] or chemical shifts in ^{1}H nuclear magnetic resonance (NMR) spectra[14]. These

methods typically require a few milligrammes of the isolated compound and their application to studies of the components of small quantities of complex mixtures is limited.

Chromatographic separation of C-24 isomers of sterols or steranes has proved difficult[15–17]. The only report describes partial separation of milligramme quantities of (24*R*)-24-methyl-5α-cholestane (I) and its 24*S* isomer (II) on alumina[18]. In these conditions, previous separation of coeluting steranes is required[7]. Figure 2*a* shows the partial chromatogram of a 50:50 mixture (quantitated accurately by spiking with 5α- and 5β-cholestane) of (24*R*)- and (24*S*)-methyl-5α-cholestanes ((I) and (II)) obtained with a Carlo Erba Fractovap (series 2151) chromatograph fitted with a 100 m × 0.24 mm glass column, roughened and deactivated by the barium carbonate technique of Grob *et al.*[19], and coated statically[20] with a dichloromethane

solution of diethylene glycol succinate (DEGS) and polyethylene glycol succinate (PEGS) (75:25; wt:wt) to produce a 0.06 µm film; H_2 was the carrier gas (2.3 kg cm^{-2} back pressure ~7.5 cm^3 min^{-1}); the oven was programmed from 40 to 160 °C at 4 °C min^{-1} and then maintained at 160 °C. Figure 2*b* shows partial separation of a 50:50 mixture of (24*R*)- and (24*S*)-24-ethyl-5α-cholestane ((III) and (IV)) (quantitated as above) in the same conditions. Elution orders were established in both cases by co-injection, with (II) and (IV) respectively, and amounts injected were 5–15 ng of each component. Although both standard mixtures comprise equal amounts of the two isomers, the peak heights are not equal. This is most apparent for the ethylcholestanes (Fig. 2*b*) where there is a contribution to the second eluting 24*R* isomer peak from the first eluting 24*S* isomer. The areas of the two methylcholestane peaks are equal so the first eluting 24*S* isomer peak is slightly broader (Fig. 2*a*).

The method has been used to separate the steranes in samples of the Green River shale (Colorado, Eocene) and Rozel Point crude oil (Utah, unknown age), as the C-24 stereochemistry of certain steranes has been assigned previously by ^{1}H NMR[7]. Steranes whose nuclear and C-20 stereochemistry differs from that of the presumed precursor sterols have been reported from sedimentary rocks and petroleum[7,8,17], but discussion is limited here to those which are isomeric at C-24 and which have the same configuration as the original sterols at all other chiral centres (that is, 5α, 8β, 9α, 14α, 17α(H), 20*R*). GC analysis of the branched and cyclic alkane fraction from the shale sample indicated a 75:25 mixture of (24*S*)-24-methyl-5α-cholestane (II) and the 24*R*-isomer (I), and a 75:25 mixture of the 24*S* C_{29} sterane (IV) and its C-24 isomer (III; Fig. 2*c*). These ratios are the same as those obtained independently by ^{1}H NMR[7]. The branched and cyclic alkane fraction of the crude oil was too complex for analysis without further fractionation and was subjected to thiourea adduction (twice)[21]. As expected[22], the 24-ethyl-5α-cholestanes were essentially not adducted, whereas 24-methyl-5α-cholestanes were almost completely adducted. GC analysis of the adduct and non-adduct showed, as determined previously by ^{1}H NMR, the 24-methyl- and 24-ethyl-5α-cholestanes to be present in 50:50 mixtures of 24*R* abnd 24*S* epimers (Fig. 2*d*, *e*) when compared with the mixtures of the standards. Adduction of the standards revealed no detectable fractionation at C-24.

Thiourea adduction is required for the analysis of the steranes of most shales and oils. The non-adduct is, however, sometimes too complex for direct GC analysis of the C-24 configuration in 24-ethyl-5α-cholestanes and problems of co-elution with other components are occasionally encountered in evaluation of the 24-methyl-5α-cholestanes in the adduct. Analysis of the 24-methyl-5α-cholestanes (in conditions of partial separation) from a suite of Toarcian shales from the Paris Basin shows a preference for the (24*S*) isomer (60:40 in favour of 24*S*) in samples with a mild thermal history, which is lost on increased burial depth[8]. The preservation of a preference for 24*S* components in those shales with a mild thermal history may relate to the sterols of the source organisms. Most algae and fungi seem to produce 24β (24*S* where the side chain is saturated) sterols, whilst most higher plant sterols are 24α[1,2]. However, there are exceptions and plants can contain both configurations[23,24].

The C-24 stereochemistry in sterols is related to alkylation reaction mechanisms[1,24]. Biosynthetic, taxonomic, and marine studies would clearly benefit from a routine method of separating C-24 isomers and which could be applied to the small quantities of complex mixtures commonly encountered. Hydrogenolysis/hydrogenation of two sterols, (24*S*)-24-methylcholesta-5,22E-dien-3β-ol and (24*R*)-24-ethylcholesta-5,22E-dien-3β-ol, by bubbling H_2 through a suspension of the sample (~50 µg) and PtO_2 (1 mg) in glacial acetic acid (5 cm^3) containing perchloric acid (1 drop) produced (after 4 h) yields of ~60% of sterane. The 5α-stanol acetate (~20%) and the free 5α-stanol (~20%) were also produced, but no unreacted sterol was recovered. GC analysis of the steranes showed evidence of a small extent of isomerization during the reaction, and a ratio of 4.2-4.5:1 of the two C-24 isomers in favour of the original configuration was observed. This minor extent of isomerization has already been noted by ^{1}H NMR analysis of the products of hydrogenation of certain sterols[25]. No isomerization was detected when sterols with no side chain double bond were hydrogenolysed/hydrogenated.

The technique of analysis of the steranes resulting from hydrogenolysis/hydrogenation has been applied to the study of the major free sterol of the microscopic marine coccolithophorid, *Emiliania huxleyi*, family Gephyrocapsaceae[26]. This ubiquitous marine alga[27,28] has given rise to extensive calcium carbonate (coccolith) deposits in many deep-sea areas, including the Black Sea[29]. It is remarkable in that it biosynthesizes a novel carotenoid, 19′-hexanoyloxyfucoxanthin[30] and C_{37}–C_{39} straight chain alkenes and alkenones which are abundant in many sediments[31,32]. Gas chromatographic/mass spectrometric analysis of the free desmethylsterol fraction as the TMSi ethers, using conditions described previously[6], showed 24-methylcholesta-5,22E-dien-3β-ol as the major component. The fraction was hydrogenolysed/hydrogenated as above and similar products and yields were obtained. Without purification, the products were analysed by GC on DEGS/PEGS and (24*R*)-24-methylcholestane and (24*S*)-24-methylcholestane were found to be present in the ratio 4.3:1 (Fig. 2*f*). The major free sterol of *E. huxleyi* is, therefore, (24*S*)-24-methylcholesta-5,22*E*-dien-3β-ol (V that is, 24α).

The latter isomer is the same as that produced by the diatoms, *Phaeodactylum tricornutum*[5] and *Nitzschia closterium*[33], and it is interesting that the fatty acid composition of *E. huxleyi* is also similar to those of the diatoms[34]. Phytoflagellate[34] *Ochromonas* spp. (Chrysophyceae) produce sterols with the opposite C-24 configuration to that in *E. huxleyi*[1,11] and such differences may be useful in the classification of many such microscopic algae, which can be difficult[26].

Attempts to avoid the reduction step and extend the method to the direct examination of steroidal alcohols have been partly successful. Partial separations of C_{28} and C_{29} stanol acetate isomeric pairs were obtained (Fig. 2*g*) after elution times ~9–10 h (conditions as above, but programming from 40° to −190 °C at 4 °C min^{-1}), but no separation of $\Delta^{5,22}$ steryl acetates isomeric at C-24 has been achieved.

The examples described show clearly the value of the technique in (1) the study of the sterane distributions of sedimentary rocks, and (2) structural studies of sterols in organisms. These preliminary results also suggest that the approach will be useful in assigning the input sources of sterols in sediments. Many of these samples contain complex mixtures with varying degrees and positions of unsaturation, and fractionation by argentation thin layer chromatography[35] before reduction should prove useful. Definition of the sources of sedimentary sterols also requires routine determination of the C-24 configuration of sterols biosynthesized and/or incorporated by a variety of individual organisms and the GC approach should allow rapid screening of small quantities of complex mixtures.

We thank NERC (GR3/2951 and GR3/3758) for GC/MS facilities, Drs L. J. Mulheirn and G. Ryback for donating steranes and Rozel Point alkane fraction, Mr P. A. Comet for the stanol acetate mixture, and Dr A. M. K. Wardroper for helpful discussions. A.S.M. also thanks the SRC for a Studentship and J.K.V. gratefully acknowledges support from NERC (GR3/3419).

Thermoluminescence dating of volcanic plagioclases

G. Guérin & G. Valladas

Centre des Faibles Radioactivités Laboratoire mixte CNRS-CEA,
91190 Gif-sur-Yvette, France

Thermoluminescence (TL) is a well-established archaeological dating[1] technique but the most common mineral in volcanic rocks, plagioclase feldspar, is affected by 'anomalous fading' which prevents its use for dating lava flows. We describe here how the α contribution to annual dose rate is calculated. Plagioclase ages are compared with those obtained by ^{14}C, K–Ar and TL dating on quartz. Our samples come from the Chaîne des Puys (Massif Central, France). We conclude that TL is a promising tool for dating continental lava flows in the range 3,000–300,000 yr BP.

The intensity of light emitted during thermal stimulation of a mineral is related to the radiation dose it has accumulated since its last heating (palaeodose). A basic assumption that the electronic trapping states responsible for the TL emission are stable. A routine check, the 'plateau' test, consists of plotting the ratio of the natural TL to the increment of TL induced by a laboratory-added radiation dose (artificial TL, ATL) against temperature; a constant value must be reached above a certain temperature. However, as shown by Wintle[2], most volcanic plagioclases do not have a plateau in the usual temperature range of study (620–720 K). Thus, the maximum ages obtained by TL are too small by as much as an order of magnitude. This effect was attributed to a spurious loss of electrons from their traps in the 620–720 K temperature region where the mean life of charge carriers should be larger than 10^5 yr. Bailiff's[3] has made promising attempts to avoid anomalous fading using phototransfer.

The study of high temperature TL emission (700–1,000 K) of plagioclases is restricted to the UV spectrum because having to cut off the black-body thermal emission necessitates using a thick glass UV filter. In such conditions, we have already suggested[4] that glow peaks might be unaffected by anomalous fading.

Figure 1*Aa* shows the natural TL glow curve of a Labrador aliquot (from Olby flow); Fig. 1*Ab* is the glow curve obtained when a 16 krad dose is added to another aliquot of the same weight. The ratio of the natural TL to the increment of TL induced by the added dose is plotted in Fig. 1*B*. There is no plateau but a tendency for stabilization above 850 K which indicates the onset of a region of different behaviour. As already described for quartz[5], we try to eliminate the lower temperature TL emission by preheating. Figure 1*C* shows the plateau test in different conditions of preheating. Figure 1*Cc* (850 K, for 1 min) is rather flat which indicates that the remaining glow peak is a constant function of temperature.

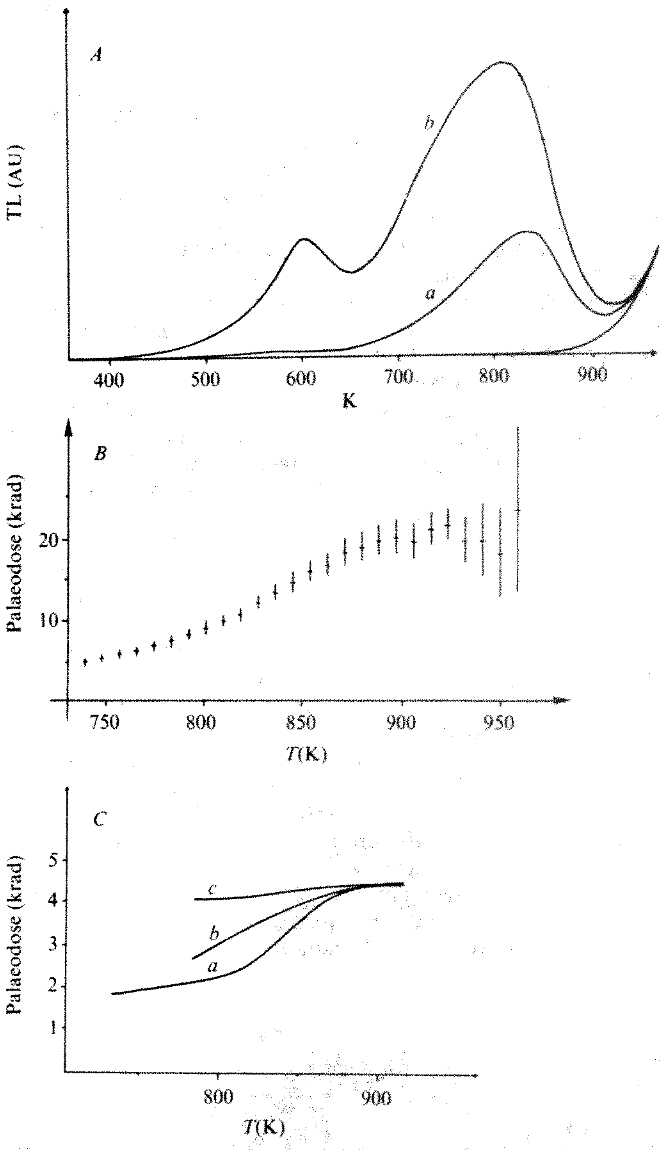

Fig. 1 *A*, TL glow curves of Olby Labrador: *a*, TLN; *b*, TLN+16 K. *B*, Plateau test of Olby plagioclase. *C*, Plateau curves for Saint-Saturnin preheated plagioclase: *a*, 1 min 735 K; *b*, 1 min 781 K; *c*, 1 min 832 K.

Wintle[2] has pointed out that anomalous fading mainly occurs soon after the sample has received an artificial radiation dose. To check for short-term fading we determined the apparent dose remaining after one year of storage of a lava sample from the Olby flow which had been previously heated to 960 K for 4 h, cooled and γ irradiated at 7.395 ± 187 rad at low dose rate. The apparent measured dose 7.238 ± 293 rad agrees with the deposited dose.

In such conditions there was no evidence of short-term fading; although these two arguments usually allow a mineral to be used for TL dating, they cannot be assumed on a geological time scale. Therefore, we studied lava flows of known age from the Chaîne des Puys (Massif Central, France)[6].

TL measurements were done on plagioclases ranging from andesine to labrador, carefully extracted from the lava by gentle crushing, and separated by sieving heavy liquid and magnetic techniques. We selected a grain size of 80–125 μm to remove finer microlites and to keep only the microphenocrysts. TL glows were measured with a glass filter (325 nm) which allows a maximum temperature of 1,100 K. The heating rate is generally 5 Ks^{-1} to 10 $K s^{-1}$, artificial irradiations were carried out with a ^{137}Cs γ source (4.02 rad s^{-1}). After preheating, usually at 830 K for 1 min, the plagioclases all presented a single glow peak around 920 K (5 $K s^{-1}$, heating rate).

The palaeodose is obtained by comparing natural TL with artificial TL, a supralinearity correction is included which results from a non-linear initial increase of the TL signal as a function of the dose (saturation curve). This correction is estimated from the second glow. Annual β and γ dose rates are computed from U–Th and K contents, measured by γ-ray spectrometry with a Ge–Li detector (Table 1*a*), using Bell's data[7]. There is no grain size correction for β radiation from K because the internal K content measured with an EDAX electron-microprobe does not substantially differ from the average K content of the lava. The very small correction, <1% of the total dose, for the β radiation from U and Th families, is neglected. Because of the very high efficiency of α particles in the production of TL in plagioclases (about five times higher than quartz), the α contribution to the annual dose rate is important even when using a grain size of 100 μm. Indeed, the TL induced by α radiation may reach one-third of the total TL as shown in Table 1*b* where the palaeodose, supralinearity correction, and the annual dose rates for α, β and γ radiation are given.

α-dosimetry present problems mainly because of the short average range of α particles in matter. We must, therefore, know the repartition of the α emitters in the middle where the plagioclase is naturally irradiated. With a resolution of several microns, comparable with the range of α particles, fission track mapping can represent U distribution in the lava. As seen in Fig. 2 microphenocrysts of plagioclase and olivine near 100 μm have a low U content. Hence the average U or Th concentration of the total lava does not accurately represent the actual concentration seen by the feldspar. As Th and U are strongly linked from a geochemical point of view, we can assume that their distributions are not very different. Thus, a single figure will relate the concentration of U in the plagioclase to the concentration of U or Th of the total rock, for example N_0, the ratio of the peripheral fission track density to the mean density of tracks in the thin section.

In the lava, a plagioclase grain is submitted to an omnidirectional flux of α particles of various energies. To simulate this flux, we used calibrated laboratory α sources and vibrated the plagioclase grains so that they were irradiated in many positions. For each α particle, omnidirectional experimental α flux was related to the equivalent γ dose which would have produced the same TL; this is termed $\chi(E)$. Up to an energy of 9 MeV, $\chi(E)$ can be fitted by a straight line cutting the χ energy axis at 500 keV. The energy spectrum of α particles from U and Th families, when they are in secular equilibrium (which is checked by our spectrometry measurements) leads to global factors $\hat{\chi}_U$ and $\hat{\chi}_{Th}$ which relate the natural omnidirectional flux to the equivalent γ dose:

$$\hat{\chi}_{U(Th)} = \frac{\int_0^{E_{\max}} \chi(E) \frac{dn}{dE}_{U(Th)} dE}{\int_0^{E_{\max}} \frac{dn}{dE}_{U(Th)} dE}$$

Note that, while assuming $\chi(E)$ to be linear, $\hat{\chi}_U$ is very close to

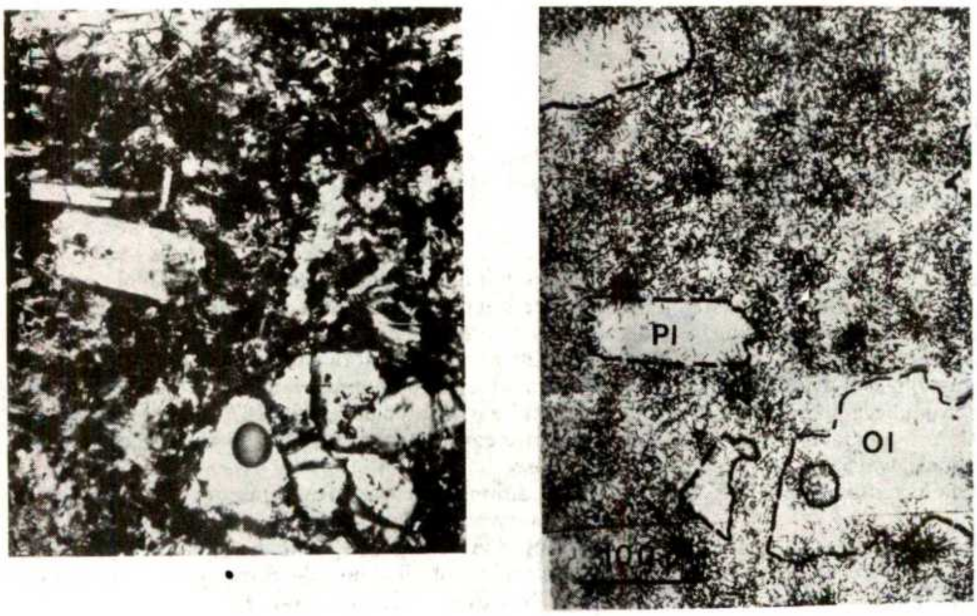

Fig. 2 Photograph of the thin section of St-Saturnin basalt and its fission track mapping. Ol, Olivine; Pl, plagioclase (Labrador).

χ(3.06 MeV) and $\hat{\chi}_{\mathrm{Th}}$ to χ (3.40 MeV). Then the contribution to the dose of α particles external to the grain can be written:

$$D = N_0(\hat{\chi}_{\mathrm{Th}}\phi_{\mathrm{Th}} + \hat{\chi}_{\mathrm{U}}\phi_{\mathrm{U}})$$

where $\hat{\chi}_{\mathrm{U}}$ and $\hat{\chi}_{\mathrm{Th}}$ do not differ much. ϕ_{Th} and ϕ_{U} are the omnidirectional fluxes, respectively, due to Th and U determinated for the total rock. Moreover, we do take into account the U (or Th) generally present inside the grain (<0.2 p.p.m.). The internal contribution to the dose can be written with a similar formula to that of the external α dose but the value of χ is obtained using a grain size of a few micrometres (fine grains technique)[12]. In general, the internal α dose rate contribution approximately represents 25% of the α dose (8% of the total annual dose rate).

Table 2 TL dated plagioclase samples compared with conventional techniques

	TL	Conventional	
St Saturnin	8,980 ± 1,150	7,880 ± 350	^{14}C*
		8,100 ± 1,100	TL (clay)†
Olby	37,300 ± 3,500	42,000 ± 3,000	TL (Q)‡
		39,000 ± 6,000	U-Th§
Laschamp	31,900 ± 2,850	34,300 ± 3,000	TL (Q)‡
	32,500 ± 3,100

Montgreleix	163,300 ± 14,500	175,000 ± 13,000	K–Ar‖
Mazoires	215,800 ± 20,500	242,000 ± 10,000	K–Ar‖

* Revised from Pelletier *et al.*[8] using a 5,730 yr half life for ^{14}C.
† Revised from Huxtable and Aitken[9].
‡ Revised from Valladas[10] TL dating on quartz, with revised calibration of reference sources.
§ Revised from Condomines[11].
‖ Revised from Gillot (unpublished work) K–Ar dating on mesostase; Egaules age is an upper limit.

Finally, the estimation of the α dose rate is carried out with an accuracy not much better than 20%.

When crushing the rock the plagioclases are fragmented which leads to an overestimate of χ and an underestimate of the age. For example, if 30% of the 100 μm plagioclases had an initial size of 200 μm, the age obtained would be 4% too low[13]. This correction has not been applied to the present data.

Our first results are shown in Table 2, and compared with the ages obtained using more conventional techniques. The agreement of TL dated plagioclases is good and indicates that within our experimental error, ±8%, there are no major systematic errors.

We conclude that high-temperature TL emission is not systematically affected by either anomalous fading or by thermal fading and can be used for dating volcanic flows. As saturation doses of plagioclases are around 400 krad, TL allows dating continental volcanics from 3,000 to 300,000 yr BP.

Palaeomagnetism of beach ridges in South Australia and the Milankovitch theory of ice ages

Mart Idnurm

Bureau of Mineral Resources, Canberra ACT 2601, Australia

Peter J. Cook

Research School of Earth Sciences, Australian National University, Canberra ACT 2600, Australia

Although the Pleistocene glaciations continue to attract new explanations[1–3], an early explanation in terms of secular variations of the Earth's orbital elements, the Milankovitch theory[4], has recently gained considerable support[5,6]. This theory predicts insolation variations with periodicities of ~20,000, 40,000 and 100,000 yr. Its popularity is attributable mostly to deep-sea sediment information on variations of the glaciation-sensitive ^{16}O/^{18}O isotopic ratio and the increasingly convincing match of those variations to the Milankovitch climatic curves[7–9]. Independently, land-based evidence is accumulating in favour of the Milankovitch theory from raised coral terrace[10], loess[11], and pollen studies[12]. We discuss here evidence for the Milankovitch theory from a South Australian sea-level record.

In the south-east corner of South Australia, a beach ridge sequence extends approximately parallel to the present-day coast line for some 250 km. It is best developed between Robe, on the coast, and Naracoorte, 100 km inland, where eight ridge systems containing 13 well defined parallel beach ridges occur (Fig. 1). The sequence ranges in altitude from near sea level at Robe to ~100 m at Naracoorte. To the east of Naracoorte the ridges become progressively less well defined but remain recognizable for a further 200 km inland. Offshore from Robe there are at least two more beach ridges representing low sea levels[13]. Detailed drilling of the Robe–Naracoorte sequence[14] has revealed that the ridges are composed of cross-bedded calcarenite, with the lower part of the sequence deposited in beach or near-beach conditions and the upper part in aeolian conditions. In general, the stratigraphy is consistent with a prograding coastal sequence developed on a slowly uplifted region, the beach ridges representing successive high sea-level stands. Sprigg[13,15,16] has argued that the Robe–Naracoorte sequence and the Milankovitch insolation curves are in good agreement, assuming that the sea-level variations were caused by melting of glaciers during periods of high insolation at critical northern latitudes. Sprigg's comparisons have, however, lacked a time scale based on biostratigraphic or absolute ages. We now date the sequence by polarity reversal, and use this age to test the Milankovitch theory.

Ten of the best preserved ridges were hand sampled between Robe and Naracoorte (Fig. 1). The material was fine- to medium-grained calcarenite composed of a framework of fine abraded biogenic material, quartz, and rare feldspar grains, all coated to varying degrees with iron oxides. Opaque grains, particularly iron sesquioxides, were rare. The cement varied from sparite to microsparite. The sediments ranged from semi-consolidated to well consolidated and their colour varied from yellow to pale reddish brown. Obvious pedogenic modifications, such as colour mottling or pronounced calcretization, were avoided during sampling. Except for the initial work, when a Digico spinner magnetometer was used, all measurements were made with an ScT cryogenic magnetometer. Thermal demagnetization, usually at 50 °C increments, was used to analyse the remanence. Magnetic susceptibilities were determined between heatings to monitor mineralogical changes.

0028–0836/80/330699—04$01.00

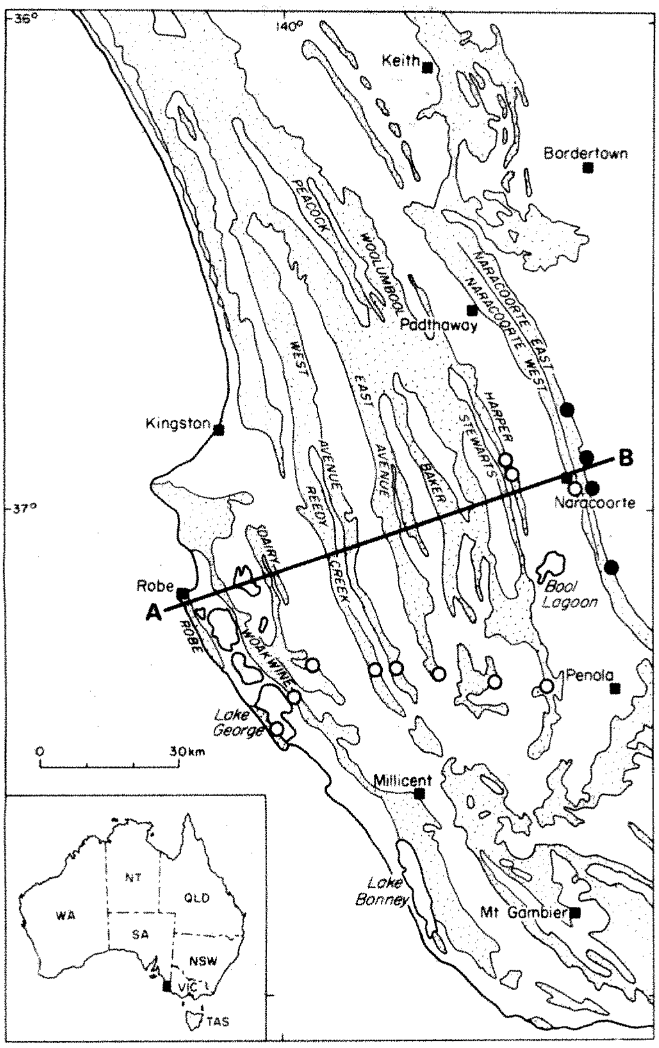

Fig. 1 The beach ridge sequence in southeastern South Australia. Open symbols indicate sampling sites with normal polarity, closed symbols indicate reversed polarity sites.

The NRM intensities ranged from 0.5 to 5 mA m^{-1}. Generally two components of magnetization were observed: a relatively low blocking temperature component which was interpreted as partly a laboratory-storage effect and partly a recent-field effect, and a harder component that exhibited normal polarity for all samples (20) collected between Robe and the West Naracoorte ridge system, and reversed polarity at the East Naracoorte ridge system (Fig. 1). Figure 2 shows thermal demagnetization behaviour of samples collected from ridges adjacent to the polarity reversal. This polarity reversal marks the 720,000 yr Brunhes–Matuyama boundary[17] and provides, for the first time, an age constraint for the ridge sequence. The presence of reversed polarity at the East Naracoorte ridge system was confirmed by sampling at different localities across the ridge and along the ridge axis (nine samples).

The measurements were complicated by an increase in magnetic susceptibility during heatings. This increase was associated with the generation of spurious moments and eventually led to a pronounced magnetic viscosity. In specimens where the onset of the spurious moments was delayed, a third stable magnetization component of very low intensity (0.1–0.2 mA m^{-1}) and high blocking temperature could be isolated. This component showed random directions between different specimens prepared from the same sample.

The most likely origin for the primary remanence is chemical, resulting from processes such as dehydration of iron oxyhydroxides and graingrowth of haematite beyond the critical superparamagnetic grain volume[18]. A detrital origin for the remanence (DRM) is inconsistent with the high-energy beach-aeolian depositional environment of the sediments. A post-depositional origin (PDR) seems unlikely because the filling of pore space by the calcite cement would have displaced and misoriented any aligned grains in the matrix. The authigenic haematite occurs as pigment in the cement and as coatings on the surfaces of framework grains, and is related to the processes of reddening of dune sands. The hard component of remanence, characterized by random directions, apparently results from the rare unaligned detrital iron sesquioxide grains in the sediments. While acknowledging that pedogenic processes could overprint and, if sufficiently intense, destroy any Matuyama magnetic epoch remanence, we believe that the intermediate blocking temperature component represents the primary chemical remanence in the samples collected. The absence of obvious pedogenic modifications, such as colour mottling, in the material selected for palaeomagnetic work, suggests that such processes are not significant. The effects of continued graingrowth, post-dating the Brunhes–Matuyama reversal, are more subtle and remain problematic.

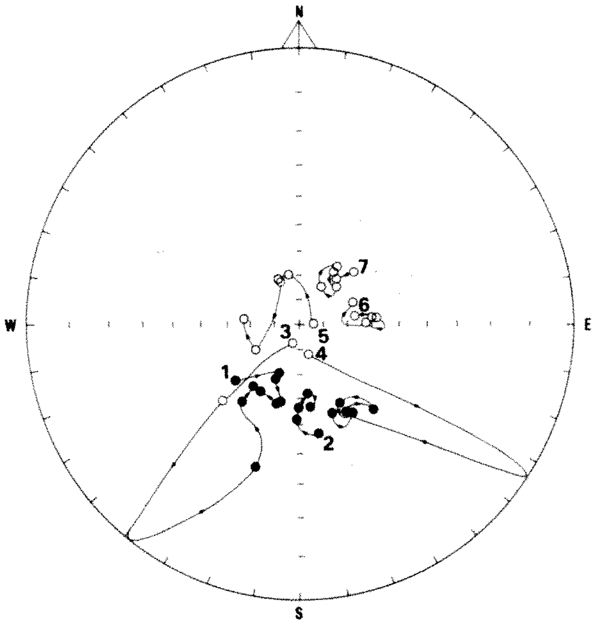

Fig. 2 Remanence directions in beach ridges adjacent to the Brunhes–Matuyama reversal boundary. The diagram shows thermal demagnetization behaviour of seven samples at 100 °C increments commencing from NRM. The arrows indicate directions of increasing heat treatments. Solid symbols correspond to positive inclinations, open symbols to negative inclinations. Samples 1–4 are from two different sites in ridge system 9; samples 5 and 6 are from ridge system 8; and sample 7 is from ridge 7b.

There was probably a time lag between ridge formation and the acquisition of chemical remanence. This time lag would have to be added to the Brunhes–Matuyama reversal date to obtain the true age of deposition. In Victoria, siliceous dunes redden down to 2 m depth within 20,000 yr of deposition. However, more calcareous dunes seem to take significantly longer, possibly of the order of 30,000 yr, for reddening to the same depth (ref. 19 and J. Bowler, personal communication). Bearing in mind that chemical remanence is likely to be acquired before the final stage of reddening has been reached, we may expect the time lag between dune formation and acquisition of chemical remanence to be <30,000 yr. Assuming a remanence acquisition time lag of 30,000 yr, and a depositional time of 30,000 yr for the ridge systems (the average value estimated from the secondary ridge

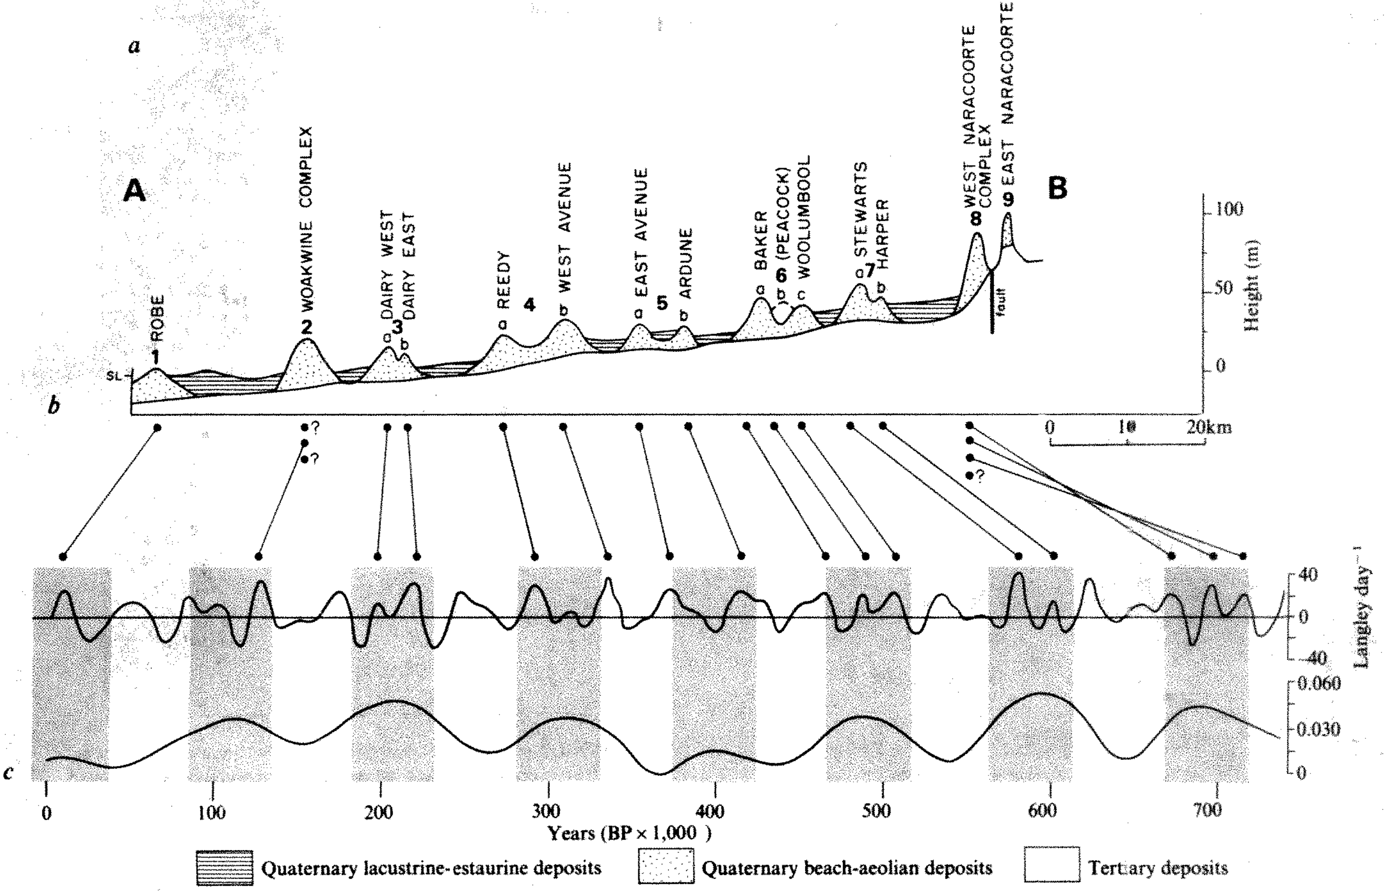

Fig. 3 *a*, Section AB of Fig. 1 through the beach ridges. Ridges 2 and 8 are compound dunes. The Peacock Ridge, which is not intercepted by the line AB, is shown by the broken outline. *b*, Summer insolation in langleys day^{-1} at latitude 65° N relative to the 1950 AD values (after ref. 20). The stippled intervals indicate interpreted interglacial phases of the (approximately) 100,000-yr climatic cycle. Tentative correlations between ridges and insolation maxima are shown by interconnecting lines. *c*, Variations in orbital eccentricity (after ref. 20).

spacings by linear interpolation between the centre points of the ridge systems which are assumed as a first approximation to be 100,000 yr apart), the mean age of the West Naracoorte ridge system is estimated as 665,000–735,000 yr, depending on the exact location of the Brunhes–Matuyama boundary between those two ridge systems. From the surface expression of the ridges (Fig. 3) and from subsurface drilling information[14], eight high sea-level ridge systems are recognized between Robe and Naracoorte where the sequence seems best differentiated. Assuming that no major ridge systems are telescoped (that the uplift has been continuous, though not necessarily at an absolutely constant rate), the average periodicity of the major ridge systems is obtained as 95,000–105,000 yr (~100,000 yr). A dominant 100,000-yr cyclicity has been found in other climatic records[7,11,12]. Most of the ridge systems contain more than one dune, suggesting the possibility of shorter-period changes in the sea-level record.

A tentative interpretation of the raised beach ridges in terms of Berger's[20] modified Milankovitch insolation curves for latitude 65° N, and the dominant 100,000-yr cyclicity, is shown in Fig. 3. The interpretation is based on the assumptions that the ridges form only during high sea-level stands and that these occur at a particular phase of the 100,000-yr cycle. It also has to satisfy two time constraints: an interglacial (ridge-forming) phase at present, and at 700,000 yr BP (during the deposition of the West Naracoorte complex). The interglacial phases for the sequence are then derived as shown by the stippling in Fig. 3. Note first that the interglacial phases coincide with high-orbital eccentricities. This agrees with the oxygen isotope results[7], but contradicts the Milankovitch theory that predicts eccentricity dependence in the opposite sense[20], and finds only a minor eccentricity contribution to climatic variation. Second, with the exceptions discussed below there is a one-to-one correlation between the ridges and principal insolation maxima belonging to the 100,000-yr interglacial phases. Third, the subsidiary ridge spacings agree qualitatively with the time intervals between the insolation maxima: the narrow (3 km average) spacings correspond to 20,000 yr intervals and the wide (7 km average) spacings, to 40,000 yr intervals (we assume here, in common with other sea-level studies[21–23], a relatively constant rate of tectonic uplift).

Problems with correlation occur in the West Naracoorte and Woakwine complexes, both of which are composed of superimposed dunes[14,15]. At West Naracoorte where the dunes are stacked against a fault pediment, some doubt exists over the presence of a fourth dune. At Woakwine correlation is possible with only the oldest of the three insolation peaks of the 85,000–135,000-yr interglacial phase: evidence from elsewhere[21–23] indicates that the high sea-level stands that would correspond to the two youngest peaks of the interglacial phase were well below the first stand. The superposition of Woakwine dunes, indicating repeated transgressions, cannot, therefore, be explained by the Milankovitch theory. Aharon *et al.*[24] have recently considered evidence for a non-Milankovitch sea-level high at 120,000 yr that seems to have reached the earliest high mark, and have proposed an Antarctic ice-surge[25] as the explanation.

Finally, we note the relevance of the present results to geoidal sea-level changes. The geodetic sea level contains regional irregularities that are subject to change, and any significant geoidal variation would modify the interpretation of sea levels in terms of glacio-eustatic changes[26]. Although, with the exceptions noted above, the present results are consistent with Milankovitch's predictions of climatic variation and do not require geoidal changes to be invoked, this does not rule out significant geoidal changes that occur in phase with Milankovitch glacio-eustatic changes, nor major geoidal changes with periods in excess of 700,000 yr.

We conclude that the South Australian ridge sequence contains components related to the Earth's orbital elements. Except for the dominance of the 100,000-yr component and its phase relative to the eccentricity variations, the ridge evidence is consistent with the Milankovitch theory.

We thank P. Aharon, J. M. A. Chappell, D. Denham, M. W. McElhinny and P. Wellman for comments. M.I. publishes with the permission of the Director, Bureau of Mineral Resources.

Note added in proof: Recent geochronological results (D. A. Schwebel, personal communication) confirm the interpreted age of the Woakwine complex.

Quaternary temperatures and precipitation for the north-west coast of North America

C. J. Heusser*, L. E. Heusser*† & S. S. Streeter†

* Department of Biology, New York University, Box 608, Tuxedo, New York 10987
† Lamont-Doherty Geological Observatory of Columbia University, Palisades, New York 10964

Palynologists utilize present-day pollen rain to interpret the climatic setting of pollen records from Quaternary deposits. Analogues are sought which relate the present with the past. Because climatic conditions at mid-latitudes during the Quaternary were diverse, often ranging from a tundra type at one extreme to a closed forest type at the other, a modern data set should cover the extremes of vegetation and climate expected during this time. For interpreting climatic parameters from Quaternary pollen in land and marine cores, we calculated a pair of regression equations relating modern pollen rain from the Pacific coastal forest and tundra to mean July temperature and mean annual precipitation at a series of sites from the Aleutian Islands to northern California. We describe here how application of these equations to Quaternary pollen profiles from western Washington enabled us to quantify temperature and precipitation over the past ~80,000 yr.

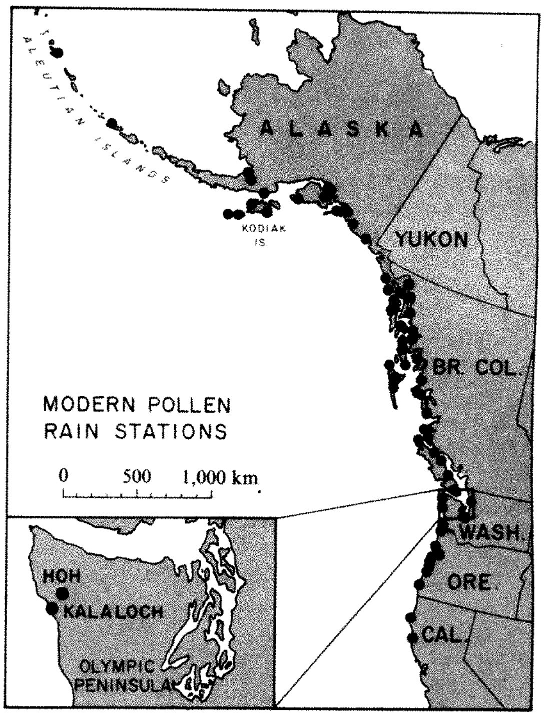

Fig. 1 Distribution of 59 composite sites on the north-west coast of North America showing where modern surface pollen was collected and the location of fossil pollen sites.

Temperate coniferous forest is the outstanding arboreal vegetation along >4,000 km of the north-west coast of North America between northern California and southwestern Alaska (36–61° N)[1,2]. In western Washington and southwestern British Columbia its leading constituents, western hemlock, Sitka spruce, and western red cedar, grow to their greatest proportions. Douglas fir and alder are widely distributed throughout this region chiefly because of disturbance. Southward into California, Douglas fir, pine and redwood rise in proportion in the communities, and a broadleaf sclerophyllous element, consisting notably of oak, tanoak, chinquapin and madrone, enters at the drier inland and southern limits of the forest. Northwestward in Alaska, the hemlock, spruce and cedar become mixed with other species, for example, mountain hemlock, Pacific silver fir and Alaska yellow cedar, which are montane-subalpine to the south. Lowland forest communities increasingly give way to muskeg and, at the same time, lose their complexity, so that on Kodiak Island and on the adjacent Alaska Peninsula, Sitka spruce alone forms the edge of the forest. Beyond this, westward to the Aleutian Islands, the forest is replaced by tundra, at first through an ecotone of shrubby alder and willow.

Optimum conditions of the maritime climate of Washington and British Columbia cause the long growing season and richness of coniferous species that are characteristic of the Pacific coastal forest in this region. Precipitation annually averages near 3,000 mm but decreases to 2,000 mm or less towards the interior; mean July temperature is ~14 °C on the coast and ~15 °C inland[3–7]. Precipitation is heaviest in southeastern Alaska–British Columbia and falls off to less than 1,000 mm in California and southwestern Alaska. July temperatures of 8–10 °C in coastal tundra rise by ~6° to ~16 °C in California.

Modern pollen rain data are for surface samples from 178 sites at <100 m in elevation located between Attu, furthest west of the Aleutian Islands in Alaska, and the vicinity of San Francisco in California. Data from the sites were consolidated in the form of 59 composite records (Fig. 1). This averaging process ensures that site data represent the broad features of the pollen rain[8]. Surface samples were mostly collected, and analysed by one of us (C.J.H.) to avoid inconsistencies in identification. Thirteen numerically important taxa selected for multivariate statistical analysis from 67 different kinds of pollen identified are pine, spruce, western hemlock, mountain hemlock, fir, Douglas fir, redwood, alder, birch, oak, grass, sedge and composite. Pollen values, percentages of the sum of the 13 taxa at each site, were row normalized and *Q*-mode, rotated principal components (factor) analysed[9]. Four resultant pollen factors, which are basically monotypic and account for 93% of the data, are western hemlock, alder, grass and pine. Although pollen rain has many sources of variation[8,10], the vegetation of the north-west coast as it varies geographically is the dominant control underlying the distribution of the pollen factors.

A stepwise regression relating the four factors to mean July temperature and annual precipitation yielded a pair of transfer functions (Table 1). Temperature and precipitation data used in calculating the equations were interpolated from 10-yr averages (1968–77) of records from 43 meteorological stations located near sea level between Attu and San Francisco[3-7]. The western hemlock and pine factors were found to be significant predictors of precipitation, and these along with the grass factor predicted temperature. Alder predicted neither variable at the 5% level of significance. The temperature and precipitation equations, respectively, have standard errors of 13% (1.1 °C) and 19% (620 mm) of the observed ranges. Plotting observed values against predicted values of temperature and precipitation show the residuals to be distributed normally.

The regression equations were applied to fossil pollen percentages (Fig. 1) obtained from a core taken in a bog in the Hoh River valley of western Washington and from a section of biogenic and alluvial sediments exposed in a seacliff some 23 km away near Kalaloch[11,12]. Pollen derived from the Hoh–Kalaloch sediments provides a continuous data base for the past ~80,000 yr. Chronostratigraphy is based on 14 ^{14}C dates reaching ~16,000 yr BP in the Hoh core and 14 ^{14}C dates extending from ~16,000 to >47,000 yr BP in the Kalaloch section.

The resulting curve of mean July temperature for the western Washington coast over the period of record shows a range from ~10 to 15 °C (Fig. 2). The modern mean of 14.5 °C differs from our best estimate of the actual mean by 0.3 °C. The high frequency fluctuations in the Kalaloch values, which partly reflect changes in rates of sedimentation in a fluvio-lacustrine complex, display two relatively warm intervals at ~60,000 and ~30,000 yr BP and the most protracted cold interval during the late Pleistocene. This latter, beginning ~28,000 yr BP and continuing until ~13,000 yr BP, was abruptly terminated by a rapid temperature increase of 3 °C. Amelioration continued until ~8,000 yr BP when temperature reached a maximum for all the time represented by the curve. Subsequent cooling after 8,000 yr BP seems to have been replaced only recently by a warming trend that continues to the present.

Application of the regression equation for mean annual precipitation to the Hoh-Kalaloch pollen data resulted in a curve with a range 1,300–2,400 mm (Fig. 2). The modern annual total is 600 mm less than that measured nearby but is within the error of estimation. Principal features of the curve are the direct relationship shown with temperature during the Pleistocene and the inverse relationship during the Holocene. The pervasive, relatively moist intervals, mostly between 2,000 and 2,400 mm, of the first 50,000 yr of record were replaced ~28,000 yr BP by an extended dry interval. Except for a brief peak in precipitation of 2,200 mm at ~18,000 yr BP, values were on the whole between ~1,300 and 1,600 mm. At the close of the Pleistocene, precipitation increased synchronously with temperature, reaching a maximum of >2,400 mm. It then decreased, as abruptly as it had increased, to a minimum of ~1,500 mm at ~8,000 yr BP which coincides with the time of the Holocene temperature maximum. Conditions of dryness and warmth ended relatively rapidly, and precipitation since has remained between ~2,200 and 2,300 mm except for a very recent drying trend.

Table 1 Transfer function equations for the north-west coast of North America

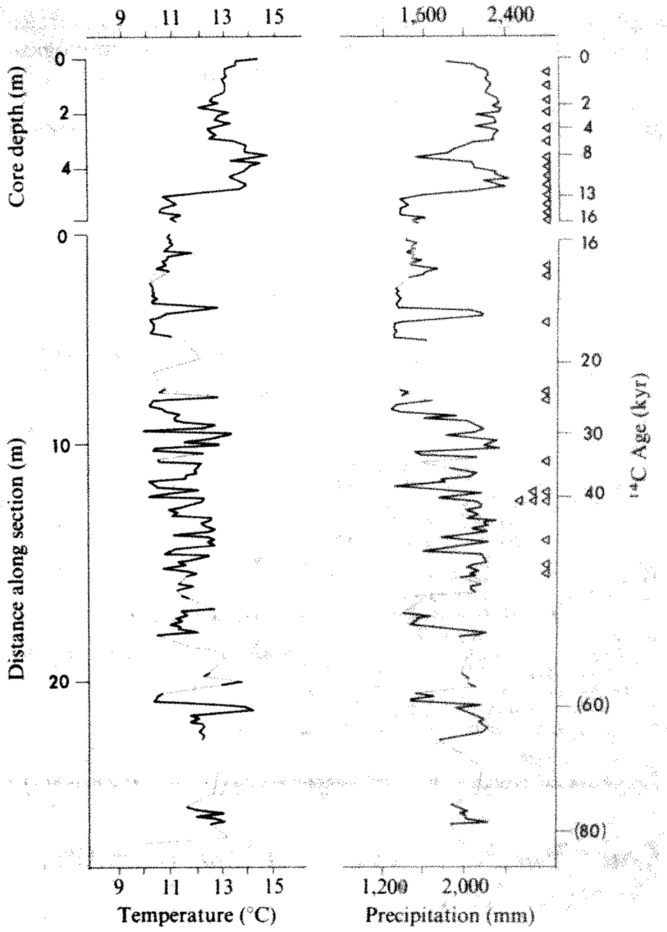

Fig. 2 Mean July temperature and annual precipitation for the past ~80,000 yr represented by the Hoh bog core (upper portion) and Kalaloch seacliff section (lower portion) in western Washington. Arrows indicate ^{14}C-dated levels; bracketed ages shown are estimates from finite ^{14}C ages and the rate of sedimentation. Dotted portions of the curves indicate samples with communalities of <0.5 which thus do not correspond strongly to the surface data set.

These results extend the application of multivariate statistics to North American Pleistocene pollen records earlier than the late-glacial. Transfer functions applied to pollen data previously yielded temperature estimates for the past 15,000 yr in Minnesota[13] and the past 5,500 yr in the Northwest Territories of Canada[14,15]. The curves generated by our data refine trends recorded for the Pacific slope of Washington on semi-quantitative grounds[16] and compare well with records of sea-surface temperature and oxygen isotope stratigraphy of the nearby continental rise[17,18]. The differences between Holocene interglacial and Pleistocene glacial modes generally agree with models of North Pacific region[19,20]. The glaciation periods during the Pleistocene were cold and relatively dry with ameliorated moist episodes intervening. During the Holocene, coolness was associated with greater precipitation, and intervals of warmth were drier. This suggests that the prevailing mechanism controlling climate on the north-west coast during the present interglaciation contrasts with the mechanism in effect during glaciation.

We thank R. F. Black and W. L. Coonrad for Alaskan surface samples, F. D. Manning for British Columbia meteorological data, and W. F. Ruddiman and J. T. Andrews for critical reviews. Goat Paddock, a crater slightly over 5 km in diameter (18°20′ S, 126°40′E), lies at the north edge of the King Leopold Range/Mueller Range junction in the Kimberley district, Western Australia (Fig. 1). It was noted as a geological anomaly in 1964 during regional mapping by the Bureau of Mineral Resources, Geology and Geophysics and the Geological Survey of Western Australia. The possibility of its being a meteorite impact crater has been discussed[1], although this suggestion was subsequently ignored[2]. Two holes were drilled by a mining corporation in 1972 to test whether kimberlite underlay the structure. Here we report the findings of five days of reconnaissance in August 1979 which established that Goat Paddock is a cryptoexplosion crater containing shocked rocks and an unusually well exposed set of structural features.

Goat Paddock is a circular plain bounded for most of its circumference by steep cliffs 100–150 m high (Fig. 2). To the north, the rim has been eroded, opening a broad connection with the valley of the O'Donnell River. To the south and east, the ground is higher and more rugged, so that a raised rim is not evident. The circularity of the rim is reduced by erosion and by the presence of remnants of crater fill within the wall. Its topography is clearly unusual but not immediately suggestive of a crater.

The two drill holes, one at the centre and one about 1,250 m north-east of the centre, penetrated 211 and 212 m of lacustrine sediments before entering brecciated sandstone. The nearly equal depths suggest the absence of a central peak, which might have been expected as the critical diameter for the transition from simple to complex terrestrial cryptoexplosion craters is 2–3 km in sedimentary strata and about 4 km in crystalline rocks[3]. The fine-grained nature of the mudstone at the base of the crater fill, immediately above untransported breccia in both drill holes does, however, suggest that there may be a moat in the outer crater floor that acted as a trap for coarse debris. The small depth/diameter ratio is closer to those of larger, complex craters than to those of smaller, simple craters[3].

The canyons eroded into and through the walls of Goat Paddock offer some of the best exposures of the upper rim wall and rim flank of any cryptoexplosion crater in the World (Fig. 2). Nearly everywhere in the walls, bedrock has been upturned from its regional dip of 15° NNW to dip away from the crater. Dips reach the vertical near the crater lip and are overturned to the horizontal or inverted outward dips on the rim flank. In some sections, the rim flank appears to be composed of moderately dipping and presumably overturned imbricate plates a hundred metres or so across which are separated by screens of breccia. Intensely disturbed rock reaches as far as 800 m from the present rim crest. At one locality, a fault surface with a dip of 75° towards the crater and with striations pitching 75° separates undisturbed sandstone from overturned sandstone (Fig. 2*b*). The sense of motion on the fault was not determined: it may be either a thrust fault or a normal fault produced by slumping of the rim into the crater. On the south rim, no overturned flap is

apparent, but the autochthonous rock is deformed into at least one open anticline (Fig. 2*c*).

The disturbed beds show a high degree of fracturing everywhere and grade into breccia inside and particularly outside the rim crest. At many breccia occurrences, attitudes of the larger clasts are close to those of nearby coherent bedrock, and the lithologies are the same, showing that little mixing or long-distance transport has taken place. On the south rim, a series of ridges ~20 m high have fractured bedrock at the base and breccia at the top. No fallout (air-sorted debris) was found on the rim, and we are uncertain whether the breccia at high levels on the rim includes throwout (debris ejected ballistically).

The true crater wall (at the edge of the upturned beds) has a slope of 35°, locally reaching 50° or more. A breccia of unoriented clasts, tentatively interpreted as autochthonous breccia is usually immediately adjacent. This generally grades over a short distance into breccia having a roughly oriented texture, which is apparently talus. Above this breccia is a well-cemented conglomerate with rounded clasts and distinct bedding. The transition is locally gradational, but more commonly conglomerate dipping 20° discordantly overlies talus dipping 35°. The conglomerate, in turn, grades into grit, interbedded grit and siltstone, and finally the mudstone of the crater floor.

Conglomerate (and breccia) occurs not only within the crater bowl but also in depressions outside the crater rim. Some of these depressions appear to be crescentic troughs concentric with the rim. In one section the entire series of overturned plates seems to be displaced outwards to produce a double rim crest, with the gap between the outer edge of upturned bedrock and the inner edge of the displaced plates filled by breccia and conglomerate (Fig. 2*b*). Other conglomerate bodies appear to be approximately radial rather than concentric, and some of the gorges seem to be exhumed from conglomerate rather than freshly eroded through bedrock. Radial conglomerate bodies may occupy zones opened during the cratering process or they may simply fill pre-cratering valleys. The local topography at the time of the cratering event was probably no less rugged than the present topography and should have affected the details of the crater form.

The level of fill within the crater is close to that of a break in slope of the original crater wall, which may be a junction of the steep wall with the gently sloping outer crater floor or with a bench between the steep wall and floor. Thus, although around most of the circumference early crater fill laps onto the wall or is concealed by fans formed during the present erosion cycle, at several points overturned bedrock crops out as far as a 350 m from the base of the cliff. A small patch of melt breccia was found in one creek between the base of the wall and the innermost bedrock outcrop (Fig. 2c). The substrate is not exposed, but apparently slopes gently, as the larger melted clasts are approximately horizontal.

The central drill hole penetrated 19 m and the northeastern hole 5 m below the crater floor. Core recovery was poor, probably because of abundant incoherent rock flour, but recovered core shows sandstone with well-developed shatter cones or with a rhombic shatter fracturing. A few fragments with poorly developed shatter cones were also found in the breccia at the crater wall. Shock features in quartz (cleavage, planar features, basal deformation lamellae, plastic deformation, reduced birefringence) are abundant in clasts from breccia outcrops. These features culminate in the melt breccia which contains, besides clasts of various lower degrees of shock, twisted sheets of vesicular silica glass, now largely recrystallized to fine-grained quartz. To date, coesite or stishovite have not been found.

More than 20 pollen or spore species were identified in a sample of sediment from a depth of 139 m in one of the drill holes. The assemblage is dominated by proteaceous-like grains. Despite differences, there are sufficient species in common to indicate a correlation with the *Malvacipollis diversus* zone of Stover and Partridge[4] in southeastern Australia and therefore a probable early Eocene age. This is supported by a very low frequency of *Nothofagidites* spp. and the association of species such as *Latrobosporites amplus* (Stanley), *Proteacidites leightonii* Stover, *P. confragosus* Harris, and *Triporopollenites ambiguus* Stover.

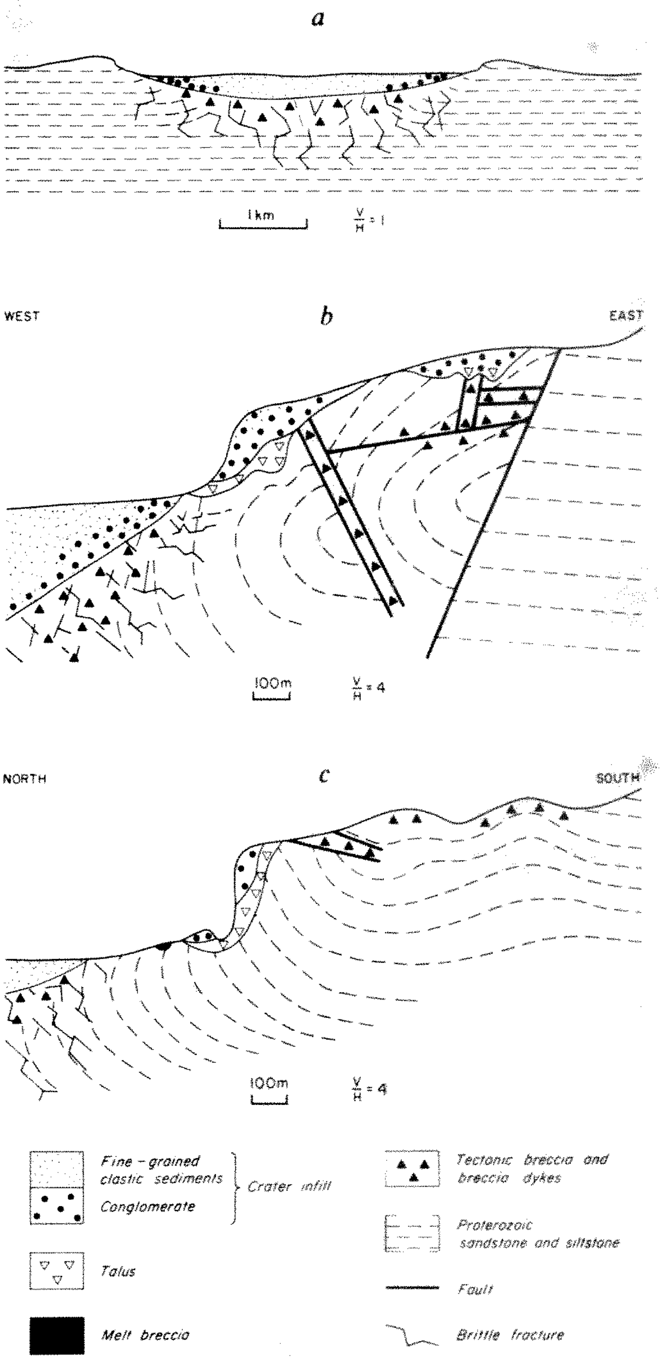

Fig. 2 Cross-sections of Goat Paddock Crater. *a*, Generalized structure; *b*, section along gorge eroded through east wall; *c*, section through south wall. Sections are based on photographs and sketches, and are hypothetical below the level of the crater floor.

The orientation of remanent magnetism in the melt breccia is normal and not significantly different from that of the present local field, but samples have not been magnetically cleaned. An Eocene orientation should be recognizable but could have been lost during weathering.

Goat Paddock is clearly a cryptoexplosion crater, of a type generally attributed to meteorite impact. Nevertheless, in the absence of meteoritic material, hypotheses of endogenous origin are defensible. The 875 m diameter Wolf Creek Crater[5,6], which is only 160 km to the south-east, is associated with oxidized meteoritic iron, although the association could be coincidental[7]. Wolf Creek seems to be less eroded than Goat Paddock, so an age as old as Eocene and a paired relationship seems unlikely although not impossible. About the same distance north-west of Goat Paddock is another cryptoexplosion structure, known as 'The Spider' (Fig. 1), which we have also briefly examined. Disturbed and shatter-coned strata occupy an area about 5 km in diameter. The structure resembles that of central uplifts of other cryptoexplosion structures and is apparently exposed at a level considerably below an original crater floor. The depth of erosion indicates an age greater than that of Goat Paddock. The Spider and probably Wolf Creek are in tectonically stable blocks, but Goat Paddock lies near the intersection of the King Leopold and Halls Creek Mobile Zone (Fig. 1), which have been intermittently active through geological time. Adjacent to the King Leopold Mobile Zone is a major province of salic alkaline igneous intrusion[8,9] dated as early Miocene[10]; this province, and an area adjacent to the Halls Creek Mobile Zone, have also recently been identified as areas of major kimberlite intrusion of unknown age.

Did Iapetus start to open during the Cambrian?

R. Anderton

Department of Applied Geology, University of Strathclyde,
Glasgow G1 1XJ, UK

The geological evolution of the British Isles during the Lower Palaeozoic was dominated by the presence of the Iapetus Ocean. Although the timing of the major events in its later history are reasonably well known, its pre-Ordovician evolution is far less clear because of the absence of rocks of that age in the area of the Iapetus suture. To deduce the early history of the Ocean, circumstantial evidence from rocks originally deposited on the adjacent continental crust is needed. Petrographical evidence, from such rocks in the Dalradian, is discussed here and implies that Iapetus had still not opened by ~670 Myr ago. A dramatic increase in tectonic instability after this date, culminating in the extrusion of the Lower Cambrian Tayvallich Volcanics, is considered to date the continental rupture that led to the formation of Iapetus. This view is in contrast to the assumption that continental break-up must have preceded the earliest Dalradian sedimentation[1] and that the red-bed fluvio-lacustrine sediments of the Torridon Group, dated at ~810 Myr, could be a consequence of this initial rifting[2].

The Dalradian Supergroup contains a virtually continuous record of largely marine deposition from the late Precambrian (sedimentation starting at least 700 Myr and possibly as long as 800 Myr ago) until the Cambrian or possibly Lower Ordovician. Within this sequence are several psammite formations that are largely composed of mineralogically mature quartzofeldspathic detritus that tells one little about its source area. However, within the middle Dalradian (Argyll Group) Jura Quartzite are occasional rounded pebbles of what was, before Caledonian metamorphism, ferruginous chert or jasper[3]. These show a range of textures typical of the oolitic and banded facies of the Proterozoic cherty iron-formations found in early Proterozoic shelf sequences. Furthermore, they are very similar to pebbles described from the Applecross Formation of the Torridon Group[4] which is known from palaeocurrent and radiometric evidence to have been derived from an area to the north-west of the present Scottish mainland[5]. The mineralogical maturity and absence of all but these very stable clasts, probably recycled from older conglomerates, suggests that the Jura Quartzite source area consisted largely of Proterozoic sedimentary rocks, with only minor first cycle input from the Archean basement. The Scottish 'Torridonian' together with the Eriksfjord Formation[6] and the Ketilidian sediments[7] of South Greenland may just be remnants of what was, in late Proterozoic times, a more extensive sedimentary cover over the now exposed Archean basement.

The similarity between the Dalradian and some of the Torridon Group pebbles, together with evidence of a clastic input from a northwesterly direction into some Argyll Group turbidite basins[8], suggests a northwesterly, largely sedimentary source for Argyll Group psammites. This source must have lain in the area of the present Scotland–Greenland continental margins although it may have stretched even further to the north-west (Fig. 1*a*).

Most lower Dalradian Appin and Grampian Group coarse-grained sediments are also composed of mineralogically mature quartzofeldspathic detritus without distinctive clasts[9] that could similarly have been derived from a largely sedimentary source area lying to the north-west throughout the late Proterozoic. The position of the Moine metasediments in this palaeogeographical picture is, however, as unclear as the status of the Moine itself. The ~750 Myr ages from Moine pegmatites have been interpreted as either the date of a 'Morarian' orogenic event[10] or Grenvillian ages partially reset by Caledonian metamorphism[11]. The lack of petrographical evidence for a nearby orogenic belt in the Appin and Grampian Groups, whose deposition probably spans the period of the Morarian event, is more consistent with the latter hypothesis. However, if the timing of the Morarian event is confirmed, its significant tectonometamorphic effects may have only been felt at depth with its palaeogeographical impact being restricted to mild uplift and erosion of the low grade top of its metasedimentary pile.

The hypothesis of a northwesterly, largely sedimentary, source could well apply to all the Dalradian Grampian, Appin and Argyll Group coarse-grained sediments except for one, the Port Askaig Tillite. This lies at the base of the Argyll Group stratigraphically below the Jura Quartzite and is correlated with the Varangian or Eocambrian tillite found throughout the Caledonian belt and dated in Finmark[12] at ~670 Myr. It contains a suite of granite clasts throughout its outcrop from Banff to Connemara, quite unlike anything found in the other psammites, and must have been derived from a largely igneous and metamorphic source[13,14]. If the area to the north-west was blanketed by Proterozoic sediments at this time, a southeasterly source is required for the Tillite as previously suggested by Howarth[14] and Spencer[15]. This is consistent with the direction of ice-pushed folds from the Tillite in Argyll[13], Donegal[14] and elsewhere in the Caledonian belt[15]. The Midland Valley landmass, which may have acted as a southeasterly source for the Southern Highlands Group[16] during the Cambrian (Fig. 1*c*) and was probably of the right composition to supply granite and quartzite clasts, would not have been large enough to nourish the extensive and persistent glaciers of Port Askaig Tillite times. Rather, the glacier source most probably lay in a more extensive area further to the south-east which, on petrographical grounds, could have been in northern continental Europe[15] (Fig. 1*b*). It is, therefore, most unlikely that there could have been an ocean basin between this presumed source and the present Dalradian outcrop at this time.

Fig. 1 Location of source areas during Dalradian times, arrows show suggested directions of main sediment influx into the Dalradian depositional area for: *a*, most of Grampian Appin and Argyll Group times; *b*, Port Askaig Tillite times; and *c*, Southern Highland Group times. Position of palaeogeographical elements drawn very schematically with respect to present rock outcrops and without any correction for tectonic shortening. Ice front drawn for one instant in time, the ice limit may have lain far to the north-west.

If Iapetus had not opened by Port Askaig Tillite times, when did it open? Before the deposition of the Tillite, there is little evidence for tectonic instability. Broad, differential subsidence can account for thickness and regional facies variations. However, after the Tillite, major syndepositional faults exerted an increasing control over sedimentation. Rapid subsidence along these faults produced turbidite basins with steep, unstable slopes as exemplified by the Scarba Conglomerate/Easdale Slates[8], Crinan Grits (A. K. Barraclough, personal communication) and Tayvallich Limestone[17]. Finally, eruption of the tholeiitic Tayvallich lavas and intrusion of sills[18] marked the peak of tectonic instability and crustal tension. The rapid basin subsidence is considered to be a precursor of rifting due to regional crustal tension with the lavas signifying the final break. An alternative hypothesis is that the tectonism and volcanism relate to back-arc spreading following the initiation of subduction. Both are considered feasible by Graham and Bradbury[19] on petrochemical grounds, but the latter is rejected here because of the petrographical evidence discussed above.

The precise dating of the suggested rifting is not possible because of the minimal fossil and radiometric control on Dalradian events. However, the base of the Cambrian probably lies not far below the Tayvallich Volcanics[20] and the Argyll Group turbidite basins range from roughly the middle of the Vendian or Eocambrian, say 640 Myr ago, onwards. A period of crustal tension leading to increasing tectonic instability after 640 Myr, culminating in volcanism and final continental break-up around 600 Myr, is therefore indicated. This is in close agreement with an end Proterozoic/Lower Cambrian age for rifting in Newfoundland, suggested originally by Bird and Dewey[21], on the basis of the stratigraphic relationships of a suite of lavas correlated with the subsequently dated ~605 Myr old Long Range Dykes[22]. This leaves only ~90 Myr for ocean expansion, about the same as the time available for closure, if subduction started in the Lower Ordovician as suggested by evidence from the Ballantrae ophiolite[23] and final (probably diachronous[24]) closure took place during the late Silurian to early Devonian[25]. At, say, a total spreading rate of 4 cm yr^{-1} this would still produce an ocean 3,600 km across, as wide as is required by available faunal[26] and palaeomagnetic[27] evidence from the Ordovician. However, the existence of well defined trilobite provinces in Britain does require the existence of an effective barrier by the late Lower Cambrian[28], possibly only 20 Myr after the suggested rifting. A faster spreading rate may, therefore, be indicated.

The hypothesis of a late opening for Iapetus has, if correct, several implications. (1) The existence and location of the area of Dalradian sedimentation were unrelated, at least in its early stages, to Iapetus. The Dalradian developed in an ensialic crustal environment[16]. (2) Continental rifting subsequently took place to the south-east of the Dalradian basin in an area of more brittle crust. There is, therefore, no stratigraphic mirror image of the Dalradian to the south-east of Iapetus, although because of the possible oblique opening and closing of the Ocean, this cannot be demonstrated until the relative positions of northern and southern Britain during the late Proterozoic are known. This uncertainty also makes it difficult to relate the evidence for late Proterozoic subduction in Anglesey, which may be more closely related to the evolution of a southerly Cadomian Ocean[29], to the Dalradian picture. (3) The direct stratigraphic evidence for the timing of rifting, such as plateau lavas, fluvial facies and salt, is not visible in the British part of the Caledonian belt, although it may be buried beneath younger rocks near the suture or have been thrust under the Dalradian during its collision with the Midland Valley microcontinent during the Grampian orogeny[30]. The presently exposed Dalradian rocks were deposited at least 100 km (possibly several hundred kilometres after allowance for tectonic shortening) away from the rifted continental edge, in a pre-existing marine basin well away from the more obvious effects of continental rupture.

Equilibrated Nd–unequilibrated Sr isotopes in mantle xenoliths

E. Jagoutz*, R. W. Carlson & G. W. Lugmair

Scripps Institution of Oceanography and Chemistry Department,
University of California, San Diego, La Jolla, California 92093

Isotopic analyses of mantle xenoliths transported to the surface by alkali basalt eruptions complement data obtained from studying basic magmas. These xenoliths also enable mantle characteristics to be examined before they have been affected by the fractionation processes which occur during magma genesis. The data on ultramafic nodules demonstrate Sr isotopic disequilibrium between mineral phases within a single xenolith[1–5]. This suggests that isotopic disequilibrium on a grain-size scale may be important in determining the isotopic composition of melts derived from the mantle. However, recent work on carefully cleaned mineral separates from alpine peridotites[6] and ultramafic nodules[2] has shown that, in many cases, the highly radiogenic $^{87}Sr/^{86}Sr$ found in minerals with low Sr concentrations (olivine, orthopyroxene) can be considerably reduced by leaching the sample in dilute acids before analysis. To investigate the nature of isotopic disequilibria between minerals of lherzolitic nodules, we report here a combined study of the Nd and Sr isotopic composition of two spinel lherzolites from New Mexico and Arizona. These samples were selected from a large number of ultramafic xenoliths for which major and trace element compositions had been determined[7]. The two nodules measured represent two end members of a distinct group of nodules which have major element compositions that would make them suitable parent materials for basaltic melts. These two nodules show no obvious signs of metasomatic alteration or re-equilibration under more than one pressure and temperature regime. Interstitial glass does not occur in either nodule investigated. Hence, the Nd and Sr isotopic composition of these nodules and constituent minerals were expected to provide important constraints on the nature of basalt source regions in the mantle in general, and, in particular, that underlying the American South-West.

Sample KH-1 is a spinel lherzolite from Kilbourne Hole, New Mexico, a recent maar-type volcano in the Rio Grande Rift. Major and trace element compositions of KH-1 were reported by Jagoutz *et al.*[7]. This sample is characterized by considerable depletion of the light rare earth elements (LREE), but still has relatively high Ca and Al abundances (2.45 and 1.89 wt % respectively)[7]. KH-1 is coarse granular in texture and, based on petrographical and chemical evidence, was defined as 'primitive'. From sample KH-1, carefully separated and cleaned clinopyroxene (cpx) and orthopyroxene (opx) separates, as well as a leached whole rock (WR) aliquot and its surface leachant, were measured.

Sample SC-1 is from the recent, xenolith-laden, alkalic magmas of San Carlos, Arizona. As reported[7], SC-1 has an almost flat relative REE pattern with many other refractory elements also in nearly unfractionated 'chondritic' relative abundances. From this sample, an acid leached whole rock aliquot and two cpx separates were analysed. The first cpx separate was subjected to the acid leaching procedure used for KH-1 mineral separates. The second cpx aliquot was more harshly etched to investigate possible zoning which may be reflected in the isotopic composition, as well as to determine the effect on the acid treatment on possible differential leaching of ^{87}Sr.

The two samples were very friable and were gently crushed and sieved to a grain size of 0.1–0.3 mm. Clean grains without visible inclusions were separated by handpicking. For the opx separate of KH-1, only grains >2 mm were taken. These grains were then washed in warm 2M HCl for 20 min in an ultrasonic bath. After a 5-min treatment with 5% HF, the samples were crushed and a fraction between 100 and 200 mesh was taken for final handpicking under a binocular microscope. This separate was leached for 5 min in 5% HF and then again washed in warm 2M HCl, followed by an ultrasonic treatment in warm 2M HCl for 20 min.

The KH-1 whole rock leach was produced by leaching an aliquant (0.9779 g) of powdered (<200 mesh) bulk rock in 2M HCl for 20 min. The HCl solution was then filtered. Weight loss in this procedure (57.9 mg) is not representative of the actual amount of material which went into solution due to the loss of a very fine-grained fraction during filtering.

Two SC-1 cpx separates were prepared by the method described above. One cpx fraction (26.8 mg) was further treated for 45 min in concentrated HF and $HClO_4$ in an ultrasonic bath. After this etching, the sample was washed with high purity water. The etching solution plus the water wash were evaporated and processed as sample 'SC-1 cpx etch'. The remaining cpx (19.3 mg) was dissolved to become sample 'SC-1 cpx residue'. Weight loss during this procedure was 7.5 mg (28%) and is believed to have been completely retained in the etch solution.

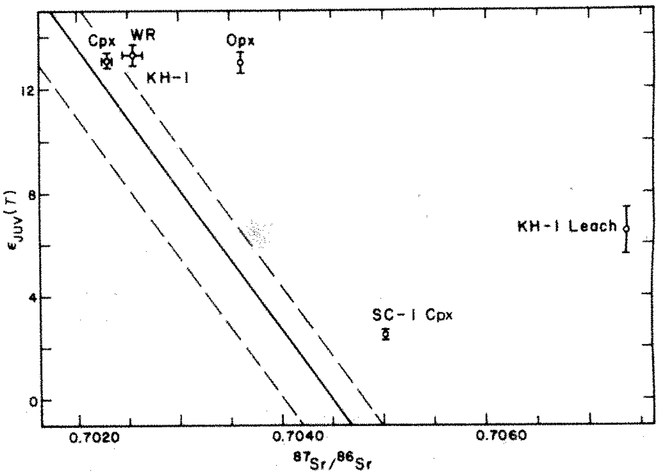

Fig. 1 $\varepsilon_{JUV}(T)$ plotted against $^{87}Sr/^{86}Sr$. $\varepsilon_{JUV}(T)$, expressed in parts per 10^4, is the fractional deviation of $^{143}Nd/^{144}Nd$ in samples from that existing in a chondritic reference reservoir. The Sr–Nd trend line observed for young basaltic rocks and the approximate range of values (dashed lines) about this trend are adopted from O'Nions *et al.*[16] and DePaolo and Wasserburg[17]. Note the observed Nd isotopic equilibration, but Sr disequilibrium in the minerals of KH-1 and the offset of the SC-1 cpx point to higher $^{87}Sr/^{86}Sr$ than found for the basalts.

Procedures for dissolution, chemical separation, and isotopic analysis have been reported previously[8,9]. Samples were totally spiked after dissolution for Sm and Nd concentration determination. Only the etched cpx separate and its leach from SC-1 were spiked for Sr concentration measurement. Blanks for Sm, Nd and Sr for the chemical procedures used were 8, 50 and 300 pg respectively.

Nd and Sr isotopic results and Sm and Nd concentrations are presented in Table 1. Distinct differences are apparent in the $^{143}Nd/^{144}Nd$ of samples SC-1 and KH-1. However, minerals within a single sample have Nd isotopic compositions which agree within analytical uncertainty. This is dramatically demonstrated in the case of KH-1 where a large spread in $^{147}Sm/^{144}Nd$ was measured for opx and cpx. On the other hand, despite the careful pretreatment of the samples, $^{87}Sr/^{86}Sr$ in KH-1 is considerably higher in opx than in cpx.

The observed equilibrium for Nd between cpx, opx (and the whole rock) of KH-1 demonstrates that Nd was in diffusive equilibrium at the time of the nodule's eruption on to the surface. These findings are similar to those reported by other workers[16–18] who found cpx and garnet to be in Nd isotopic equilibrium in garnet lherzolite xenoliths at the time of their inclusion in South African kimberlites. On the other hand, in KH-1, the measured Sr fractions derived from the different mineral separates are not isotopically equilibrated.

Possible explanations for the observed differences in $^{87}Sr/^{86}Sr$ in KH-1 could be: (1) Sr diffusion in the mantle is much slower than that of Nd; (2) radiogenic growth of ^{87}Sr since the last time of Nd equilibration; (3) residual contamination of the measured mineral phases not removed by the leaching procedure; (4) (partial) equilibration with a fluid enriched in ^{87}Sr.

Although there is no direct experimental evidence for a difference between the diffusivity of Nd and Sr, some inferences could be drawn from the diffusive behaviour of M^{3+} and M^{2+} ions and the influence of ionic radii on diffusivity in silicate melts[13]. These data suggest the importance of charge in influencing diffusivity and imply that Nd should diffuse slower than Sr. The evidence above implies that, at least in the case of KH-1, the measured differences in $^{87}Sr/^{86}Sr$ were introduced after, or at the time of, the last equilibration of the Nd system. Because of the high precision obtained in the Nd isotopic measurements and the large spread in $^{147}Sm/^{144}Nd$ between opx and cpx, an upper limit of 8 Myr can be set for the time of the last Nd equilibration. If this also records the time of the last complete Sr equilibration, then taking the extreme limit of no ^{87}Rb decay in cpx ($^{87}Rb/^{86}Sr = 0$) an $^{87}Rb/^{86}Sr = 11.6$ would be required in opx to produce the measured differences in $^{87}Sr/^{86}Sr$ between the mineral separates within the 8 Myr upper limit imposed by the Nd equilibration. This ratio is 50–100 times the actual value measured for opx from other ultramafic nodules[1,3–5]. Therefore, it seems very unlikely that the observed Sr disequilibrium is the result of *in situ* radiogenic growth of ^{87}Sr within the minerals.

Results for the surface leach of the KH-1 whole rock sample show the presence of an HCl soluble surface coating with $^{87}Sr/^{86}Sr = 0.70736$. Nd in this surface leach was very low in concentration ($<10^{-8}$g Nd per g of bulk rock) with $^{143}Nd/^{144}Nd = 0.51297$ corresponding to $\varepsilon_{JUV}(T) = +6.5$. Two sources for this radiogenic Sr component can be proposed: (1) surface contaminant deposited from the vapour phase of the host basalts in the Kilbourne Hole area. However, the observed $^{87}Sr/^{86}Sr$ in the leach is considerably higher than found for the basalts in the area[1]; (2) deposition on to the minerals of salts contained in the groundwater of the area. This is supported by the similarity in $^{87}Sr/^{86}Sr$ measured for this surface wash and that found for caliche from the Rio Grande Rift (E. Padovani, personal communication). Therefore, it follows that the disequilibrium found for $^{87}Sr/^{86}Sr$ in the minerals from KH-1 may be due to incomplete removal of this surface contaminant, or possibly even a small degree of diffusion of this Sr contaminant into the mineral grains. The effect of this contaminant would be much more pronounced for minerals with low Sr content such as opx (and olivine), but would have little effect on cpx due to its high Sr content. On the other hand, the leaching experiment performed on SC-1 cpx does not indicate the presence of any residual contaminant after the initial acid washings. However, note that, due to the very high Sr concentration of SC-1 cpx (126 p.p.m.), this experiment may not be very sensitive towards detecting residual contamination. In addition, there is no evidence from this experiment to indicate preferential leaching of ^{87}Sr by the various acid treatments.

Although the exact cause of the observed mineral Sr isotopic disequilibrium is not tightly constrained by the data presented here, it is apparent from this and previous work[10–12] that Nd isotopic equilibration between major mantle minerals (cpx, opx, garnet) is achieved on time scales which are much shorter than predicted from experimental subsolidus diffusion data.

Figure 1 displays the isotopic results as $\varepsilon_{JUV}(T)$ plotted against $^{87}Sr/^{86}Sr$. This figure and the major element data[7] indicate that KH-1, with $\varepsilon_{JUV}(T) = 13.1$, is a suitable parent material from which a magma similar in composition to mid-ocean ridge basalts could be derived. If KH-1 is representative of LREE-depleted primitive nodules in this area, then the results provide evidence for the existence of oceanic-type mantle underlying the Rio Grande Rift. A similar conclusion was reached by Reid and Woods[14], based on a major element comparison for nodules from the same area with those found at Salt Lake Crater, Hawaii.

The Sm–Nd model ages of SC-1 and KH-1 (T_{ICE}) of 814 ± 157 and 819 ± 26 Myr, respectively, are in reasonably good agreement. One explanation for this concordance is that the source for these two samples was initially depleted in incompatible elements close to 800 Myr ago from a primordial reservoir with 'chondritic' relative REE abundances. If the group of 'primitive' nodules, of which KH-1 and SC-1 are only two examples, do represent mantle samples which have rather uncomplicated differentiation histories, then these nodules can provide important constraints on the nature of the mantle. Of particular interest is that this group of nodules shows very similar major element compositions, yet has highly variable abundances of the incompatible elements. As all the radiometric systems also belong to the group of incompatible elements, the large variability in the degree of depletion of these elements in 'primitive' nodules such as KH-1 and SC-1 has profound implications for the interpretation of the isotopic data. In particular, the similar major element compositions of SC-1 and KH-1 clearly show that incompatible element mobilization can be accomplished without significant depletion in the basaltic component (that is, CaO, Al_2O_3). Therefore, the isotopic data presented here for KH-1 suggest that mantle with 'undepleted' abundances of CaO and Al_2O_3 can have Nd and Sr isotopic composition similar to that assumed for the 'depleted' oceanic mantle.

We thank H.-G. Stosch for treating the SC-1 clinopyroxenes with appropriate harshness and for many beneficial discussions. Irene Spellman typed the manuscript for which we are grateful. This work was supported by NASA grant NGL 05-009-150.

Effects of biotic and abiotic elicitors on phytoalexin metabolism in soybean

P. Moesta & H. Grisebach

Department of Biochemistry, Biologisches Institut II der Universität, Schänzlestr. 1, D-7800 Freiburg, FRG

Elicitors induce accumulation of phytoalexins in plants[1]. Recently Yoshikawa[2] concluded that biotic and abiotic elicitors act by different mechanisms. Thus a biotic elicitor, such as the cell walls of *Phytophthora megasperma* var. sojae, stimulated glyceollin synthesis in soybean cotyledons but had no significant effect on glyceollin degradation. In contrast, the abiotic elicitor $HgCl_2$ had only a slight effect on the biosynthetic activity but strongly inhibited glyceollin degradation. Here we report results which are contrary to Yoshikawa's conclusion.

Yoshikawa estimated biosynthetic activity by pulse-labelling with ^{14}C-L-phenylalanine. It is, however, not known whether uptake of this compound was influenced by elicitor treatment. For measurement of glyceollin degrading activity, cotyledons were incubated with glyceollin. The drawback of this method is that externally supplied glyceollin could be converted differently than the glyceollin in the internal pool. Because of the importance of elicitors in phytoalexin research[1], we have reinvestigated the effect of a biotic and an abiotic elicitor on glyceollin synthesis and conversion in soybean cotyledons by pulse-labelling with $^{14}CO_2$. By using high pressure liquid chromatography (HPLC) for separation of products, it was also possible to determine rate of synthesis and conversion of 3,6α,9-trihydroxypterocarpan, a precursor of glyceollin[3].

Figure 1 shows the accumulation of glyceollin (containing the three isomers[6,7]) and trihydroxypterocarpan (THP) after induction with the glucan from *P. megasperma*[5] or $HgCl_2$ as elicitor. Induction with glucan results in somewhat faster and higher accumulation of both compounds compared to the induction with $HgCl_2$. In the latter case glyceollin accumulation levels off earlier than THP accumulation. Controls with sterile cut cotyledons, treated only with buffer, contained only very small amounts of both compounds (<1 μg per g fresh weight) which could not be quantitated.

The integrated curves for the rates of synthesis of glyceollin and THP after induction with either elicitor (Fig. 2) show no significant differences between the effects of the biotic and abiotic elicitor. In both cases the rate of THP synthesis is higher than that of glyceollin synthesis. Half-times of conversion were

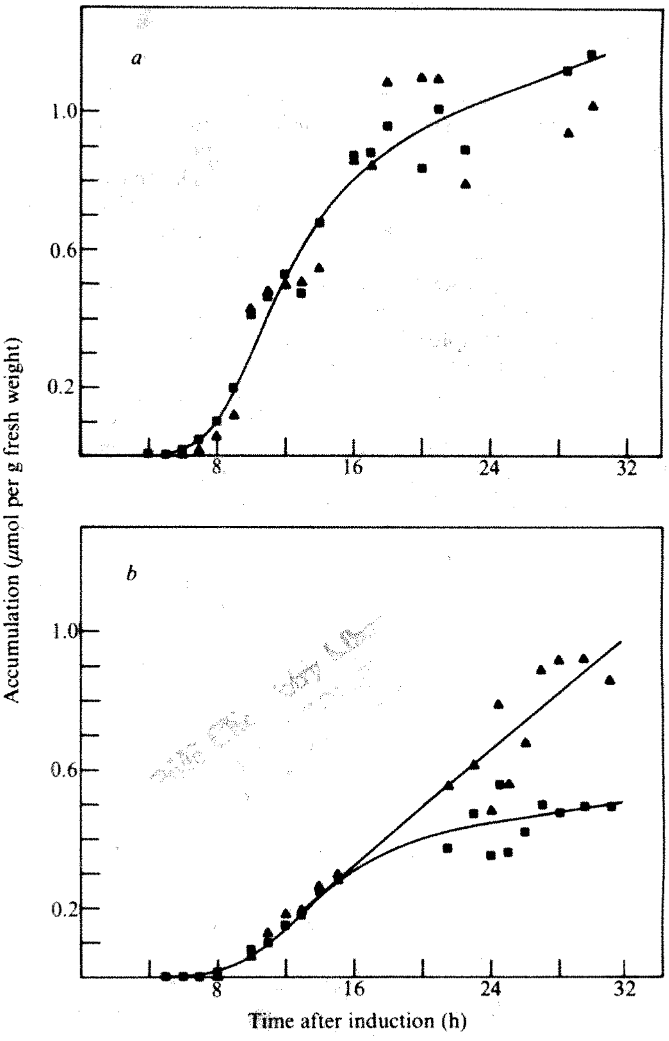

Fig. 1 Effect of glucan from *P. megasperma* and of mercuric chloride on accumulation of glyceollin (■) and trihydroxypterocarpan (▲) in soybean cotyledons. Detached cotyledons from 5-day-old seedlings of the soybean [Glycine max (L.) Merr.] cultivar Harosoy 63 were wounded as described by Ayers *et al.*[4], except that wounds were made on the lower surface of the cotyledons. An aliquot (100 μl) of an elicitor solution (*a*, biotic elicitor: heat-solubilized mycelial wall of *P. megasperma* var. sojae[5] (glucan), 300 μg glucose-equivalents ml^{-1}; *b*, abiotic elicitor: 1.5 mM $HgCl_2$) was placed on wounded areas of each of 20 cotyledons, and these were incubated on moist filter paper in Petri dishes at 30 °C in the dark. Both elicitors were used in concentrations optimal for glyceollin accumulation. At the times indicated, the cotyledons were extracted with 100 ml of 60% ethanol by vacuum infiltration for 30 min, then the ethanol was removed under reduced pressure, the remaining solution was extracted with 100 ml of ethylacetate and the organic phase dried over Na_2SO_4. After removing the solvent under reduced pressure, each sample was chromatographed on Sephadex LH-20 (30 × 2.5 cm) in methanol. Separation of glyceollin, 3,6α-9-trihydroxypterocarpan and minor isoflavonoid components was then achieved by HPLC as described by Zähringer *et al.*[3]. The pterocarpan components were quantitated with a Waters Modul 730 using an extinction coefficient of 10.000 (ref. 4).

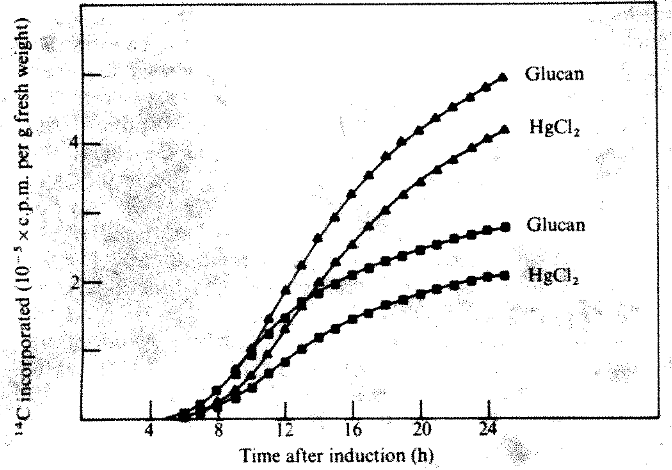

Fig. 2 Synthetic activity for glyceollin (■) and trihydroxyperocarpan (▲) production after treatment with glucan or mercuric chloride. Each set of 20 cotyledons was incubated in a 800-ml capacity gas-tight chamber with 100 μCi $^{14}CO_2$ (53.5 mCi mmol^{-1}) under illumination (Osram L 40 W/25, 9,500 lx) for 1 h before sampling. Radioactivity of the components was determined in the efflux of HPLC column with a Beckman Model LS-335 scintillation spectrometer using a toluene scintillation fluid. Radioactivity of glyceollin and THP (in c.p.m. per g fresh weight) was plotted against time after induction. For better comparison with the data obtained for accumulation, the curves were graphically integrated. Estimation of degradation activity (data not shown): 20 Petri dishes, each with 20 cotyledons, were transferred 8 h after induction with the elicitors into a 35 l chamber and were incubated under illumination with 1 mCi $^{14}CO_2$ (53.5 mCi mmol^{-1}) for 5 h. The pulse was followed by a chase phase (with illumination), in which $^{14}CO_2$ was replaced by air blown through the chamber. Twenty samples were analysed between 20 and 50 h after induction for radioactivity as described above.

obtained from pulse-chase experiments. Straight lines on semilogarithmic plots were obtained by linear regression analysis from which the following half-times were estimated: glyceollin (glucan) 112 ± 63 h; glyceollin ($HgCl_2$) 89 ± 53 h; THP (glucan) 39 ± 8 h; THP ($HgCl_2$) 36 ± 13 h. Determination of half-times in the controls was not possible due to the very low amounts of glyceollin and THP.

These results are not in agreement with Yoshikawa's conclusion[2] that biotic and abiotic elicitors have a diverse mode of action, at least in soybean cotyledons. Rates of synthesis of glyceollin and of its precursor trihydroxypterocarpan, as well as rates of conversion, are very similar with the two types of elicitors. From the relatively long half-time of conversion of glyceollin, one can conclude that accumulation of glyceollin isomers results mainly, if not exclusively, from stimulation of their synthesis by the elicitors. The rate of conversion of THP very probably represents its transformation to the 2-prenyl derivative, a potential precursor of glyceollin[3].

Our results are in agreement with the suggestion of Hargreaves[8] that mercuric chloride causes the production or release of constitutive phytoalexin elicitors. Such elicitors would be expected to have the same mode of action as externally supplied biotic elicitors.

Precocenes induce effect of juvenile hormone excess in *Locusta migratoria*

S. Fridman-Cohen & M. P. Pener*

Department of Zoology, The Hebrew University, Jerusalem, Israel

Precocene I and II (PI and PII)[1] and synthetic analogues[2–4] induce symptoms of permanent juvenile hormone (JH) deficiency in certain hemipteroid[1,5,6] and orthopteroid[7–11] insects. Younger nymphs treated with precocenes moult to precocious prothetelic nymph–adult intermediates, termed adultiforms[8], whereas treatment of older nymphs (too late for obtaining morphogenetic response) or of adults results in lack of oocyte development. The precocenes act as 'anti-allatins', causing atrophy of the corpora allata (CA)[8,12–14]. Recent findings suggest that the CA specifically metabolize precocenes to cytotoxic 3,4-epoxy-recocenes, possibly due to the epixidases present therein for JH biosynthesis; the accumulating precocene-epoxide seems to poison the glands[15,16]. This theory is supported by the claim that active CA are required for the effect of PII in *Oncopeltus*[6,17]. We demonstrate here that 7-ethoxy-PII ('Precocene III' = PIII), or PII itself, applied to last instar *Locusta* nymphs, induce an effect strictly typical of that of JH excess, in spite of eventually exerting the conventional anti-allatin effect. Our findings provide strong circumstantial evidence that supposedly inactive CA of these nymphs are temporarily activated by the precocenes, resulting in an outburst of JH biosynthesis before the glands are inhibited or destroyed.

Crowded nymphs of *Locusta migratoria migratorioides*, kept in routine conditions used in our laboratory[8], were used for the experiments. PIII (ZR 3623, Zoecon) topically applied in acetone to 0–27-h-old fifth (last) instar nymphs caused a portion of them to moult to metathetelic adultoids, that is, to sixth (supernumerary) instar nymphs with some adult characteristics, or to sixth instar nymph–adult intermediates (Fig. 1, AD). These adultoids were morphologically similar to those obtained after implantation of extra CA into early fifth instar nymphs[18,19]. Some adultoids even exhibited an extra (sixth) moult, although they died in its course, being unable to shed off the exuvium. Another portion of the fifth instar nymphs treated moulted to 'imperfect adults' (Joly's[18] 'imago imparfait'). These are adults with curled or twisted wings which occasionally (5–10%) also occur among normal locusts (controls, C in Fig. 2), usually due to external disturbances during adult emergence and/or expansion of the wings. Imperfect adults are obtained, however, much more frequently after implantation of extra CA, presumably mostly due to internal disturbances; their presence in relatively large numbers indicates a slight metathetelic effect[18]. The third portion of the nymphs moulted to morphogenetically normal adults.

With increasing doses of PIII the number of metathetelic individuals increased (Fig. 2), up to a maximum (10 adultoids and 6 imperfect adults out of 23 nymphs treated) at 50 μg per nymph. Further increase of the dose, however, resulted in a decrease of the metathetelic forms. At 500 μg per nymph metathetely disappeared; with regard to morphogenesis (but not for other effects, see below) the results were similar to those obtained in acetone treated controls. Were PIII a JH analogue, increasing doses would have eventually resulted in 100% adultoids. As a reverse trend was observed, PIII would not seem to act as a JH analogue in spite of inducing the effect of JH excess at lower doses.

The duration of the fifth instar was not distinctly affected by the dose when subsequent adultoids or imperfect adults were obtained; the respective averages for these two categories were

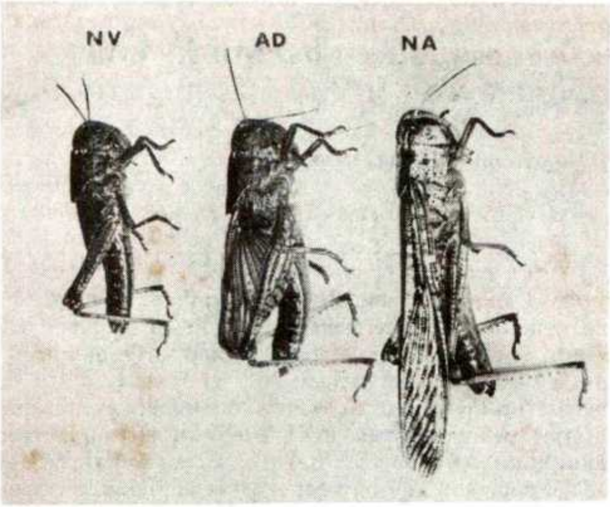

Fig. 1 Sixth instar metathetelic adultoid (AD) of *Locusta migratoria* obtained after topical application of 7-ethoxy-precocene II ('precocene III') to 0–27-h-old fifth (last) instar nymphs, in comparison with normal acetone-treated fifth instar nymph (NV) and normal (sixth instar) adult (NA).

189 (range 122–242) h and 228 (122–315) h. For morphogenetically normal adults the overall value was 245 (187–357) h, but here some dose-dependent trend was observed; with increasing doses the average duration of the fifth instar increased from 220 (187–286) h (25 or 50 μg PIII per nymph) to 275 (215–357) h (500 μg PIII). Morphogenetically normal acetone-treated controls gave 258 (215–311) h. Metathetely seems to be correlated, therefore, with shorter duration of the previous instar.

The same locusts from which Fig. 2 was obtained were maintained for 23–37 days after moult to adults or adultoids. The colour of all survivors was then recorded and the locusts were dissected; the state of the oocytes was noted in females and the CA were examined in both sexes. Lack of vitellogenetic oocytes, absence of yellow colour and atrophied CA indicated an anti-allatin effect (see ref. 8). Vitellogenetic oocytes and presence of yellow colour were sufficient for recognizing functional CA in imperfect or morphogenetically normal adults. Adultoids, however, especially with dominating larval features, often did not show signs of sexual maturation (see also ref. 18); in these cases conclusions were limited to the results of the examination of the CA. Dose–response data (Fig. 3) yielded the customary sigmoid curve, revealing that PIII did induce the conventional anti-allatin effect of the precocenes, in spite of exerting the metathetelic effect. Interestingly, 50 μg PIII per nymph, the dose which induced maximum methathetely (Fig. 2), was the closest to ED_{50} (50% of locusts with non-functional CA) for the anti-allatin effect (Fig. 3).

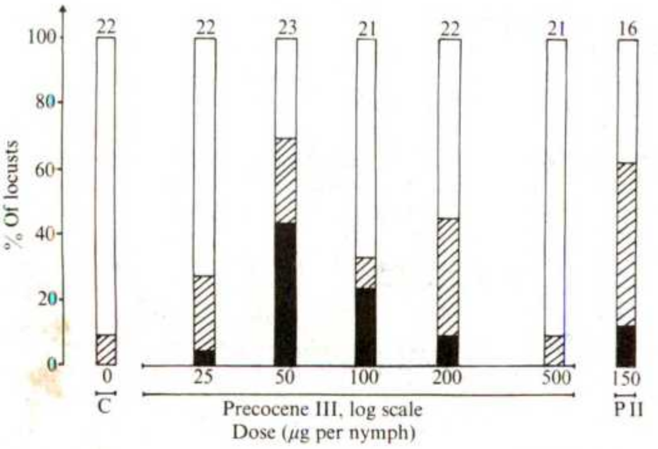

Fig. 2 Dose–response of precocene induced metathetely. 'C', acetone-treated controls: 'Precocene III' treatment with 7-ethoxy-precocene II: 'PII' treatment with precocene II. Each column represents a single experimental group. Number of locusts in each group after the next (from fifth to sixth instar) moult (constituting 100% for the ordinate) is noted on the top of each column. Mortality during the fifth instar did not exceed two locusts in any group. Filled area sixth instar adultoids; hatched area; sixth instar imperfect adults; unshaded area; sixth instar morphogenetically normal adults.

A single experiment with PII (Calbiochem) revealed that the double effect, induction of metathetely (PII, Fig. 2) and anti-allatin action (PII, Fig. 3), is not confined to PIII. Studies of dose–response relationships of PII with regard to both effects are under way.

Only JH or bioanalogues are known to induce metathetely. Since precocenes do not seem to act as JH analogues (see above), the metathetely observed by us is presumably a result of endogenous JH excess. The CA are the only known source of endogenous JH in *Locusta* and JH titre in the haemolymph is undetectable or very low in early last instar nymphs[20–22]. Thus, in accord with conventional concepts, *in situ* CA seem to be rather inactive at this time (although transplanted necessarily denervated CA may show activity, see refs 20, 23). At present the sole feasible explanation for metathetely seems to be, therefore, that PIII (and PII) directly or indirectly activates the nymphs' own CA resulting in an outburst of JH biosynthesis and release. Activated CA, however, presumably rapidly metabolize the precocenes to cytotoxic precocene-epoxides which then inhibit or destroy the glands[15,16]. Thus, precocene-induced CA activation is probably very temporary. More active CA may destroy themselves more quickly, leaving less time for JH biosynthesis. If so, with increasing doses the balance would be gradually shifted to produce less JH and more precocene-epoxide, resulting in decrease of metathetely and increase of anti-allatin effect. This reasoning exactly fits our results, including the eventual complete loss of the effect of JH excess at high doses.

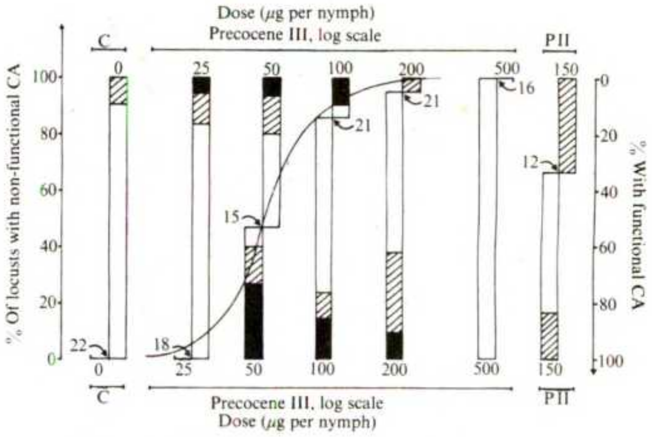

Fig. 3 Dose–response relationships of the anti-allatin effect of precocenes. Number of locusts at the examination of the anti-allatin effect (23–37 days after moult to sixth instar adultoids or adults) is noted with arrows at the meeting point of rising and hanging columns for the same dose and substance. Locusts were the same as used for Fig. 2, except for some which died (naturally, accidentally or during extra moult of some adultoids) or were lost between examination of metathetely (Fig. 2) and of anti-allatin effect. The sigmoid curve is the dose–response curve for the anti-allatin effect of 7-ethoxy-precocene II ('Precocene III'). Abbreviations and shading as in Fig. 2.

None of the adultoids or adults turned green in the present experiments. Green colour is caused by JH in *Locusta* nymphs[18,19,23], but its absence can easily be explained if precocene-induced CA activation is indeed temporary. The timing of susceptibility of the integument to JH may differ for morphogenetic and for colour effects, or alternatively, a longer lasting or continuous JH titre (but a low one, as normal solitary nymphs are mostly green without morphogenetic disturbances) may be needed for green colour induction. Both explanations can be reconciled with previous experimental findings and theoretical considerations[18,21]. If this is so, precocene-induced temporary activation of the CA may occur in other stages too, but it may not become overt. In younger instars no metathetely would be discernible and a short outburst of JH excess may be just as insufficient for inducing green colour as in last instar nymphs. Moreover, if our interpretation of the results is correct (on the basis of present knowledge of insect endocrinology no other explanation can be offered without wild speculation), differences in susceptibility of different species, or of different instars of the same species, differences in effectiveness of different methods of administration (such as topical application and residual coating methods) and eventually possible development of precocenes to insect control agents, may all be related to precocene-induced activation of the CA.

We thank Dr G. B. Staal of Zoecon Corporation for a gift of precocene III, Mr Y. Toren for keeping the locust cultures and Mr P. Amitai for taking the photograph of Fig. 1 and drawing the other figures. This research was supported by a grant from the US–Israel Binational Science Foundation (BSF), Jerusalem, Israel.

Killed *Listeria monocytogenes* vaccine is protective in C3H/HeJ mice without addition of adjuvants

Hans van Dijk, Frans M. A. Hofhuis, Els M. J. J. Berns, Cees van der Meer & Jan M. Willers

Immunology Section of the Laboratory of Microbiology, State University, Catharijnesingel 59, 3511 GG Utrecht, The Netherlands

Resistance of mice to the facultative intracellular parasite *Listeria monocytogenes* involves cellular immunity[1], as it can be transferred passively with viable lymphoid cells[2] but not with serum. Induction of protective immunity can only be achieved by vaccination with sublethal numbers of viable listeria[3,4] or with dead listeria in combination with certain adjuvants[5,6]. Killed listeria vaccines as such are not protective. Effective adjuvants are lipopolysaccharide (LPS)[5], dextran sulphate (molecular weight 500,000) and suramin[6], whereas Freund's complete adjuvant is ineffective[6]. All these polyanionic substances have a shortlived deleterious effect on macrophage function[5–7]. It seems necessary for their adjuvant activity that they be present during the induction of immunity, most probably resulting in incomplete degradation of the dead listeria within the macrophage. During the effector phase, however, the adjuvants need to be virtually absent[8,9], so that macrophages are unhampered in eliminating the infective bacteria of an eliciting listeria injection. We describe here our finding that LPS-nonresponder C3H/HeJ mice, unlike H–2 identical C3HeB/FeJ or H–2 unrelated mice, can develop resistance to a lethal dose of viable *L. monocytogenes* on a single injection with dead listeria vaccine without any adjuvant added. This suggests that the C3H/HeJ mouse has some kind of 'intrinsic adjuvant'. If present, such an intrinsic adjuvant would, in analogy to the effective adjuvants[5–7], probably be a polyanionic substance. By means of protamin precipitation[10], we have found evidence for the presence of such a substance in the serum of C3H/HeJ mice.

C3H/HeJ (H–2^k), C3HeB/FeJ (H–2^k) and BALB/c (H–2^d) mice, aged 10–14 weeks, received 10^8 heat-killed listeria or a control saline injection. The dose of 10^8 listeria was shown to be optimally protective if injected in combination with adjuvant[6]. Seven days later, protective immunity was tested by injection of $20 \times LD_{50}$ of live listeria and subsequent daily inspection of the animals for two weeks (LD_{50} = the dose resulting in 50% death of unimmunized BALB/c mice in similar conditions). None of the saline-injected mice, except for one C3H/HeJ mouse, survived the challenge with viable listeria (Table 1). Vaccinated C3H/HeJ mice, however, in contrast to BALB/c and even to H–2 identical C3HeB/FeJ mice, were significantly protected against the lethal challenge.

In view of the current ideas about the development of resistance towards intracellular parasites[6,7], our results suggest the C3H/HeJ mouse to bear a kind of intrinsic adjuvant. This adjuvant might be cell-linked, perhaps identical to the macrophage defect[11]. According to this hypothesis, defective macrophage processing would result in incomplete degradation of immunogenic elements of the dead vaccine, promoting the induction of protective immunity. During the effector phase, however, the macrophage defect of the C3H/HeJ mouse could be corrected by lymphokine production[12]. Another explanation of our findings might be that the intrinsic adjuvant of the C3H/HeJ mouse is not cell (macrophage) linked, but that it is, for instance, a soluble serum factor. As the effective adjuvants are polyanionic substances, the serum of C3H/HeJ mice was investigated for such a substance by protamin sulphate precipitation[10], and the C3H/HeJ mouse was compared with the C3HeB/FeJ and the BALB/c mouse. As Table 2 shows, a 'protamin precipitable factor' (PPF) was indeed present in C3H/HeJ serum. PPF was also found in C3HeB/FeJ and BALB/c serum, but in substantially lower concentrations.

It is possible that there is no relationship between the relatively high PPF level, the macrophage defect and other errors of the C3H/HeJ mouse, such as a defect in the early classical complement system[14], most probably residing in the C_{3b} or C_{4b} inactivator system[15]. An interesting alternative explanation is, however, that there is a relationship or even identity between the abnormalities of the C3H/HeJ mouse. In that construction,

Table 1 Resistance of the mouse strains to a lethal listeria infection after injection with a dead vaccine

Mouse (sub)strain	Injection	
	Vaccine	Saline
C3H/HeJ	24/30	1/30
C3HeB/FeJ	2/30	0/30
BALB/c	0/30	0/30

Groups of five male C3H/HeJ, C3HeB/FeJ and BALB/c mice were injected intraperitoneally with 10^8 heat-killed (60 min, 56 °C) listeria or saline. Seven days later, the animals were challenged intraperitoneally with live ($20 \times LD_{50}$) listeria. The numbers of survivors on the numbers of mice challenged were recorded for 2 weeks. Results of six such experiments are summarized above.

0028-0836/80/330713—02$01.00

Table 2 Serum levels of protamin precipitable factor

Mouse (sub)strains	PPF serum level (units ml^{-1})	*P* value (Student's *t*-test)
C3H/HeJ	291 ± 32	
C3HeB/FeJ	133 ± 20	<0.0005 (two-sided)
BALB/c	68 ± 4	$\ll 0.0001$

Groups of 20 male C3H/HeJ, C3HeB/FeJ and BALB/c mice were bled for individual sera by retro-orbital puncture at 11.30 p.m. To 20 μl of serial dilutions of these sera, 2 ml Veronal-buffered saline, *p*H 7.4, containing 0.15 mM Ca^{2+} and 0.5 mM Mg^{2+} (VSB^{++})[13] and 250 μg protamin sulphate, dissolved in 25 μl of VSB^{++}, were added. The mixture was incubated at room temperature for 20 min, whereafter the turbidity was determined by measuring the E_{450} against a serum blanco. As found for heparin, which was used as reference, a linear relationship between the serum concentration and the turbidity was observed. PPF concentrations have been expressed in equivalents of heparin units.

PPF would resemble heparin in more than one respect: heparin is easily precipitated by protamin, it is an inhibitor of several enzyme activities[16], most probably also within the macrophage into which it is easily incorporated[17]. Moreover, it mimics the effects of the C_{3b} inactivator system in preventing C_{3b}-B complex formation[18]. The identity and activities of PPF will be subject of further study.

Whatever the case, our observations on the development of protective immunity on injection with a dead listeria vaccine and on the high PPF levels in the C3H/HeJ mouse are expected to bring new insights in both the acquisition of resistance to intracellular parasites and the defect(s) of the C3H/HeJ mouse.

Mechanism of origin of complete hydatidiform moles

Patricia A. Jacobs*, Carola M. Wilson*, Joyce A. Sprenkle†, Neil B. Rosenshein‡ & Barbara R. Migeon†

* Department of Anatomy and Reproductive Biology, University of Hawaii School of Medicine, Honolulu, Hawaii 96822
† Departments of Pediatrics and ‡ Gynecology and Obstetrics, Johns Hopkins University, Baltimore, Maryland 21210

Complete or 'true' hydatidiform mole, an abnormality of human gestation, is characterized by hydropic degeneration of all placental villi, marked hypertrophy of the trophoblast, absence of a fetus and a propensity to become malignant. The chromosome constitution of complete moles is usually 46,XX[1,2], and Kajii *et al.* reported that the entire genome in seven out of seven cases was paternal in origin, with all centromere markers homozygous for paternal heteromorphisms[3]. These observations, since confirmed[4,5], can be explained by the fertilization of an 'empty' egg—no effective genome—by either a haploid sperm that then duplicates without cytokinesis, to restore the diploid number, or by a diploid sperm resulting from failure of the second meiotic division. We report here a study of a series of complete moles that shows the first alternative to be correct in the majority of cases.

Diploidization of the sperm would result in an entirely homozygous conceptus, while fertilization with a diploid sperm would give rise to heterozygosity for some of those genes heterozygous in the father and situated distal to the points of exchange. As all chromosome heteromorphisms are situated at or very near the centromere they cannot be used alone to distinguish between the two mechanisms of origin. We therefore studied the phosphoglucomutase$_1$ (PGM_1) genotypes, as well as both C and Q-band chromosome heteromorphisms of an unselected series of complete moles and their parents from Baltimore and Hawaii.

PGM_1 has two common alleles with gene frequencies of approximately 0.76 and 0.24 (ref. 6). The locus is on the short arm of chromosome 1 and maximum likelihood estimates suggest that in males it is 50 centimorgans from the centromeric heteromorphic band at q12 (ref. 7). We restricted our analyses of non-centromeric markers to PGM_1 because that is the only locus available to us (1) with a genotype that can be determined reliably in both parental blood and fetal tissue; (2) with a high frequency of parental heterozygosity; and (3) which is situated sufficiently far from the centromere to ensure frequent recombination with it.

Results for 24 moles are shown in Table 1. In 20 cases successful chromosome studies were completed on cells cultured from the mole and both parents, and in a further 4 from mole and mother alone. Twenty-one moles had a 46,XX constitution, one had an additional medium-sized chromosome in the few cells we could analyse, one had a variable count with a mode at 85,XXXX and one was 46,XY. Cultures from nine 46,XX moles were treated with 5-bromodeoxyuridine (BUdR) and the cells were stained with acridine-orange to investigate X-chromosome allocycly[8]. All nine moles had a single allocyclic X in more than 96% of metaphases examined and were thus indistinguishable from cells from normal females.

In 22 moles the centromeric heteromorphisms in all informative chromosomes appeared homozygous and clearly of paternal origin. The PGM_1 genotype of the mole and both parents was determined for 14 of these 22 moles and in a further 3 cases for the mole alone. In all 17 cases, including 6 in which the father was known to be heterozygous, the mole was homozygous. Based on gene frequencies, it can be estimated that, if the moles originated from a diploid sperm resulting from failure of the second meiotic division, 6.2 of the 17 tested moles would be heterozygous at the PGM_1 locus as would 4.0 of the 6 in which the father is known to be heterozygous. The absence of heterozygosity at the PGM_1 locus is significant both for the total number of moles tested ($P<0.001$) and for the offspring of known heterozygous fathers ($P<0.01$) and is therefore strongly supportive of a haploid sperm origin for most of the 46,XX moles.

Yamashita *et al.*[9] reported the HLA specificities of 13 moles and their parents and in 11 informative matings the moles showed no heterozygosity. However, the maximum likelihood estimate for the distance of the HLA loci from the centromere of chromosome 6 in males is only 8 centimorgans (B. J. B. Keats, personal communication). Thus HLA is an inefficient locus for determining the exact origin of 46,XX moles and in a series of 11 the expectation of heterozygosity, given an origin by failure of meiosis II leading to a diploid sperm, is only 1.8, not significantly different from the zero observed. Lawler *et al.*[10] tested five different loci in parents and moles and found the mole to be

* Heteromorphisms of chromosomes 3, 4, 13, 14, 15, 21 and 22 were studied on Q-banded preparations[12] while those of chromosomes 1, 9 and 16 were studied on C-banded slides[13]; a, b and c are symbols and do not represent specific heteromorphisms.

† PGM$_1$ genotyping was carried out on parental red cells, molar tissue and cultured fibroblasts by cellulose acetate electrophoresis[14]. In each case, the result from molar tissue assay was confirmed in cultured cells derived from the specimen.

homozygous in 18 informative tests in which the father was heterozygous. However the distribution of the 18 tests among the loci examined is not given and, as the centromere distance is not shown for many of the loci, it is not possible to determine the significance of their data, although they support a haploid origin.

Two atypical moles in our series are worthy of comment. In one, a 46,XX mole (K739), many of the centromeric heteromorphisms appeared heterozygous and comparison with the parental chromosomes showed this mole to be the product of a normal conception containing both a paternal and a maternal genome. We could not determine the origin of the single 46,XY mole (S41) because the centromeric heteromorphisms and PGM_1 observations were compatible with either a normal conception or fusion of two sperm with an empty egg, although they excluded fertilization by a diploid sperm. Observations on a 46,XY mole have been reported that suggest a paternal origin resulting from the fertilization of an empty egg by either two haploid sperm or a diploid sperm that arose by failure of the first meiotic division[11].

The observation that there are at least three mechanisms of origin for complete moles, each with different genetic implications, is important in the formulation of a hypothesis to explain the propensity of complete moles to undergo malignant transformation. It would be interesting to know whether such a propensity is a property of all three types of complete moles or whether it is restricted to, or more prevalent in, any one class.

We thank Tai Do and David Hilbert for PGM_1 assays, and Aileen Matsuyama and Irene Buchanan for culturing moles. This work was supported by grants HD 07879 and HD 05465 from NIH.

Bone-forming cell line derived from embryonal carcinoma cells

J. F. Nicolas, J. Gaillard, H. Jakob & F. Jacob

Unité de Génétique cellulaire du Collège de France et de
l'Institut Pasteur, 25 rue du Dr Roux, 75724 Paris Cedex 15, France

The use of established cell lines of various types has provided information on the properties of certain stem cells and on the conditions of their differentiation. No bone-forming cell line has so far been described. We report here the isolation, from *in vitro* differentiating teratocarcinoma cells[1], of a line which, on subcutaneous injection into syngeneic mice, gives rise to ossicles. The appearance of ossicles is preceded by the formation of a cartilaginous matrix, thus reproducing what has been described as endochondral differentiation[2]. The ossicles obtained are rapidly colonized by host marrow, are non-malignant and stop growing 2 weeks after injection of the cells. In certain conditions, however, osteosarcomas, chondroosteosarcomas and fibrosarcomas can be obtained. From these tumours, cell lines have been isolated which retain *in vitro* the properties of the cells found in the tumour.

Cell line 3/A/1D-1 was isolated from differentiated cultures of the embryonal carcinoma line PCC3/A/1 after *in vitro* differentiation[1]. These cells have a pseudo-epithelial appearance, are contact-inhibited and aligned at confluency. In electron micrographs, numerous intracisternal virus-like A particles, but no C particles, can be seen.

Two weeks after subcutaneous injection of 2×10^6 cells into 129/Sv mice, an ossicle is formed at the injection site in 50% (45/91) of the mice. The formation of these tumours has been followed by histological examination (Fig. 1*a–f*). The initial step seems to correspond to the development of primitive mesenchymal cells (Fig. 1*a*) which, after 2 weeks, give rise to chondroblasts and chondrocytes (Fig. 1*b*,*c*). These cells show the typical transformation that is observed in endochondral ossification, with mineral deposits near the surface of the hypertrophied chondrocytes and in the peripheral matrix (Fig. 1*c*,*d*). Then, foci of haematopoiesis and typical marrow appear inside the bone cavity (Fig. 1*e*,*f*). Marrow smears show classical bone marrow cells, including erythrocytic and granulocytic cells as well as megakaryocytes. The ossicles thus obtained are benign tumours; they stop growing 2–3 weeks after injection of the cells and some ossicles have been observed for 1 yr without further changes. However, within 2–4 months, fibrosarcomas frequently appear (20 out of 42 129/Sv mice observed during 6 months). These tumours develop independently of whether or not the mice form ossicles. Thus, between the 20 mice presenting fibrosarcomas, only 10 had previously developed an ossicle. Three independent fibrosarcomas were transplanted 5 to 10 times in 129/Sv. In some of these tumours, bone cells could be observed.

The manner in which the cells were injected was of importance for further development of the tumours. When subcutaneous lesions were provoked by scratching, the percentage of ossicles formed increased from 50 to 100% (41/41). Furthermore, in most cases malignant osteosarcomas and/or fibroosteosarcomas developed (Fig. 1*g*,*h*). In certain species, such as rabbit and rat, various treatments[3,4] or inert substances[5,6] are known to cause subcutaneous development of ossicles. Therefore the origin of the different elements found in ossicles formed upon injection of 3/A/1 D-1 cells was studied. First, no ossicle was ever observed in control 129/Sv mice injected with medium alone, with or without subcutaneous lesions (0/18). Therefore, the mere production of lesions is not sufficient to induce ossicle formation in mice. Second, mice from strains other than 129/Sv were injected with 3/A/1 D-1 cells. Whatever their major histocompatibility (H-2) haplotype, none developed any ossicles (0 out of 42 allogeneic injections). Even mice bearing an H-2^b haplotype (as do 129/Sv) were negative. The injection and the presence of the cells for only a few days (before allogeneic rejection) are insufficient for the development of ossicles.

To reduce the possibilities of a contribution by the host, 3/A/1 D-1 cells were injected into the eye of 129/Sv mice. In every case, the development of bone tissue could be observed. As in the case of subcutaneous injections, the process began by the appearance of mesenchymal cells, rapidly followed by chondrocytes and osteoblast cells. However, no bone marrow could be observed in these conditions.

A direct study of the origin of the different elements of the ossicles was then carried out. After injection of 3/A/1 D-1 cells into (129/Sv × C57BL)F_1 mice, marrow-containing ossicles were formed at the site of injection. The origin of the marrow cells present in such H-2^{bc}/H-2^k hybrids was studied by cytotoxicity tests with anti-H-2 sera. Bone marrow cells were found to respond to both anti-H-2.2 (which detects private specificity 2 of H-2^b) and anti-H-2.32 (which detects private specificity 32 of H-2^k) sera (Fig. 2). Thus, the majority of bone marrow cells appear to be of host origin. To study stromal cells[8,9], 3/A/1 D-1 cells were injected into (129/Sv × Rb 163)F_1 mice which carry a metacentric chromosome (9-19) as marker. The bone cavities of the ossicles obtained were flushed and the cells put in culture. Karyotype analysis of epithelial and pseudofibroblastic cells 18

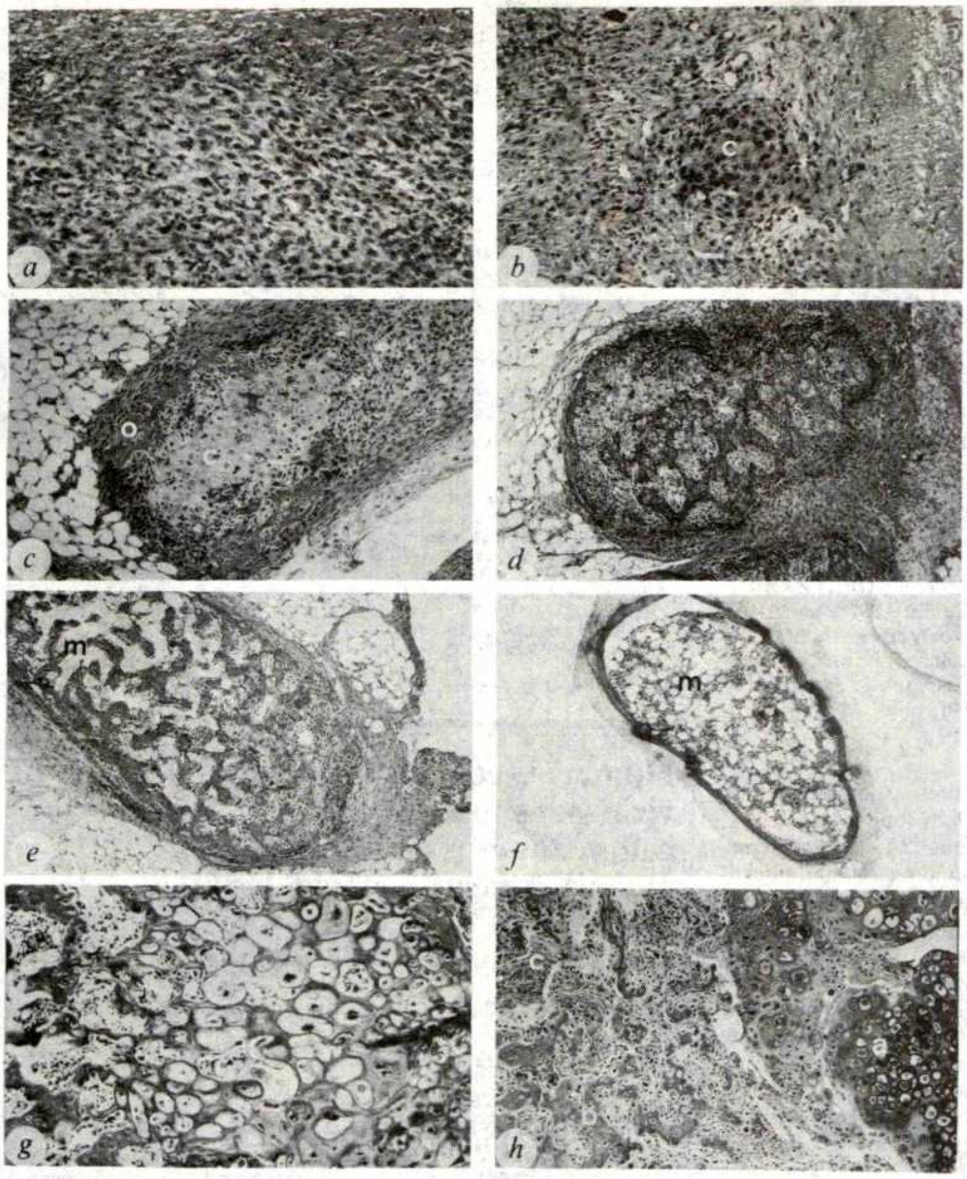

Fig. 1 Types of tumours obtained by subcutaneous injection of 3/A/1 D–1 cells. *a–f*: Ossicle formation. Detectable tumours appear 9–14 days after subcutaneous injection of cells. Final ossicle (as shown in *f*) is found 2–3 weeks after injection. *a–e* Illustrate earlier aspects of tumours dissected shortly after their appearance. *a*, Primitive mesoblast (12-day old tumour); *b*, precartilaginous nodule (10-day old tumour); *c*, ossification (o) at the periphery of cartilage (c) (10-day old tumour); *d*, trabeculation of the bone (13-day old tumour); *e*, formation of medullar cavity (14-day old tumour); *f*, mature ossicle with marrow (transversal section, 60-day old tumour); *g*, *h*, malignant proliferation; *g*, abnormal cartilage (45-day old tumour); *h*, osteochondrosarcoma. a, cartilage; b, trabecular bone; e, mesenchyme (90-day old tumour). Cell line 3/A/1 D–1 was isolated from embryonal carcinoma cell line PCC3/A/1 after *in vitro* differentiation[1,7]. 2×10^6 PCC3/A/1 cells were plated on tissue culture Petri dishes (Falcon, diameter 10 cm) and kept at confluency. 25 days later, various types of mesodermal derivatives were apparent. The cells were dissociated with 0.05% trypsin and replated at different densities. One week later the culture medium was replaced for three days by a medium enriched in KCl (1 M final), a treatment found to kill selectively embryonal carcinoma cells. After several weeks, surviving differentiated cells stopped growing. Two months later some clones began to multiply. One of these was isolated and recloned. It was called 3/A/1 D–1. The cells were cultivated in Dulbecco's modified Eagle medium (DMEM) with 15% fetal calf serum (Gibco). Cells were maintained at high density (not below 10^4 cm^{-2}) and replated every 2 days after mild treatment with trypsin (0.05%). To obtain benign bone formation (F), 10^6 to 5×10^6 cells were injected subcutaneously into mice (in a total volume of 0.5 ml of DMEM). Tumours appeared not later than 2 weeks after injection, in 50% of injected mice. No delayed appearance of bone was observed in the negative mice. To obtain malignant growth (*g*, *h*), lesions have to be provoked by scratching at the time of cell injection. In this case, 100% of the mice present an irregular ossicle after 2 weeks. In the majority of cases, this ossicle continued to grow (*g*, *h*) and was found to be transplantable.

Table 1 Origin of osteosarcomas and fibrosarcomas obtained in F_1 (129×C57BL) as shown by reinjection into parental mice

	No. of mice developing tumours		
	No. of mice injected		
	F_1 H-2^{bc}/H-2^k	129/Sv H-2^{bc}/H-2^{bc}	C57BL H-2^k/H-2^k
Osteosarcoma			
1903	2/2	2/2	0/2
1860	2/2	2/2	0/2
1969	3/3	3/3	0/3
2055	2/2	2/2	0/0
Fibrosarcoma			
1738	2/2	2/2	0/2

The tumours were dissected and dissociated by mincing with scissors in DMEM + 1% fetal calf serum. They were reinjected subcutaneously or subcutaneously and intraperitoneally using a needle of 0.8 mm diameter. The injected mice were males approximately 8 weeks old.

days after the beginning of the culture showed the presence of both host cells (39 chromosomes, 1 metacentric and 78 chromosomes, 2 metacentrics) and 3/A/1 D–1 cells (75 chromosomes, no metacentric) (Fig. 3). The latter cells behave like established cells and continue to proliferate when femoral marrow control cultures have stopped growing. A cell line (3/A/1 D–1 M) has been re-isolated from these cultures. After subcutaneous injection of such cells into 129/Sv mice, a typical ossicle colonized by marrow cells is formed. Osteosarcomas, however, have never developed from these ossicles. Similar behaviour has been observed with a 10-month old ossicle of a 129/Sv mouse. Thus, even long after the formation of the ossicle, cells derived from 3/A/1 D–1 that conserve certain of their properties can be isolated among stromal cells of the bone.

The origin of the bone cells found after injection of 3/A/1 D–1 cells into a mouse cannot be studied directly in the ossicles formed. However, it can be reasonably assumed that the osteochondrosarcomas that are frequently formed when lesions are provoked at the site of injection have the same origin as the bone cells of ossicles. Thus, we have investigated the origin of osteochondrosarcomas obtained in (129/Sv×C57BL)F_1 mice. If derived from F_1 mice, these tumours should be rejected by

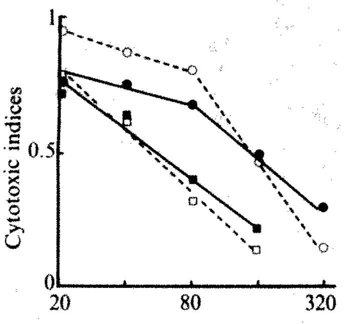

Fig. 2 Origin of ossicle marrow cells found in F_1 mice: cytotoxic effect of anti-H-2^b and anti-H-2^k sera. Cytotoxicity experiments were carried out as described in Artzt *et al.*[10]. Cell viability was estimated by trypan blue exclusion. Marrow cells from the ossicle were obtained by flushing the bone cavity with DMEM+5% immunoglobulin precipitated treated serum (IPT, Gibco). The cells were centrifuged, washed and red blood cells were lysed with a solution of ammonium chloride (0.87% in H_2O). After one additional centrifugation, cells were finally resuspended in Hank's+4% IPT at 10^6 cells ml^{-1}. The anti-H-2^b serum (B10D2×A)F_1 anti-B10A (2R) recognizes only private specificity 2. The anti-H-2^k serum (B10A×A) anti-B10K recognizes only private specificity 32. These two sera are a gift of Dr D. Schreffler. ●, Anti-32 serum and ■, anti-2 serum on ossicle marrow cells; ○, anti-32 serum and □, anti-2 serum on lymph node cells.

129/Sv and C57BL mice. However two tumours obtained in F_1 could be successfully transplanted in 129/Sv (but not in C57BL mice (Table 1). In several transplantations (5 to 15 transfers), these tumours retained their osteochondrosarcoma nature. Cells of one of these tumour lines have been established in culture (3/A/1 D-1 T°). The cells are not contact-inhibited; they have an aneuploid karyotype different from that of 3/A/1 D-1 (Fig. 3). Electron microscopic analysis reveals the presence of A-type virus particles (like in 3/A/1 D-1). When injected into mice, these cells always produce osteochondrosarcomas, even after conversion into the ascitic form.

A similar analysis was done with some of the fibrosarcomas which develop when 3/A/1 D-1 cells are injected without scratching. Like the osteosarcomas, these tumours are derived from injected cells (Table 1).

In conclusion, when injected into compatible mice, 3/A/1 D-1 cells induce the formation of a structure very similar to normal bone and/or osteochondrosarcomas. All the available evidence supports the hypothesis that the bone cells are formed directly from 3/A/1 D-1 cells. Although not completely excluded, the alternative hypothesis, that is, that 3/A/1 D-1 cells induce host cells to differentiate into bone, seems unlikely.

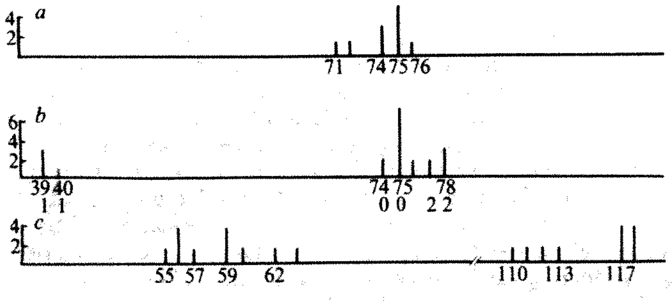

Fig. 3 Karyotype analysis of 3/A/1 D-1 (*a*), of stromal cells from ossicles obtained in (129/Sv×Rb 163)F_1 after 18 days in culture (*b*), and of 3/A/1 D-1 T° cells (osteochondrosarcoma cells) (*c*). Mitotic figures were obtained as described in Rothfels and Siminovitch[11]. Rb 163 refers to strain Rb(9-19) 163 Harwell, carrying a robertsonian fusion of chromosomes 9 and 19. The number of such metacentric chromosomes is given under the number of chromosomes (lower part).

The host, however, contributes to the marrow cells which populate the ossicle. In certain conditions, malignant cells can be selected *in vivo* from such tumours. These cells may (osteochondrosarcoma) or may not (fibrosarcoma) express chondrocyte and bone potentialities. They probably derive from pre-existing variants of the cloned cells and are selected in unknown conditions. All these cell lines provide valuable model systems for the study of normal and abnormal behaviour of osteogenic cells.

Human T-cell cultures from virus-sensitized donors can mediate virus-specific and HLA-restricted cell lysis

K. K. Sethi, I. Stroehmann* & H. Brandis

Institut für Med. Mikrobiologie und Immunologie, Universität Bonn, 5300 Bonn-Venusberg, FRG

Human cells infected with viruses such as herpes simplex virus (HSV) or Epstein–Barr virus (EBV) become susceptible to the lytic action of a distinct population of lymphocytes termed natural killer (NK) cells present in the blood of normal (sero-negative) and sero-positive individuals[1,2]. Although NK cells probably represent a subset within the T-cell lineage[3,4], they are apparently not restricted in their lytic activity by the major histocompatibility complex (MHC) determinants as are most cytotoxic T lymphocytes (CTLs; ref. 5), but can potentially lyse a variety of unrelated virus-infected[6] or uninfected cultured cells[4,7]. In studies with murine models, it has been demonstrated that HSV[8,9] or murine cytomegalovirus (MCMV) specific[10,11] CTLs show the phenomenon of H-2 restriction initially described by Doherty and Zinkernagel with the LCM virus system[12], which is that the CTLs and targets must share H-2K or H-2D products. However, studies in man have not demonstrated the existence of HSV- or human cytomegalovirus (HCMV)-specific CTLs showing HLA (human analogue of mouse H-2) restriction in their lytic activity towards virally infected targets. We demonstrate here that T cells from the peripheral blood of patients recently cured of HSV or HCMV infections, when triggered *in vitro* with specific antigen and grown as long-term cultures in the presence of T-cell growth factor (TCGF), can mediate virus-specific and HLA-restricted lysis of virus-infected targets. We believe this to provide the first evidence that HLA-restricted and virus-specific T-cell mediated cytotoxicity can be demonstrated in human–HSV and HCMV systems. These HSV- or HCMV-specific CTLs could be important in limiting the *in vivo* spread of the respective viruses and/or in the pathogenesis of the disease caused by them.

Data are presented for eight blood donors; three of them (Ar, Ru, Se) had very recent (15 days–2 months) histories of herpes labialis; three (Ki, Nn, Tr) had recovered from recent (1–2 months) CMV pneumonitis and two (Me, Nk) were hospitalized for infectious mononucleosis. PBLs from heparinized blood of each donor were isolated on Ficoll–Hypaque (Lymphoprep; Nyco) gradients[13]. Washed PBL suspensions were prepared in growth medium (GM) containing RPMI 1640 (Flow), 20% heat-inactivated human serum (sero-negative for HSV, CMV and EBV), 25 mM HEPES buffer, 200 mM glutamine, 5×10^{-5}M 2-mercaptoethanol and antibiotics Aliquots (5 ml) of 10×10^6 fresh or cryopreserved PBLs sensitized to each particular virus were mixed with UV-ray inactivated samples (0, 1 μl) of specific virus (10^6 plaque-forming units (PFU) of HSV-1 strain Thea, 10^6 PFU of MCMV strain AD 169 or 100 μl of EBV obtained as stock virus from Dr Roggendorf, University of Munich). After 5 days at 37 °C in a humidified atmosphere with 5% CO_2, T cells were separated from stimulated PBLs as previously described[14,15]. Briefly, washed suspension (10^7 cells ml^{-1}) was added to equal volumes of 2% washed SRBC and normal human serum pre-absorbed with SRBC. After centrifugation at 50g for 5 min, the mixture was layered on Ficoll–Hypaque, incubated at 4 °C for 30 min and then centrifuged for 30 min at 200g. Rosetting cells, that is, the T-cell enriched population, were sedimented with SRBC which were subsequently lysed by hypotonic shock and the remaining cells suspended in GM. These stimulated T cells were maintained in long-term cultures by seeding 10^5 cells in individual wells of 24-well Costra tissue culture dishes with GM plus 20% TCGF (1.5 ml $well^{-1}$). TCGF was prepared as described elsewhere[16,17]. Briefly, PBL (5×10^6 ml^{-1}) from normal donors were cultured with PHA (1 μg ml^{-1}) in a total volume of 5 ml GM. After 48 h at 37 °C, the cell-free supernatant was filtered (0.22 μm Millipore filter) and stored (−20 °C) until required. T cells maintained in TCGF had increased in density after 5–7 days and were split at 1×10^4 cells ml^{-1} in fresh GM–TCGF. On days 15–45, the cells were washed and used as effectors in cytotoxicity assays. As targets, secondary human skin monolayer cultures from HLA-typed individuals were prepared in 25-cm flasks and inoculated with 5 PFU per cell of HSV or MCMV. After virus adsorption (37 °C for 1 h), the monolayers were washed and fed with GM containing 100 μCi $Na_2{}^{51}CrO_4$. Mock-infected cultures were incubated with ^{51}Cr as usual. After 4 h (HSV-infected) or 8 h (HCMV-infected) monolayers were disaggregated by 0.25% trypsin, washed and suspended in GM. Aliquots (100μl; 10^4 cells) of test targets were mixed in round-bottomed plastic tubes with 100 μl ($2-5\times10^5$ cells) of appropriate effectors. After centrifugation (50g for 10 min) the tubes were incubated for 4 h at 37 °C. The tubes were recentrifuged (400g for 10 min) in the cold and, from each tube, 100 μl of supernatant was collected and counted in a γ counter. The results are expressed as % specific ^{51}Cr release according to the formula: $100\times(E-S)/(M-S)$, where E = release in test, S = spontaneous release in medium alone, M = maximum radioactivity releasable in c.p.m. in 1% Triton. During the 4-h assay period the leakage of ^{51}Cr from HSV- or CMV-infected or uninfected targets in the presence of medium alone ranged from 8–12% of detergent-releasable counts. Since standard errors of triplicates seldom exceeded 3% they are omitted from the data.

* HLA-A/B antigens shared with effectors are underlined.

† Patients sensitized to HSV were negative for HCMV and vice versa.

Heparinized blood was obtained from selected donors sensitized to HSV-1 (three subjects), HCMV (three subjects) and EBV (two subjects). Peripheral blood mononuclear leukocytes (PBL) were purified over Ficoll–Hypaque density gradients by centrifugation[13]. Freshly isolated or cryopreserved PBL samples from sensitized donors were stimulated with specific antigen for 5 days *in vitro*. The activated T cells were separated by rosetting with sheep red blood cells (SRBC) as described previously[14,15]. T cells collected from each individual were maintained in long-term proliferating cultures using TCGF obtained as 48-h supernatant from phytohaemagglutinin (PHA; Wellcome)-stimulated normal PBL[16,17]. After 20–45 days of *in vitro* culture, the proliferating T cells of each donor were tested for lytic activity against selected panels of HSV or HCMV infected targets in a 4-h ^{51}Cr release assay (all attempts to detect the presence of immunoglobulin-producing cells in these cultures failed). In initial experiments, target cells were prepared by stimulating normal PBL from individual donors for 4 days with PHA (T blasts). The T blasts were then infected with virus and simultaneously labelled with ^{51}Cr. However, when the effectors were titrated against such targets, the level of spontaneous ^{51}Cr release was very high (up to 25%). Because of this drawback (although it had no significant influence on the interpretation of the results), human skin fibroblast cultures were established from HLA typed individuals by a standard procedure[18], infected with HSV-1 or HCMV, labelled with ^{51}Cr and then used as targets.

Table 1 shows that long-term T-cell cultures originating from three HSV sensitized individuals (Ar, Ru, Se) exerted reproducibly strong lytic activity towards HSV-infected but not

HCMV-infected autologous or HLA-A/B related fibroblast targets when assayed at an effector-to-target cell ratio of 50 : 1. Conversely, cultured T cells from three donors (Ki, Nn, Tr) sensitized to HCMV exerted a high level of lytic activity towards HCMV- but not HSV-infected autologous or HLA-A/B-matched targets. Freshly isolated PBL from sensitized donors or those stimulated *in vitro* with specific antigen for 5 days showed lytic activity towards virus-infected targets but this was not HLA restricted (data not shown). Apparently, for the generation of virus-specific and HLA-restricted secondary CTLs, the growth of specific antigen-triggered CTL precursors in nonspecific TCGF was mandatory. Controls, in identical conditions, proliferating long-term T-cell cultures from two donors sensitized to EBV showed no preferential HLA-restricted lysis of HSV- or HCMV-infected targets; these T cells, however, could lyse EBV-infected autologous or HLA-matched B blasts to very high levels (unpublished data). Generally, T cells from normal donors (seronegative for HSV and HCMV) were difficult to maintain in continuous cultures. However, T cells from two selected sero-negative donors could be established as long-term cultures but these, although highly efficient in mediating nonspecific lysis of targets, showed no evidence of virus specificity and HLA restriction (data not shown).

It is obvious (Table 1) that both HSV- and HCMV-sensitized T-cell cultures could mediate low but significant levels of cytotoxicity against homologous virus-infected and HLA-A/B-different (unmatched) targets. However, the amounts of ^{51}Cr released in these instances are no greater than the values when the same effectors were titrated against heterologous virus-infected targets. In separate experiments (data not shown), blocking attempts with cold HSV-infected or HCMV-infected HLA-matched fibroblasts gave a reduction in cytotoxicity against specific targets, which paralleled that ascribed to virus-specific CTLs; the amount of ^{51}Cr released due to NK cell activity being unchanged.

The above observations imply that even though the bulk of lytic activity exerted by long-term cultured T cells from HSV- or HCMV-sensitized donors was virus-specific and HLA-restricted, they also sometimes display significant nonspecific NK-cell-like activity. From the data it can be visualized that lowering the E : T cell ratio to 20 : 1 tended to eliminate the nonspecific lysis of targets and thereby gave generally low but exclusively virus-specific and HLA-restricted lytic values. We are now attempting to clone the long-term cultures of T cells containing potentially virus-specific and HLA-restricted CTLs in an attempt to study in detail the role of HLA-A and/or -B specificities in the recognition phenomenon.

In human–viral systems, HLA restriction of CTL-mediated cytotoxicity has been previously reported to occur only against influenza[19,20] and measles[21,22] virus infected cells. The issues of specificity and HLA restriction in the EBV system is still unresolved[23,24]. The cytotoxicity data presented here have revealed HLA restriction of lysis mediated by secondary HSV- or HCMV-specific long-term T-cell cultures. However, because of the small number of sensitized donors used for establishing virus-specific T-cell cultures, one might question whether the HLA-restricted lysis mediated by them is a general phenomenon or, as in the case of the influenza virus system[25], donors carrying certain HLA gene product(s) lack the ability to generate virus-specific CTLs. This aspect is under investigation. Some data have been obtained (K.K.S., manuscript submitted), which suggest that for the *in vitro* generation of secondary HSV or HCMV-specific CTLs, human Ia-like HLA/D antigens have an essential role. The precise reason(s) for the failure to demonstrate the presence of virus-specific and HLA-restricted CTLs in *in vivo* situations during primary or secondary infections remains unclear; it is probably not due to the lack of development of CTL precursors during primary virus infections. In this connection, it has been shown in the mouse–HSV model[26] that the generation of CTLs is prevented by suppressor cells which can be eliminated by treatment of animals with cyclophosphamide.

IgM-autoantibodies against isologous erythrocytes also react with isologous IgG(Fc)

David A. Cunliffe & K. O. Cox

School of Biological Sciences, Flinders University of South Australia,
Bedford Park, South Australia 5042, Australia

The mechanisms by which the adaptive immune system of animals discriminate between foreign and self components are not known. It is generally believed that antibodies are produced only in response to foreign agents. However, against this axiom there is mounting evidence that normal animals produce autoantibodies against a variety of self components[1–6]. In two murine model systems, a high proportion of IgM-producing cells secrete autoantibodies. In one model, the autoantibodies are specific for isologous mouse IgG(Fc)[5] and in the other, the autoantibodies are specific for antigens revealed on the surface of mouse erythrocytes (RBC) by proteolytic enzymes[6]. The function of these two autoimmune responses is a mystery. Here we show that the two responses are related. The lysis of mouse RBC, modified with bromelain (brom), by IgM autoantibodies was completely inhibited by isologous IgG(Fc), and antibodies against mouse IgG(Fc) formed precipitin bands with solubilized membranes from mouse RBC. We conclude that mouse RBC membranes and IgG(Fc) have at least one antigenic determinant in common and that this determinant is the target for autoimmune responses in normal mice.

Plaque-forming cell (PFC) assays of mouse spleen cells secreting antibodies were performed by the liquid monolayer system of Cunningham and Szenberg[7]. The methods for modifying RBC with brom and for estimating the haemolytic activity of sera for mouse brom RBC have been described elsewhere[8]. The low levels of circulating IgM directed against mouse brom RBC in normal mice were increased by injections of lipopolysaccharide (LPS), an established polyclonal B cell activator[9].

The possibility of an antigenic relationship between mouse IgG and mouse brom RBC was first noted in an assay for the haemolysis of mouse brom RBC. Antisera against mouse brom RBC were collected from mice 4 days after an intraperitoneal injection of 40 μg of LPS. Incubation of the antisera with mouse IgG before adding the target RBC reduced its haemolytic titre from 512 to less than 2 (Table 1). The inhibition of haemolysis

0028–0836/80/330720—03$01.00

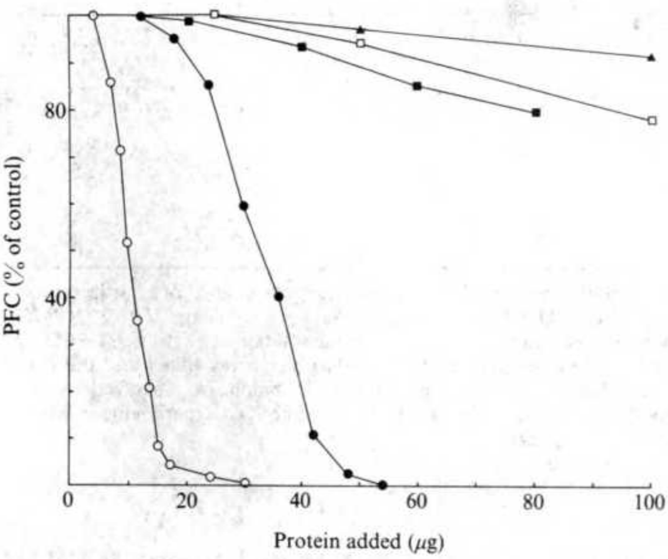

Fig. 1 The inhibition of PFC by isologous IgG(Fc). The effect of IgG on PFC directed against three target RBC, mouse brom RBC, sheep RBC and rat RBC, was measured. To lyse mouse brom RBC, spleens were collected from normal mice while for the latter targets spleens were collected from mice 4 days after an intraperitoneal injection with either 0.2 ml 6% sheep or rat RBC. The PFC assay was performed using a reaction mixture with a final volume of 200 μl[8]. Rabbit serum was used as the complement source for all assays. PFC against mouse brom RBC; ●, +IgG; ○, +IgG(Fc); ■, +IgG(Fab); PFC against sheep RBC: □, +IgG; PFC against rat RBC: ▲, +IgG. The 100% values were 9,000 PFC/spleen against mouse brom RBC; 88,000 PFC/spleen against sheep RBC and 34,000 PFC/spleen against rat RBC.

Table 1 Inhibition by mouse IgG of the haemolysis of mouse brom RBC

Antibody source	Target RBC	Protein added Identity	Amount (μg)	Haemolytic titre
Mouse anti-rat RBC sera	Rat RBC	—	—	128
		Mouse IgG	50	128
Mouse anti-sheep RBC sera	Sheep RBC	—	—	512
		Mouse IgG	50	256
Mouse anti-mouse brom RBC sera	Mouse brom RBC	—	—	512
		Mouse IgG	50	<2
IgM fraction of mouse anti-mouse brom RBC	Mouse brom RBC	—	—	1,024
		Mouse IgG	50	<2
		Rabbit IgG	100	256
		Guinea pig IgG	100	512
		Human IgG	100	1,024
		Mouse IgG_1	50	<2
		Mouse IgG_{2A}	50	<2
		Mouse IgG_{2B}	50	<2
		Mouse IgG(Fc)	20	<2
		Mouse IgG(Fab)	100	256

The antisera specific for mouse brom RBC, sheep RBC and rat RBC were collected from groups of five mice, 4 days after mice in each group had been injected intraperitoneally with 40 μg LPS or 0.2 ml 6% sheep RBC or 0.2 ml 6% rat RBC. The IgM fraction was prepared from 10 ml of mouse anti-mouse brom RBC sera by $(NH_4)_2SO_4$ precipitation, followed by chromatography on sepharose 6B. The IgG component of the fraction was then further reduced by passage through a protein A-sepharose CL-4B column[14]. The mouse IgG subclasses and fractions of IgG from mice, guinea pigs, rabbits and humans were each prepared from individual pools of sera (10 ml) using protein A-sepharose CL-4B (ref. 14). The Fab and Fc fragments were prepared by papain digestion of serum IgG (ref. 15). Undigested IgG was removed by chromatography on sephadex G100 and the Fab and Fc fragments separated using protein A-sepharose CL-4B. The assays were performed by incubating 50 μl of the required antibody source with 50 μl of PBS containing the appropriate IgG for 30 min at 37 °C. After the addition of 5 μl of 10% RBC as indicated and 10 μl of rabbit serum (source of complement), the incubation was continued for a further 30 min at 37 °C. The haemolytic titre was recorded as the final dilution in which complete lysis of the RBC occurred.

was not due to an anticomplement effect because the haemolytic activity of mouse antisera directed against either rat or sheep RBC was not inhibited by preincubation with mouse IgG (Table 1). The failure of the IgG in the antiserum to inhibit the haemolytic activity against mouse brom RBC is puzzling. The concentration of IgG relative to that of specific antibody may be critical.

The inhibition, by mouse IgG, of haemolysis of mouse brom RBC was further examined using an IgM fraction prepared from the sera with specificity for mouse brom RBC. The IgG content of the fraction was reduced by affinity chromatography. Table 1 shows that the haemolytic activity against mouse brom RBC was inhibited by isologous IgG of various subclasses and by IgG(Fc) but not by IgG(Fab) or by heterologous IgG. These results are compatible with the reactivity of mouse IgM antibodies specific for isologous IgG[5,10].

Mouse IgG was also used to inhibit antibodies against mouse brom RBC secreted by cells in a PFC assay (Fig. 1). The effector cells were prepared from the spleens of normal mice. The inhibition was not due to a cytotoxic or anticomplement effect because PFC assays using sheep or rat RBC as targets for spleen cells from mice immunized with either RBC type were relatively insensitive to the addition of mouse IgG. Again it was shown that IgG(Fc), rather than IgG(Fab), inhibited plaque formation.

The results presented in Fig. 2 provide direct evidence of at least one antigenic determinant being common to both mouse RBC membranes and IgG(Fc). Triton-soluble extracts of membranes prepared from either normal or brom-modified RBC[11] contained a component that reacted with rabbit antiserum specific for mouse IgG(Fc). Significantly, there was no line of precipitation between an antiserum specific for mouse IgG(Fab) and the two membrane preparations. Thus it seems very unlikely that the precipitin band between RBC membranes and anti-IgG(Fc) was due to the non-specific association of IgG with the RBC.

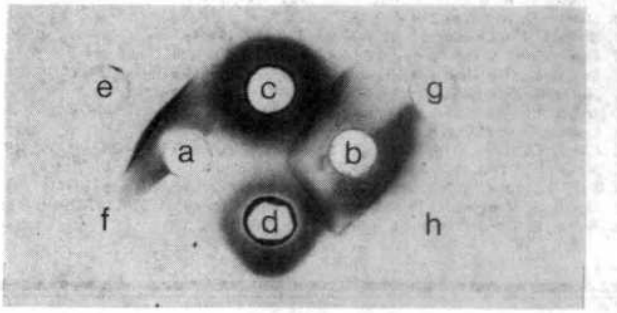

Fig. 2 Immunological cross-reactivity between mouse IgG(Fc) and mouse RBC membrane proteins. The wells contained *a*, rabbit anti-mouse IgG(Fab); *b*, rabbit anti-mouse IgG(Fc); *c* and *d*, triton soluble extracts of membranes from normal and brom RBC respectively; *e* and *g*, mouse IgG(Fab); *f* and *h*, mouse IgG(Fc). Dr P. L. Ey provided the specific sera. The method of triton-solubilization of RBC membranes has been described elsewhere[11]. The immunodiffusion was performed in 1% (wt/v) agarose which also contained 1% (v/v) Triton X 100 and 1% (wt/v) NaCl. The gels were stained using Coomassie Blue[16].

The biological significance of the autoimmune responses against determinant(s) common to IgG(Fc) and mouse RBC membranes is not shown by these results. One question that arises is whether both IgG molecules and RBC elicit autoantibodies. It is possible, for example, that the primary stimulus for autoantibody production is the IgG molecule and that the autoantibodies cross-react with structures in the membranes of RBC. Thus, there may be no physiological role for the autoimmune response against RBC. If the autoimmunity is primarily against IgG(Fc), its biological role could be important in terms of functioning of immune responses. Dresser[4,5] has proposed that IgM antibodies specific for IgG antibodies could play a role in reacting with IgG–antigen complexes and serve to amplify the initiation of the complement cascade. However, this explanation does not account for the extremely high proportion of Ig-secreting cells from the peritoneal cavity of normal mice that are specific for mouse brom RBC. Following a short-term culture, the number of cells producing antibody against mouse brom RBC can represent up to 85% of the Ig-secreting cells present[6,12]. It is possible that B cells in the peritoneal cavity undergo some hormonal and/or antigenic influence before being distributed throughout the body. For example, antigens present in the peritoneal cavity to which early B cells may respond could generate diversity of B cells by some, at present, unknown mechanism. Dresser[5] has already suggested that the high level of IgM anti-IgG(Fc) secreting cells in the spleen may be involved in generating diversity. Similarly Möller and her colleagues[13] have proposed recently that IgM antibodies against IgG(Fc) may be involved in stimulating the immune system non-specifically to generate and maintain an adequate repertoire of B cells. Experimental support for any of these suggestions would change our concept of the development and functioning of adaptive immune responses.

A binding site on mast cells and basophils for the anti-allergic drug cromolyn

Nachman Mazurek, Gilad Berger & Israel Pecht

Department of Chemical Immunology, The Weizmann Institute of Science, Rehovot, Israel

Calcium permeability of basophil and mast cell membranes is stimulated on allergen binding to its specific membrane-bound IgE[1–3]. This entry of Ca^{2+} ions into the cell triggers the degranulation and secretion process[4]. Disodium cromoglycate (cromolyn DSCG), the disodium salt of 1,3-bis(-2-carboxychromon-5-yloxy)-2-hydroxypropane, inhibits the degranulation and release of anaphylactic mediators, and has found wide application in the treatment of allergic bronchial asthma[5–7]. Accumulated evidence indicates that this inhibition takes place by blocking the calcium uptake[8,9]. To localize its site of action, the drug has been covalently conjugated to fluorescent polyacrylamide and polyglutaraldehyde beads (0.7 and 0.2 μm in diameter, respectively)[10]. We show here that these drug–bead conjugates (DBC) do prevent the drug penetrating into the cell without reducing its ability to inhibit histamine release (Table 1). Furthermore, we show a specific Ca^{2+}-dependent binding of the DBC to the membranes of rat peritoneal mast cells (RPMC) and basophils.

Table 1 Inhibition of histamine release from rat peritoneal mast cells by DSCG and DBC

DSCG	Beads	DBC	% Release
—	—	—	3*
—	—	—	35
200 μM	—	—	6
—	10^7–10^8 ml^{-1}	—	34
—	—	10^7–10^8 ml^{-1}†	8

Inhibition of histamine release after preincubation of sensitized mast cells[14] with DSCG or DBC before antigen challenge. 2×10^5 RPMC were preincubated for 5 min in Tyrode solution at 37 °C with DSCG or DBC. Then antigen (ovalbumin 40 μg ml^{-1}) was added and the cells incubated for an additional 10 min. Histamine was assayed by the method of Shore[15]. Results are the mean of two experiments in which each is a duplicate.

* Spontaneous release.

† Drug/DBC ≈ 10^6–10^{10} molecules per bead.

Figure 1 shows the visualization and localization of DSCG binding sites on mast cells using image intensified fluorescence microscopy. The representative fluorescence histograms obtained by fluorescence-activated cell sorter (FACS) analysis of cells stained with DBC are shown in Fig. 2. When rat basophilic leukaemia cells are incubated with DBC, areas of bright fluorescence are clearly observed over the whole cell surface (Fig. 1), and 97% of the cells are stained (Fig. 2, Table 2).

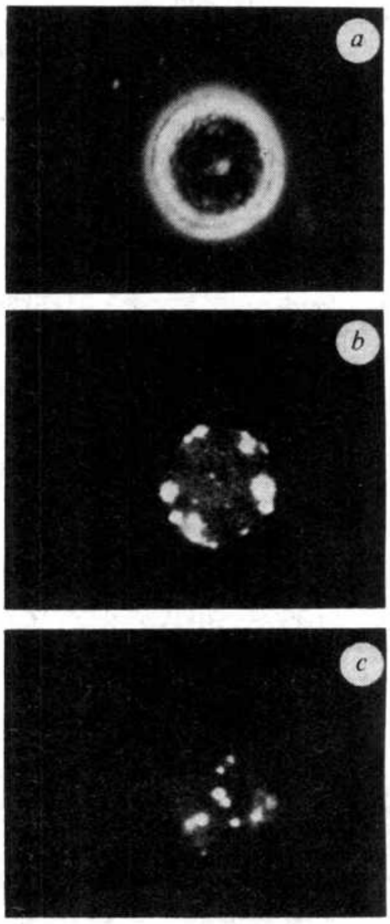

Fig. 1 Fluorescence and phase micrographs of the labelled cells were taken from a TV screen that projects an intensified image of the cells[16]. Rat basophil leukaemia cells (RBL-2H3) were incubated with 50 μg ml^{-1} of DBC in Tyrode solution (NaCl 137.0 mM, KCl 2.7 mM, NaH_2PO_4 0.4 mM, HEPES 10 mM, glucose 5 mM, $CaCl_2$ 1.8 mM, $MgCl_2$ 1.0 mM, BSA 2%) at 25 °C for 30 min. *a*, The phase mode; *b* and *c* are both in the fluorescence mode, but at different focal depths.

The possibility of DSCG acting in the extracellular fluid was excluded by the following experiment: when DSCG and Ca^{2+} ions were added to sensitized RPMC, and the cells were sedimented and resuspended in a fresh medium and exposed to antigen, inhibition of histamine release was still maintained.

Specificity of DBC binding to the cells was examined using two approaches (Table 2). One group of controls was concerned with excluding nonspecific binding of beads free of the drug. Nonspecific binding due to the extra electrostatic charges of the drug's carboxylates was tested using beads to which glutamate had been covalently conjugated. Trypsinization of mast cells (resulting in removal of membrane proteins) significantly reduced the binding of the conjugated beads. Another group of controls was concerned with the target cells' specificity of binding of DBC. BW5147 AKR/J thymoma cells and the P-815 BALB/c mastocytoma cell line, which do not secrete histamine, were not stained with DBC. Competitive inhibition of binding was found between the conjugated drug and DSCG (Fig. 2, Table 2). DSCG prevents ^{45}Ca uptake by mast cells[8,9]. When RPMC are incubated with DBC in a Ca^{2+}-free medium, a drastic reduction of staining is observed (Fig. 2, Table 2). The phenomena reported here all demonstrate strict calcium dependence. That combined with our observation that cromoglycate forms complexes with Ca^{2+} in solvents of low polarity[11,12], leads us to suggest that the cromoglycate–Ca^{2+} complex binds to a specific site on the cell membrane, possibly the calcium 'gates'. For the formation of this specific ternary complex, both the cromone nucleus of the drug and its Ca^{2+}-chelating capacity are considered to be essential.

Table 2 DBC staining monitored by the FACS

Cells	Beads	Treatment	% Cells stained
RPMC	—	Regular	5
RPMC	Free beads	Regular	8
RPMC	DBC	Regular	71
		Competition by:	
RPMC	DBC (1)	Preincubation with DSCG (5×10^{-3} M)	33
RPMC	DBC (2)	Co-incubation with DSCG (10^{-2} M)	19
RPMC	DBC	Ca^{2+}-free medium	6
RPMC	DBC	Preincubation with trypsin	30
RPMC	Beads conjugated to glutamate	Regular	20
RBL-2H3	—	Regular	7
RBL-2H3	Free beads	Regular	20
RBL-2H3	DBC	Regular	97
RBL-2H3	DBC	Preincubation with DSCG	32
RBL-2H3	DBC	Ca^{2+}-free medium	40
Lymphocytes	—	Regular	14
Lymphocytes	Free beads	Regular	18
Lymphocytes	DBC	Regular	14
P-815	—	Regular	4
P-815	Free beads	Regular	4
P-815	DBC	Regular	4

Each sample contained 10^6 cells incubated with DBC (10^7–10^8 beads ml^{-1}) in Tyrode solution for 30 min at room temperature. The RBL-2H3 cells were incubated in Tyrode containing 2% bovine serum albumin (BSA). Trypsinization of cells was carried out with a 0.25% trypsin solution for 30 min at 37 °C. Preincubation with DSCG was carried out at room temperature. As controls for staining other cells we used the BW5147 AKR/J thymoma cells for lymphocytes and also the P-815 BALB/c mastocytoma.

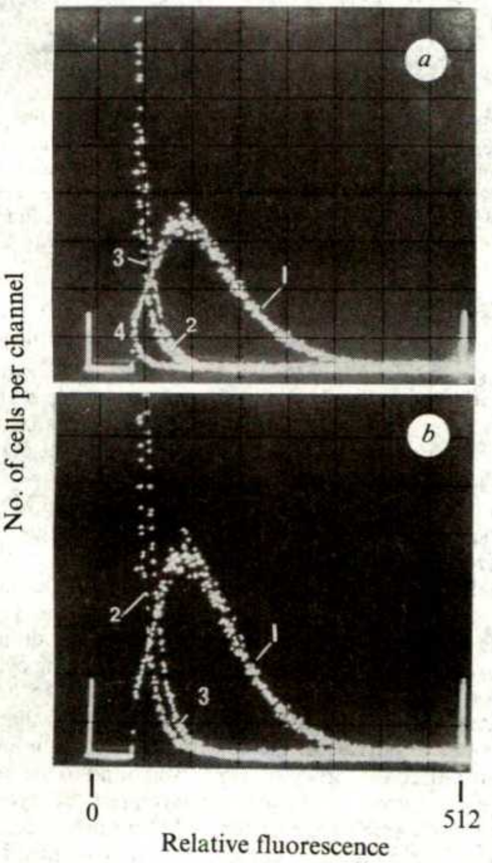

Fig. 2 Fluorescence histograms representative of rat basophilic leukaemia secreting cells (RBL-2H3) labelled with drug–tetramethyl rhodamine isothiocyanate polyglutaraldehyde bead conjugates were obtained by a fluorescence-activated cell sorter (FACS-II, Becton-Dickinson)[13]. The 400-mW, 514.5-nm line from an argon ion laser (Model 164, Spectra-Physics) intersects the stream just below the nozzle so that the cells are illuminated while they are in the fluid jet. The 580-nm large-pass filter (Dictric Optics) and the 590-nm long-pass filter (No. 2-73 Corning Glass Works) improved the red colour separation. Only living cells in the size range of 14 μm were analysed, that is, FACS was size-gated to exclude small cells (as lymphocytes) and smaller-appearing dead cells. The cells were treated as for fluorescence microscopy. *a*, Four histograms are shown: 1, specific binding of DBC; 2, cells with DBC in a Ca^{2+}-free medium; 3, cells in the presence of drug-free beads; 4, auto-fluorescence of the cells. *b*, Competitive inhibition exerted by the addition of free DSCG (see Table 2) causes a shift towards low fluorescence which resembles that due to the nonspecific staining (2), compared with the specific binding curve (1).

We thank Drs A. Rembaum and S. Margel for the supply of microsphere beads, Mr A. Petrank for the operation of the FACS II, Dr C. Geller-Bernstein for advice, Dr J. Schlessinger for help with the intensified microscopy, and Dr H. Metzger for the 2H3 cell line.

Asymmetric F_c receptor distribution on human PMN oriented in a chemotactic gradient

Robert J. Walter, Richard D. Berlin & Janet M. Oliver

Department of Physiology, University of Connecticut Health Center, Farmington, Connecticut 06032

Phagocytosis of antibody-coated particles and immune complexes by polymorphonuclear leukocytes (PMN) and macrophages is initiated by binding to F_c receptors[1–3]. While it appears that subsequent ingestion requires receptor–F_c interactions to occur along the entire periphery of the particle[4], the distribution of F_c receptors over the leukocyte surface is unknown. We show here that during chemotaxis the F_c receptors of human neutrophils are localized to the cell's leading edge. This restricted receptor topography coincides with cell orientation and does not require net forward movement of PMN. Thus, F_c receptors are located in precisely that region of the cell most likely to first encounter opsonized particles.

IgG-opsonized sheep erythrocytes were used as F_c receptor probes. Since we found that aldehyde fixation (paraformaldehyde, formalin, or glutaraldehyde) destroyed or drastically altered F_c receptor activity, opsonized erythrocytes were bound to living cells. Incubation conditions were selected to minimize the redistribution and internalization of F_c receptor complexes[5].

Human PMN were allowed to settle on to coverslips which were then inverted on to a chemotaxis chamber consisting of an elevated bridge between two parallel wells[6]. One well of the chamber was filled with 10^{-7} M *N*-formyl-methionyl-leucyl phenylalanine (FMLP) and the other well with Hank's balanced salt solution. A concentration gradient of the chemoattractant was thus established across the bridge. After 10–15 min, when cell orientation had occurred, coverslips were floated off the chambers with buffer, and opsonized erythrocytes at a 5% haematocrit were placed on the coverslip for 15–60 seconds at 37 °C. Unbound erythrocytes were rinsed off and the PMN fixed with 2% glutaraldehyde. Most of the PMN (>80%) in these preparations bound one or more erythrocytes. We showed previously[5] that little redistribution and no internalization of particle–receptor complexes occurs during this brief period of incubation at 37 °C.

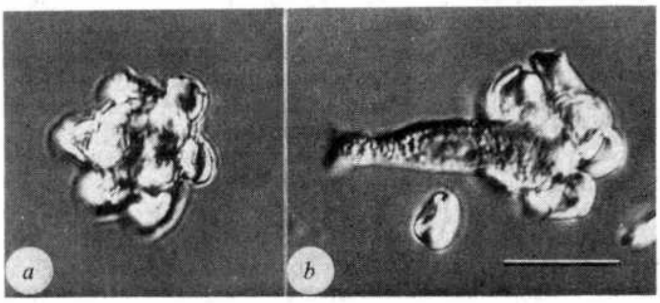

Fig. 1 Human PMN obtained by venipuncture were separated from heparinized whole blood by allowing erythrocytes to sediment at 1 × *g* in 1.25% dextran (pyrogen-free). The leukocyte-rich plasma was drawn off, 1 ml aliquots layered on to 0.5 ml of Lymphocyte Separation Medium (Bionetics), and the gradient centrifuged in a Brinkmann–Eppendorf centrifuge for 1 min. The resulting pellet was rinsed once in Hank's balanced salt solution and contaminating erythrocytes lysed by hypotonic shock. In the final leukocyte suspension, more than 95% of the cells were PMN and the remainder were eosinophils. *a*, After settling on to glass coverslips, PMN were usually rounded or somewhat flattened. Opsonized erythrocytes bind more or less uniformly over their exposed cell surface. *b*, PMN in a gradient of FMLP for 10–15 min are oriented and motile. The nucleus is localized in the bulge of cytoplasm that marks the anterior pole. Frequently, one or more lobes of the nucleus may extend posteriorly toward the trailing uropod. In the incubation conditions used here, opsonized erythrocytes bind avidly and almost exclusively to the anterior portion of the oriented PMN. (Scale bar, 10 μm.)

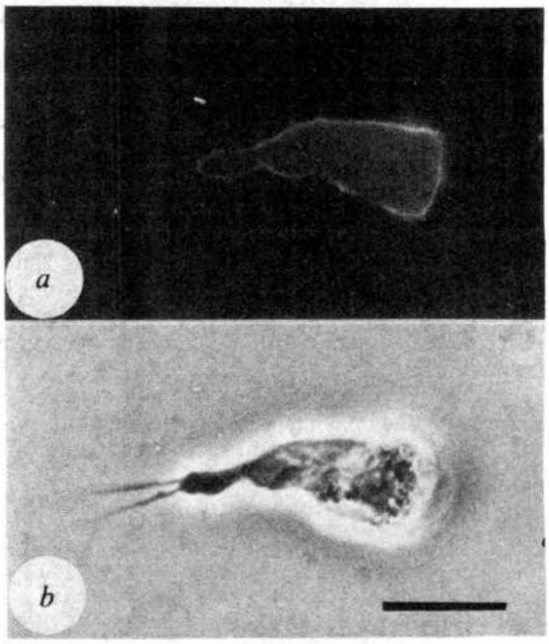

Fig. 2 PMN oriented in an FMLP gradient, fixed in 2% paraformaldehyde, and then labelled with fluorescein–Con A (25 μg ml^{-1}). *a*, Con A binding is essentially uniform except for a slight enhancement in the anterior region of the oriented cell. *b*, Phase contrast micrograph of the same PMN. Two long retraction fibres are evident posteriorly. (Scale bar, 10 μm.)

The rounded or somewhat flattened non-oriented PMN (seen in the absence of FMLP) bound opsonized erythrocytes more or less uniformly about their circumference (Fig. 1*a*). Oriented PMN are elongated with the nucleus localized in a bulge near the anterior pole of the cell (Fig. 1*b*) pointing toward the well containing FMLP. A fine membrane ruffle (lamellipodium, protopod) may form the actual leading edge while a long cytoplasmic uropod trails behind the cell. More than 98% of oriented PMN that bound opsonized erythrocytes displayed them only over the anterior portion of the cell. In the few remaining cells (<2%), opsonized erythrocytes were also bound to the extreme tip of the trailing uropod. The marked asymmetry of erythrocyte binding to the leading edge of the cell is probably due to the preferential distribution of receptors, although it is possible that receptors in this region have a higher apparent affinity.

Under the conditions described above, PMN were oriented and actively motile at rates exceeding 35 μm min^{-1} along the gradient (as seen by time-lapse videotape). If calcium- and magnesium-free media containing 2 mM EDTA were used throughout the experiment, PMN became oriented with respect to the gradient but did not actually move over the substrate[6,7]. Nevertheless, opsonized erythrocytes still bound only to the anterior pole of these oriented PMN.

F_c receptor asymmetry occurs without obligatory, parallel redistribution of other receptors. Thus, on oriented, paraformaldehyde-fixed PMN, fluorescein–concanavalin A (Con A) binds over the entire cell and shows only a slight increase in fluorescence intensity at the anterior pole (Fig. 2*a*, *b*). This apparent enhancement may, in fact, be caused by increased cell thickness and/or folding of plasma membrane in this region.

The mechanism for the establishment of asymmetric F_c receptor activity is not yet understood. It seems possible that coincident with cell orientation, specialized plasma membrane

0028-0836/80/330724—02$01.00

domains may be set up possibly through direct or indirect cytoskeletal interactions. Microfilaments accumulate in the anterior portion of oriented PMN[8] while centrioles along with the bulk of the microtubules are probably posterior to the nucleus[9]. This cytoskeletal architecture might directly affect the local composition of the plasma membrane[7,9,10]. Accordingly, F_c receptors might be enriched in the anterior portion of the PMN. Alternatively, local (perhaps cytoskeleton-related) changes in the lipid composition of the membrane or in membrane surface tension[11] might afford regions of minimum free energy to certain classes of molecules (such as F_c receptors). In either case, Con A distribution may appear relatively unaffected by these PMN membrane domains due to the heterogeneity of the Con A binding sites.

The chief function of the PMN is to seek out and ingest invading microorganisms. This function may be facilitated by restricting the topography of F_c receptors in the membrane during chemotaxis. In particular, the movement of F_c receptors to the leading edge as the phagocyte changes orientation ensures their localization in that part of the membrane most likely to first encounter opsonized particles.

Receptors for concanavalin A cluster at the front of polarized neutrophils

D. L. Weinbaum, J. A. Sullivan & G. L. Mandell

Department of Medicine, Box 385, University of Virginia School of Medicine, Charlottesville, Virginia 22908

Polymorphonuclear neutrophils (PMN) can recognize, engulf and kill microorganisms and are thus an important host defence against infection. The initial encounter between a microbe and the neutrophil takes place at the neutrophil surface. Receptors, including those for the Fc end of the immunoglobulin G (ref. 1), the C3b component of complement[2], formyl peptides[3] and plant lectins[4] have been identified on the surface of neutrophils. We have now examined the surface pattern and arrangement of receptors for the plant lectin concanavalin A (Con A) to determine if the surface receptor array varied with the functional state of the neutrophil. We found that receptors for Con A clustered at the front of polarized neutrophils.

Human PMN were obtained by gravity sedimentation of whole heparinized blood (10 units ml^{-1})[5] or by the formation of monolayers from freshly clotted blood. Cells obtained by the former approach were washed twice and resuspended in Hanks' balanced salt solution. Monolayers were prepared by incubating fresh blood on carefully cleaned glass coverslips at 37 °C for 30 min. The clot that formed was washed off gently, leaving monolayers consisting of 90–95% PMN. Fluorescein- or rhodamine-labelled Con A (10 μg ml^{-1}) was added to live cells and the cells fixed in either 2% glutaraldehyde or 4% paraformaldehyde in phosphate-buffered saline. They were then examined and photographed with a Zeiss Axiomat photomicroscope under phase contrast or fluorescence illumination. Neutrophils were considered polarized if they had a morphologically defined front (leading edge) and tail. Polarized PMN that migrated in a gradient of chemotactic substances were considered orientated. Each experiment was repeated at least three times, and in all cases 50 mM D-mannose blocked Con A binding.

PMN in suspension are spherical (Fig. 1*a*) with no discernible front or tail. When they were incubated with fluorescein-labelled Con A for 15 min and then examined live or fixed in suspension, a uniform surface pattern of fluorescence was observed (Fig. 1*b*)[6]. When PMN in suspension were fixed before the addition of Con A, the fluorescein-labelled lectin was again distributed uniformly. Thus, receptor sites for Con A were distributed uniformly over the surface of the nonpolarized PMN in suspension (Table 1).

We next examined receptor location on polarized but non-orientated PMN. PMN in suspension became polarized when incubated with the chemotactically active peptide *N*-formyl-L-methionyl-L-phenylalanine (10^{-6} M)[7]. Such polarized neutrophils were incubated for 15 min with fluorescein-labelled Con A and all the lectin accumulated at the tail. With prior fixation to immobilize receptor sites, there was marked accumulation of fluorescence at the leading edge in 23 ± 1.73% PMN: we call this pattern a 'headlight' (Table 1).

When cells were allowed to move across coverslips after the addition of Con A, the label moved to the tail, forming bright fluorescent buttons or 'tail lights' as described by Ryan *et al.*[4] (Fig. 1*c*, *d*). However, when polarized cells moving over coverslips were fixed to immobilize receptor sites before the addition of Con A, the headlight pattern was seen on 69.9 ± 3.1% PMN. In other experiments, PMN were orientated towards *N*-formyl-L-methionyl-L-phenylalanine (10^{-6} M) in an agarose chemotaxis system[8]. Addition of fluorescein-labelled

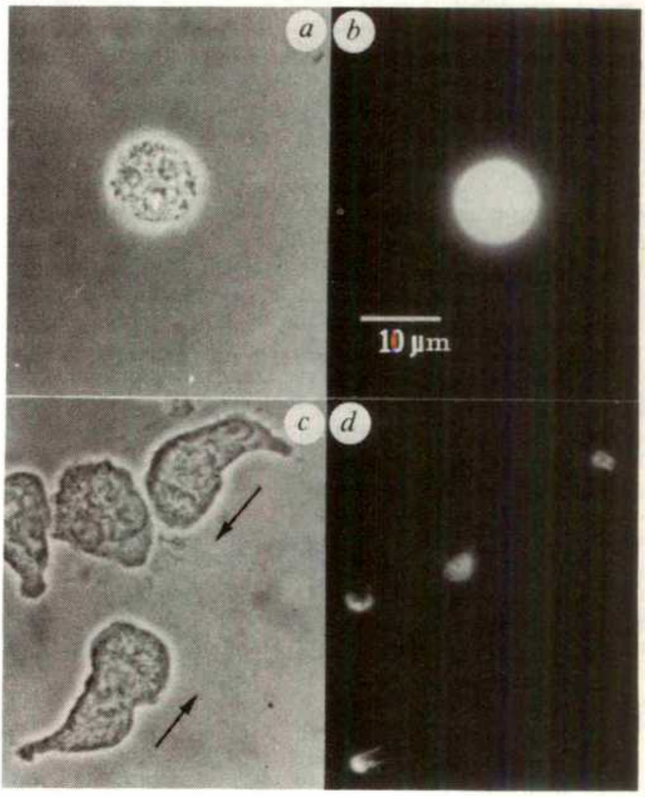

Fig. 1 Binding of fluorescein-labelled Con A to neutrophils. Each set of photographs consists of phase contrast and fluorescence micrographs of the same field. Arrows indicate direction of migration. *a*, *b*, Cells in suspension incubated with 10 μg ml^{-1} Con A and then fixed. Binding is uniform. *c*, *d*, Live neutrophils moving on a monolayer 15 min after addition of Con A. The lectin has accumulated at the tail and thus tail lights were seen.

0028-0836/80/330725—02$01.00

Table 1 Per cent of PMN with indicated distribution of fluorescein-Con A

	Head	Tail	Uniform
Nonpolarized in suspension	0	0	91.4 ± 1.2* ($n = 5$)
Polarized in suspension			
Fixed before Con A	23.0 ± 1.7	0	77.1 ± 1.7 ($n = 3$)
Fixed after Con A	0	90.8 ± 1.7	9.2 ± 1.7 ($n = 5$)
Polarized on monolayer			
Fixed before Con A	69.9 ± 3.1	0	30.3 ± 3.2 ($n = 8$)
Fixed after Con A	0	91.7 ± 2.3	8.3 ± 2.3 ($n = 3$)
Polarized and orientated on monolayer			
Fixed before Con A	76.9 ± 2.6	0	22.8 ± 2.5 ($n = 20$)
Fixed after Con A	0	91.0 ± 1.5	9.0 ± 1.5 ($n = 3$)

Each experiment represented counts of 100 neutrophils. n Is the number of times the experiment was carried out on different days. Results are expressed as the mean ± s.e.m.

* Remainder showed irregular clumping of fluorescence.

Con A after fixation revealed binding sites localized at the leading edge of $76.9 \pm 2.6\%$ PMN (Fig. 2*a–d* and Table 1).

To determine whether new Con A-binding sites were available after bound sites had been swept to the tail, a monolayer of PMN labelled with fluorescein-Con A was incubated for 15 min to enable the lectin to move to the tail. After fixation, rhodamine-labelled Con A was added. Binding sites were revealed by the formation of new headlight areas of red fluorescence (Fig. 2*e*).

Incubation of PMN with colchicine (10^{-4} M), which interferes with microtubular function[6], did not prevent the formation of head- or tail lights. However, incubation with cytochalasin B ($5\ \mu g\ ml^{-1}$), a microfilament poison[9], prevented polarization and abolished head and tail light formation. Nonpolarized PMN in suspension or on monolayers did not cap Con A receptors unless the microtubular system was first disrupted[6,10] but, as reported here, polarized neutrophils clustered unbound Con A receptors at the leading edge and spontaneously capped bound receptors at the tail.

Oliver *et al.*[11] observed a uniform pattern of microfilaments redistribute to polar aggregation when associated with Con A capping in diamide-treated nonpolarized PMN. Berlin *et al.*[12] have shown that Con A–receptor complexes aggregated in the region of pseudopod formation in phagocytosing PMN. Immunofluorescent staining has shown the pseudopods to be enriched in microfilaments[12,13]. The lamellapodium or leading edge of polarized PMN is also enriched in microfilaments[14]. This, together with our finding that cytochalasin abolished headlight formation, suggests that microfilaments are associated with receptor clustering at the leading edge.

Both Con A and certain piliated strains of *Escherichia coli* bind to mannose-sensitive receptor sites on the neutrophil surface[15,16]. This implies that their binding sites may be identical. Piliated, but not non-piliated, *E. coli* are ingested by PMN in the absence of serum opsonins[15,17]. Thus, these receptors may be important in the recognition and subsequent ingestion of microbes. We are attempting to localize complement (C3b) and immunoglobulin (Fc) receptors on polarized PMN, but we have been unable to find a fixative that maintains cellular morphology without destroying the receptor sites.

Thus, polarized PMN move with a leading edge studded with Con A receptors and when these receptors are bound, the receptor–lectin complex moves to the tail. New unbound receptors seem to be generated or uncovered at the leading edge. The array of receptors at the leading edge of the neutrophil may be important for its ability to function as an efficient phagocyte.

We thank Lillian Robertson and Joyce Henderson for their assistance with this manuscript. This work was supported in part by NIH grants AI 09504 and T32AI 07046.

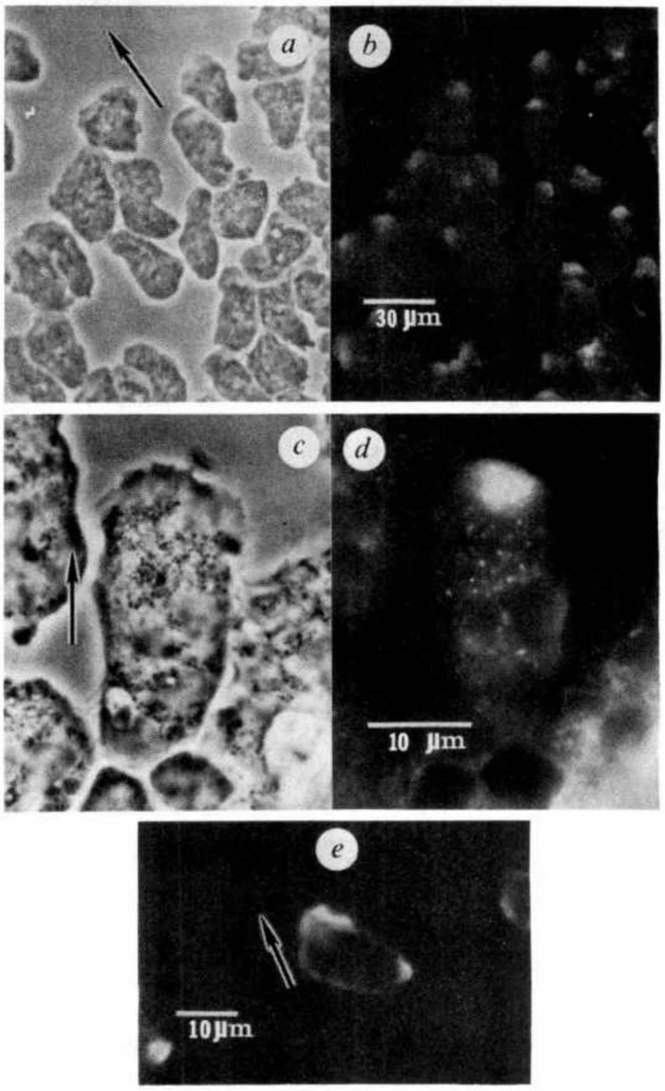

Fig. 2 Each set of photographs consists of phase contrast and fluorescence micrographs of the same field. Arrows indicate direction of migration. *a*, *b*, Neutrophils migrating in a gradient of the chemotactic peptide *N*-formyl-L-methionyl-L-phenylalanine under agarose for 30 min. Con A was added after fixation. A bright accumulation of Con A at the leading edge in a headlight pattern was seen on the oriented cells. *c*, *d*, A high power view of this phenomenon showing that Con A receptors are most dense at the leading edge. In *b* and *d* the punctate appearance of fluorescence inside the cell, not associated with the headlight, represents nonspecific granular fluorescence that is not blocked by 50 mM D-mannose. *e*, Neutrophils were incubated with Con A on a monolayer for 15 min and then fixed. Fluorescein-Con A (green in original) accumulated at the tail as in Fig. 1*d*. Rhodamine-labelled Con A was then added. Rhodamine-Con A (red in original) bound to the leading edge. Thus, the cell fluoresced in two colours, red at the leading edge and green at the tail. This indicated that new binding sites for Con A were available. These may be newly uncovered or regenerated sites.

Topographical distribution of coated pits

J. R. Pfeiffer, J. M. Oliver & R. D. Berlin

Department of Physiology, University of Connecticut Health Center, Farmington, Connecticut 06032

The internalization of a wide range of biologically significant macromolecules, particularly low density lipoproteins (LDL) and proteins such as α_2-macroglobulin and epidermal growth factor, occurs primarily through characteristic, bristle-coated indentations of the cell surface known as coated pits[1–4]. Current interest has focused on the topographical relationship between surface receptors for these ligands and the coated pits[2]. We establish here that coated pits are themselves distributed non-randomly on the J774.2 mouse macrophage cell surface. Morphometric and statistical analyses of cell profiles in electron micrographs indicate two levels of asymmetry: in all cells, pits are clustered; after colchicine treatment they accumulate over a microvillous protuberance that develops at one pole of the cell. This topographical heterogeneity suggests a new level at which cellular responses to growth substances and hormones may be regulated.

Coated pits were defined as regions of membrane indentation approximately 0.3 μm long and underlain by a fuzzy coat which in favourable micrographs appeared as periodic spikes or bristles (Fig. 1). They frequently occupied the bases of microvilli and were characteristically separated by a clear space from the adjacent cytoplasm. To determine their distribution, a cell was first selected and photographed at ×8,900. Pits with openings to the medium were then located by searching the entire perimeter of the cell at a magnification of ×160,000. Their approximate positions were marked on a sketch which guided subsequent identification of pits on the low magnification micrograph of the same cell (Fig. 2*a*, arrows). A sonic digitizer was used to determine the length between pits and the total cell circumference from these micrographs.

Untreated J774.2 macrophages[5] that were grown in Dulbecco's modified Eagle medium with 20% horse serum, fixed in suspension and processed for electron microscopy as before [6–8], maintained a rounded shape. Cell profiles were thus selected at random except that each one contained a portion of the cell nucleus. In these untreated cells, the average distance between pits in two separate experiments involving 37 pits on 12 cells and 45 pits on 10 cells was, respectively, 24.2 μm and 18.6 μm. Assuming the thickness of the section to be 70 nm and the cell-surface area to be roughly 1,500 μm^2, this corresponds to a surface density of approximately 0.35 pits per μm^2 or approximately 500 coated pits per cell.

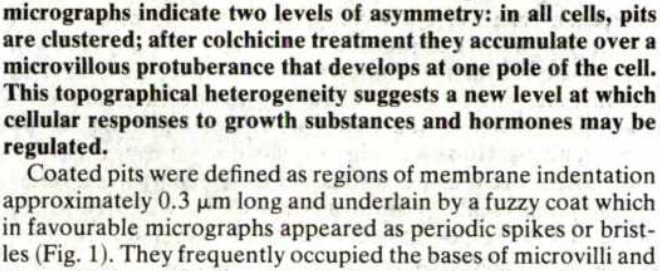

Fig. 1 The ultrastructure of coated pits. The left frame illustrates the typical thickened membrane and bristled cytoplasmic face of coated pits. The right frame demonstrates the clear zone between coated pits and the adjacent cytoplasm. Scale bar, 0.1 μm.

Table 1 Statistical analysis of coated pit distribution

Rejection of randomness hypothesis test		Untreated macrophages	Colchicine-treated protuberant macrophages
Basic quadrat* χ^2 analysis	Quadrats 6 or 10 μm	NS	$P<0.05$
Basic quadrat* χ^2 analysis	Quadrat 3.6 μm	$P<0.01$	
Variance/mean* ratio analysis		NS	$P<0.001$
Eberhardt statistic†		$P<0.01$	$P<0.005$
Contiguous quadrats‡		$P<0.005$	$P<0.005$

* These are essentially comparisons of the observed distribution of coated pits with a theoretical Poisson distribution into quadrats. Quadrats are equal-length segments along the surface profile scored for numbers of pits. The theoretical distribution is based on the mean number of pits per quadrat. In our experiments, 37–38 pits were distributed along 600–900 μm of profile, in quadrats 3.6, 6 and 10 μm long. For the basic quadrat, χ^2-test is used, and for the variance/mean ratio analysis, $t=(\text{variance/mean})-1/(2/n-1)^{1/2}$. Both tests are insensitive to fine-grained non-randomness and are affected somewhat by the choice of quadrat size.

† In this analysis a series of random points (taken from a table of random numbers) was placed on the extended profile and a distance X_i measured from the random point to the nearest pit. The Eberhardt statistic

$$A=m\sum_{i=1}^{m}X_i^2\Big/\sum_{i=1}^{m}X_i^2$$

where m = number of random points used, was then computed, and its critical values taken from the table of Hines and Hines[9]. This is a sensitive test for non-randomness, particularly for clustering over small dimensions.

‡ This quadrat analysis is based on the hierarchal design of Greig-Smith[10]. It allows analysis at various dimensional levels, systematically 'searching' for a quadrat size that reveals non-randomness. The modification of Mead[11] allows analysis over a series of scales. NS, not significant.

After colchicine treatment (2 μM, 30–45 min), greater than 80% of J774.2 cells developed a bulge or protuberance that was bordered by microvillous membrane and was frequently separated from the cell body by a constricted neck region[6,8]. In these cells, analysis of randomly selected profiles yielded 14.7 μm between pits (one experiment; 37 pits on 11 cells). Analyses of profiles that displayed both the protuberance and cell body of the same cell gave 15.3 μm and 11.6 μm between pits (two experiments involving 63 pits on 12 cells and 80 pits on 11 cells, respectively). This corresponds to an average linear density of around 0.53 pits per μm^2 in colchicine-treated macrophages. As the mean pit densities on randomly chosen profiles and profiles of clearly protuberant cells are so similar, selection of protuberant profiles for subsequent studies does not introduce counting bias. The 50% increase pit density after colchicine (0.53 compared with 0.35 pits per μm^2) is unexplained but may reflect the decreased pinocytosis observed previously[8] in colchicine-treated J774.2 macrophages.

Are coated pits distributed randomly? To answer this question the consecutive distances between pits were measured on 10–12 profiles from the untreated and colchicine-treated samples in each of two experiments. The perimeters were connected end to end by joining them at a point taken midway along the greatest inter-pit distance on each profile. This provided one continuous sample of pit distribution. A variety of statistical tests for randomness were then applied.

0028–0836/80/330727—03$01.00

The distribution of pits on untreated, rounded cells was first examined statistically by dividing the total profile length into consecutive sections or quadrats of equal length, determining the number of pits in each quadrat and calculating the proportion of quadrats with different numbers of pits (0, 1, 2, 3). This was compared by χ^2-test with a theoretical Poisson distribution based on the mean number of pits per quadrat, or by *t*-test using the method of variance/mean ratio. When the quadrat size was chosen to be 6 µm of profile, a random surface distribution of coated pits on rounded cells was indicated (that is, the statistical hypothesis that the sample is random is not rejected by these tests). When the quadrat was reduced to 3.6 µm the pit distribution appeared non-random (Table 1). This difference in statistical significance dependent on the length of quadrat suggested that the nonrandomness was based on the presence of clusters of pits. To test this, we used published methods of mathematical ecology in which nonrandomness of populations may be analysed at several scales without bias. These methods are based either on nearest-neighbour analysis, by examining the variance of distances from random points to pits along the profile[9], or by an hierarchical quadrat analysis in which the variance at each level of complexity (scale) in relation to the next is directly examined[10,11]. The results of these more refined tests, also summarized in Table 1, reinforce the simpler analysis indicating that coated pits are distributed non-randomly.

In contrast to the subtle clustering of pits on untreated cells, coated pits along profiles from colchicine-treated cells showed a non-random distribution by even the simplest statistical tests (Table 1). Furthermore, from inspection of the electron micrographs of protuberant cells (for example, Fig. 2*a*), it was suggested that coated pits were relatively more numerous in the protuberance than in the cell body. A procedure was therefore developed to combine data from different profiles so as to emphasize common topographical features. A radial grid was placed over the cell with its centre across the 'neck' region separating the protuberance from the cell body. The same grid was placed over a diagrammatic cell (Fig. 2*b*). Every coated pit from successful cell profiles was transferred into 1 of the 12 segments of the generalized profiles to build up a cumulative distribution pattern. The results of two such experiments are shown in Fig. 2*c* and *d*. Few coated pits are found on the 'body', whereas both 'head' and 'neck' regions are significantly enriched for coated pits. It can be seen from Table 2 that the linear density in the head is approximately five times that of the cell body. An eight-fold higher density of coated pits exists in the neck than in the cell body. This increased pit density in the protuberance and concomitant depletion of pits over the body surface is reminiscent of the capping of concanavalin A–receptor complexes on protuberant leukocytes[6-8,12] or the segregation of surface immunoglobulin into the uropod of lymphocytes[13].

The mechanism by which coated pits are clustered and capped is unclear. The distances between pits are too great for clustering due to ligand bridging of pits. Direct connections between pits and microfilaments that could pull them are also not necessarily involved. We have shown before that segregation of surface markers can probably occur without direct connections of the segregating species with microfilaments[6,8,12,14]. In addition, coated pits are characteristically underlain by a clear zone that seems to lack microfilaments, although at some point microfilaments may still be involved in the internalization of coated pits[15]. Based on our previous work on the segregation of membrane ligand–receptor complexes[6,8,12,14], we propose that pits (or their molecular precursors) probably move by diffusion or by inclusion in membrane flow to overlie the neck and protuberance where they are trapped by local alterations in membrane structure, the latter perhaps being stabilized by microfilaments. However, other explanations are not excluded.

Table 2 Distribution and regional linear density of coated pits on profiles of J774.2 macrophages

Region	% Total pits	Linear density	
		Pits per µm of profile	Relative density
Expt 1			
Control			
Whole perimeter	100	0.0413	1.00
Colchicine-treated			
Whole perimeter	100	0.0654	1.58

Whole perimeter	100	0.0862	1.45
Head	36	0.1225	2.06
Neck	53	0.1870	3.14
Body	11	0.0238	0.40

We emphasize that the existence of such topographical variation may represent a critical mechanism by which cells can modulate their responses to growth substances and hormones. Several investigators have stressed the inherently random distribution of membrane receptors of hormones that are internalized through coated pits[1-4]. It follows that the clustering of pits on rounded cells and particularly their redistribution following colchicine may place coated pits at a variable distance from membrane receptors and so may alter the cellular response to ligands that bind these receptors. For example, topographical phenomena may underlie the potentiation by colchicine of DNA synthesis induced in serum-starved, quiescent fibroblasts by epidermal growth factor, fibroblast growth factor, insulin and other hormones[16,17]

We thank Dr Robert Rippey for discussions on statistics. This work was supported in part by NIH grants CA185544 and grant

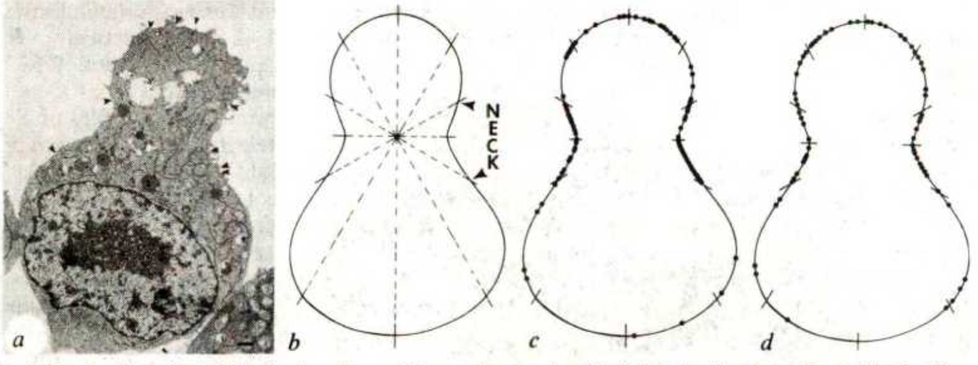

Fig. 2 The topography of coated pits on protuberant cells. Coated pits were first identified on electron micrographs of thin sections through protuberant cells (arrows, *a*). A radial grid was then placed over the profile with its centre at the midpoint of a line across the narrowest 'neck' region between cell body and protuberance and radii fanning out every 30° above and below the line. An identical grid was placed over a diagrammatic cell (*b*) whose 'head' and 'body' profiles were drawn in proportion to their average lengths on the individual cell profiles. This device allowed the ready transfer of pit distribution from the original cell profile to the generalized cell. The four segments referred to as 'neck' are marked: segments above these are the 'head' and segments below the 'body'. *c*, *d* Show the cumulative pit distributions from two separate experiments that analysed 12 (*c*) and 11 (*d*) profiles of colchicine-treated protuberant cells. The diagrams were built up of 63 and 80 pits, respectively. Scale bar 1 µm. Obviously, an analogous diagram for untreated symmetrical cells cannot be constructed because there is no common morphological feature by which to orientate the different profiles.

Insulin and antibodies against insulin receptor cap on the membrane of cultured human lymphocytes

Joseph Schlessinger*

When insulin interacts with its target cells, it binds to a specific membrane receptor and triggers a chain of events which stimulate many physiological responses[1,2]. Although the mechanism of insulin action remains uncertain[2-4], electron microscopy has suggested that unoccupied insulin receptors appear in clusters of two to six molecules and that insulin becomes internalized after binding to them[5,6]. Insulin receptors on 3T3 fibroblasts labelled with rhodamine–insulin (R-insulin) are diffusely distributed and mobile on the cell surface, with a lateral diffusion coefficient $D \sim (3\text{–}5) \times 10^{-10}$ cm^2 s^{-1}. At 37°C, hormone–receptor complexes aggregate into immobile patches which are soon endocytosed[7,8]. A new tool for such studies has been provided by the discovery of autoantibodies to the insulin receptor in the sera of certain patients with insulin-resistant diabetes[9]. These antibodies stimulate various physiological responses normally mediated by insulin[10-14]. Both the bivalent antibodies $(\mathrm{Fab'})_2$ and the monovalent Fab′ block insulin binding, but only the bivalent antibodies are biologically active[14], Fab′ acting as a competitive antagonist[14]. Similarly, antibodies raised against purified insulin receptors can mimic insulin[15], suggesting that microaggregation of receptors could be involved in the action of this hormone[14,16]. We now report that at 37°C both R-insulin and the rhodamine-labelled antibodies against insulin receptors form a single cap on one pole of the cell. Cells which were first treated at 37°C with fluorescein–insulin (F-insulin, at partial receptor occupancy), fixed with formaldehyde and then treated with either R–insulin or rhodamine-labelled anti-receptor antibodies, showed overlapping caps of the two markers. These experiments demonstrate directly the aggregation of insulin receptors and suggest either that insulin receptors are multivalent towards the hormone or that the unoccupied receptors migrate together with the occupied ones in the formation of caps.

When IM-9 lymphocytes were incubated with R–insulin (50 ng ml^{-1}) for 90 min at 4°C, the hormone appeared diffusely distributed over the cell surface. If these cells were subsequently incubated at 37°C, the labelled hormone–receptor complexes clustered within 15 min and formed a single cap on one pole of the cell. Similar caps were observed when lymphocytes were incubated for 30 min at 37 °C with R-insulin (50 ng ml^{-1}) without preincubation at 4 °C (Fig. 1*a*, *b*). Insulin-induced capping occurred in approximately 60% of lymphocytes, the rest showing weak diffuse or patchy staining. Pretreatment of cells with 10^{-2} M sodium azide for 30 min at 37 °C inhibited capping, and R-insulin formed visible patches over the cell surface (Fig. 2*a*, *b*). Capping was not affected by preincubation for 30 min at 37 °C with 10^{-5} M colchicine, a microtubule-disrupting agent, concanavalin A (Con A, 20 μg ml^{-1}), which inhibits capping and mobility of various other antigens on the membrane of lymphocytes, or 10^{-4} M cycloheximide, which inhibits protein synthesis.

When lymphocytes were labelled with 50 μg ml^{-1} of rhodamine-labelled autoantibodies against insulin receptors, similar results were obtained. At 37 °C, the antibodies induced a single cap on one pole of the cell (Fig. 1*c*, *d*). As with R-insulin, when cells were preincubated with sodium azide, patches were seen, instead of a single cap (Fig. 2*e*, *f*). Binding of anti-receptor antibody and R-insulin was specific. If the cells were incubated with 0.4 μg ml^{-1} of native insulin with either R-insulin (Fig. 2*c*, *d*) or rhodamine-labelled anti-receptor antibodies, a weak diffuse fluorescence was observed. This reflects nonspecific interactions between the antibodies and the cell surface and is similar to the pattern observed when lymphocytes are incubated with equivalent amounts of IgG fraction of normal human antibodies (data not shown).

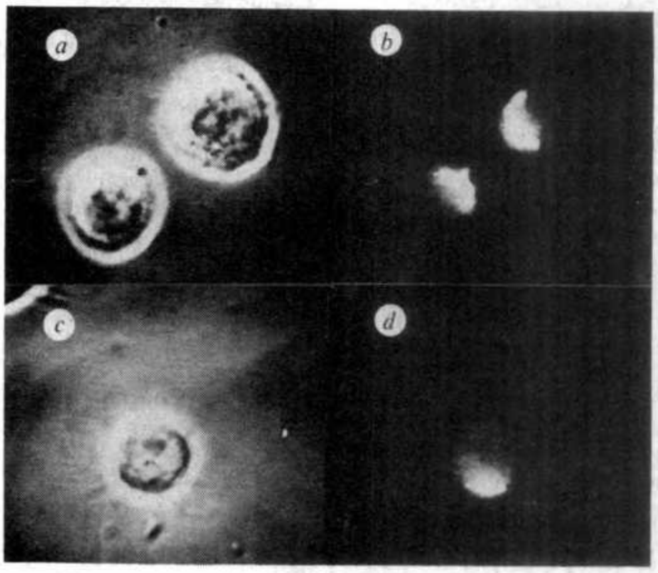

Fig. 1 The distribution of R-insulin and rhodamine-labelled autoantibodies against insulin receptors on IM-9 lumphocytes. Lymphocytes suspended in Hank's balanced salt solution (BSS) containing 1 mg ml^{-1} bovine serum albumin (2×10^6 cells ml^{-1}) were incubated with either 50 ng ml^{-1} R-insulin or 50 μg ml^{-1} of rhodamine-labelled autoantibodies against the receptors isolated from insulin-resistant diabetics for 30 min at 37 °C. After the incubation, the cells were washed twice with Hank's BSS, fixed with 1% formaldehyde for 10 min at 23 °C, washed twice more and mounted on microscope slides for microscopic observation. The fluorescence and the phase micrographs of the IM-9 lymphocytes were taken with a Polaroid camera from a television screen that projects the intensified image of these cells. Full details about this system were previously reported[8,28]. *a*, Phase; *b*, fluorescence micrographs of the same field of cells labelled with R-insulin. *c*, Phase; *d*, fluorescence micrographs of the same field of cells labelled with rhodamine-conjugated antibodies against insulin receptor. ×1,900.

Table 1 The distribution of R-insulin and other reagents on the cell surface

Expt	Reagents	Cell distribution	% Cells	Presence of co-caps
I	*a* F-insulin (5 ng ml^{-1})	Caps	55 ± 6	Yes
	b R-insulin (150 ng ml^{-1})	Caps	49 ± 8	
II	*a* F-insulin (5 ng ml^{-1})	Caps	58 ± 7	Yes
	b R-anti-insulin receptor (50 μg ml^{-1})	Caps	52 ± 6	
III	*a* F-insulin (150 ng ml^{-1})	Caps	62 ± 6	No
	b R-insulin (150 ng ml^{-1})	Diffuse background		
IV	*a* Insulin (150 ng ml^{-1})	—		
	b R-insulin (150 ng ml^{-1})	Diffuse background		
V	*a* R-insulin (150 ng ml^{-1})	Caps	50 ± 8	No
	b Fluorescein–lipopolysaccharide	Diffuse	100	
VI	*a* R-insulin (150 ng ml^{-1})	Caps	62 ± 11	No
	b Fluorescein–Con A	Diffuse	100	

In all the experiments the IM-9 lymphocytes were first incubated for 30 min at 37 °C with reagent *a*, washed with PBS, fixed with formaldehyde and after additional washing labelled with reagent *b* for 30 min at 23 °C. The values are the average of four different experiments.

Double-label experiments were carried out to examine whether insulin and antibody-induced receptor capping affect only the occupied receptors or produce a more general effect. Lymphocytes were incubated with F-insulin (5 ng ml^{-1}) for 30 min at 37 °C. (At this concentration 20–30% of receptors are occupied.) Cells were then washed twice in phosphate-buffered saline (PBS), fixed with 3% formaldehyde for 10 min at 23 °C and incubated for a further 30 min at 23 °C with a near-saturating concentration of R-insulin (150 ng ml^{-1}). The two markers seemed to be distributed in a single cap (Fig. 3, Table 1). When cells were labelled with saturating concentrations of either F-insulin (200 ng ml^{-1}) or native insulin (0.4 μg ml^{-1}), fixed and labelled with R-insulin, only background fluorescence was observed, in the spectral range of rhodamine. We have previously reported that hormone binding was not affected and that receptor clustering was inhibited by mild fixation with formaldehyde[8].

A similar experiment was carried out with F-insulin and rhodamine-labelled anti-receptor antibodies. The cells were first incubated with F-insulin (5 ng ml^{-1}, 20–30% receptors occupied), washed, fixed and labelled with rhodamine anti-receptor antibodies (50 μg ml^{-1}). As before, F-insulin and rhodamine-labelled anti-receptor antibodies appeared in the same domain. Interestingly, in all these experiments, only 50–60% of cells were capped. We do not know the reason for this. It is difficult to evaluate the pattern of the diffusely labelled cells because the nonspecific fluorescence appeared in a similar pattern.

Although occupied insulin receptors may cause co-capping of unoccupied receptors, insulin-induced receptor capping does not affect the general distribution of other membrane components. IM-9 lymphocytes were labelled with R-insulin (50 ng ml^{-1}), fixed with 3% formaldehyde and incubated for 20 min at 23 °C with fluorescein–Con A (20 μg ml^{-1}). In contrast to a single cap of R-insulin observed on 62% of lymphocytes, nearly 100% of the cells showed uniform distribution of fluorescein–ConA. Results were similar when cells were labelled with R-insulin, fixed and labelled with a fluorescein-labelled lipopolysaccharide (50 μg ml^{-1}). This molecule is embedded artificially in the lipid matrix of the membrane of various cell types[17]. In this experiment, R-insulin appeared in caps on 50% of the cells, whereas nearly 100% of the cells showed uniform distribution of fluorescein-labelled lipopolysaccharide.

Thus, insulin or antibodies against its receptors form patches and caps of insulin receptors on the membrane of IM-9 lymphocytes. This provides further evidence that insulin receptors can diffuse[8] laterally in the plane of the membrane of IM-9 lymphocytes, and that insulin or antibodies against its receptors redistribute their receptors on the cell membrane. Our data also demonstrate that insulin or antibodies against insulin receptors bind to the same domain on the cell surface, as revealed by fluorescence microscopy, and that insulin receptors are operationally multivalent towards the hormone molecule. This operationally multivalent species could also be pictured as an oligomer of monovalent recognition subunits.

It is difficult to explain how a small, presumably monovalent molecule such as insulin can induce receptor clustering, although other polypeptides such as epidermal growth factor[8],

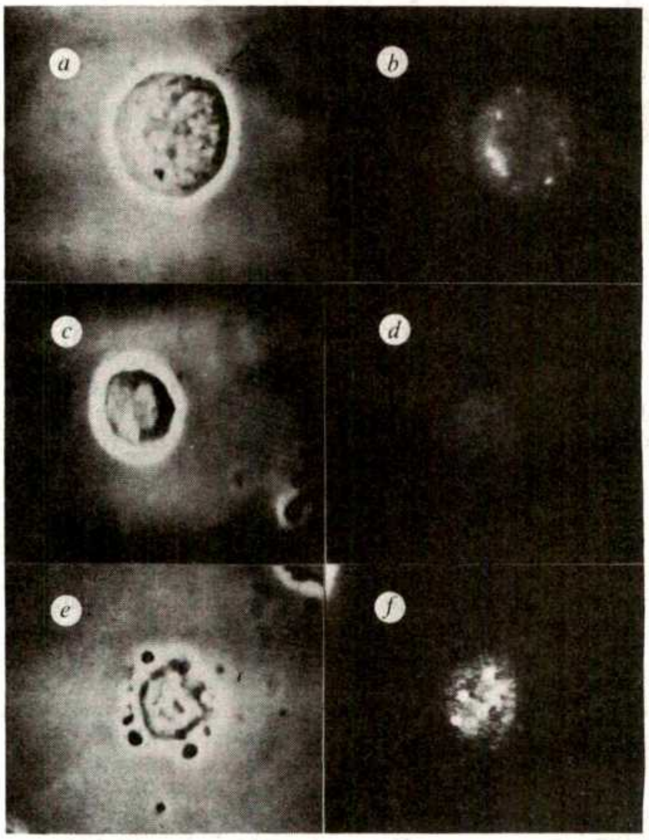

Fig. 2 Sodium azide inhibits the formation of caps of insulin or antibodies against insulin receptor on IM-9 lymphocytes. *a*, Phase; *b*, fluorescence micrographs of the same field of IM-9 lymphocytes preincubated with 10^{-2} M of sodium azide for 30 min at 37 °C and then for an additional 30 min with R-insulin. The cells were washed with PBS, fixed with formaldehyde and mounted on microscope slides for microscopic observation. *c*, Phase; *d*, fluorescence micrographs of the same field of IM-9 lymphocytes which were incubated with 0.4 μg ml^{-1} native insulin together with 50 ng ml^{-1} R-insulin. The weak diffuse fluorescence reflects the nonspecific binding of the fluorescent hormone. *e*, Phase; *f*, fluorescence micrographs of the same field of cells preincubated with 10^{-2} M of sodium azide for 30 min at 37 °C and then for additional 30 min with 50 μg ml^{-1} of rhodamine-labelled antibodies against insulin receptor. The cells were washed, fixed and mounted for microscopic observation. × 1,900.

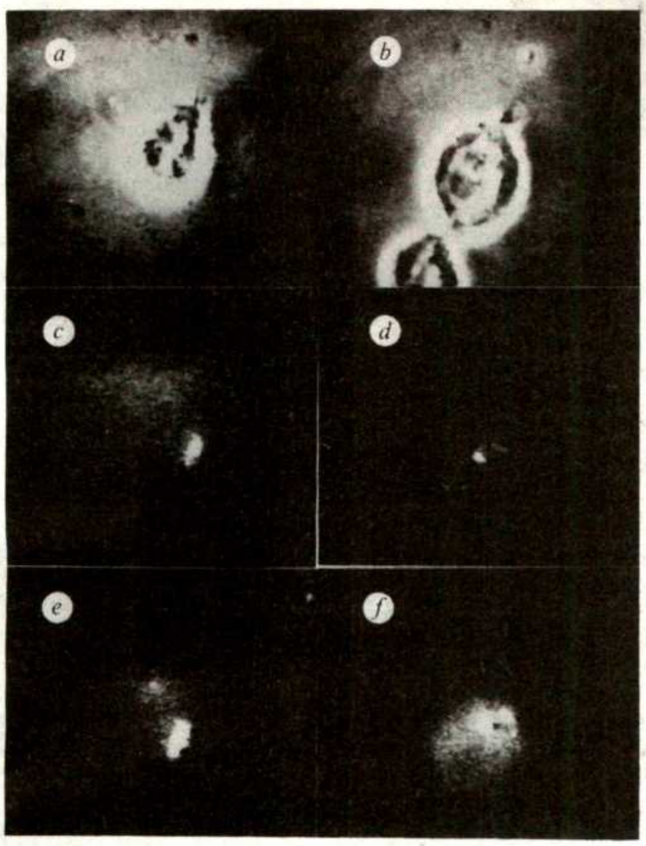

Fig. 3 Co-capping of F-insulin and R-insulin on IM-9 lymphocytes. IM-9 lymphocytes were incubated with 5 ng ml^{-1} F-insulin for 30 min at 37 °C; at this concentration 20–30% of the receptors are occupied. The cells were washed, fixed with 3% formaldehyde for 10 min at 23 °C and then incubated for an additional 30 min at 23 °C with 100 ng ml^{-1} of R-insulin. *a*, *b* and *c* are micrographs of one cell and *d*, *e* and *f* are micrographs of a second cell. *a* Is phase, *b* and *c* are fluorescence micrographs of F-insulin and R-insulin, respectively. *d*, Phase; *e* and *f* are fluorescence micrographs of F-insulin and R-insulin, respectively. ×1,900.

nerve growth factor[18] and enkephalin[19] can also induce receptor clustering. For insulin, a simple mechanism would be self-aggregation on the cell surface, for insulin dimerizes and aggregates in solution at concentrations above 10^{-6} M and its local concentration on the cell membrane is about 10^{-6} M (ref. 16). On the other hand, if surface aggregation is a biologically important process, it must differ from aggregation in solution because several insulins do not aggregate in solution, but are biologically active[14]. A more plausible mechanism is that hormone binding induces a conformational transition in the receptor molecules that increases the binding affinity between mobile receptors. Our finding that partial occupancy of insulin receptors leads to co-capping of unoccupied receptors can be interpreted in two ways. One explanation is that the receptor molecules are multivalent towards the hormone. At low levels of receptor occupancy, one or more binding sites of each multimer is occupied, and as they cap, they bring with them the unoccupied receptors. The second possibility is that the receptor molecules are independent, but the conformational transition induced in them by the binding of insulin enhances the interactions between neighbouring receptors, leading to the migration of unoccupied receptors together with the occupied one. Both explanations, however, imply that the receptor molecule is operationally multivalent towards the hormone, which is consistent with the negative cooperativity exhibited by insulin binding to its membrane receptors in IM-9 lymphocytes[20]. Hormone-induced microaggregation of multivalent receptors could be the mechanism of negative cooperativity. It is not known whether insulin receptors cluster in coated areas of the plasma membrane, as do α_2-macroglobulin and epidermal growth factor[21,22], and the biological significance of hormone-induced receptor capping is unclear. At physiological concentrations, insulin does not induce microscopically visible receptor caps or patches, but microaggregation of receptors is likely at such concentrations. Other data suggest that microaggregation of receptors is an important step in the chain of events leading to the bioactivity of insulin and epidermal growth factor[14–16]. The larger microscopically visible caps are induced at concentrations of insulin in which it 'down-regulates' its membrane receptors. Indeed, we have found a good correlation between the extent of insulin-induced receptor loss (down-regulation) and the amount of IM-9 lymphocytes which cap (unpublished results). Furthermore, both processes depend on hormone concentration, time and temperature. This suggests a possible physiological role to insulin-induced receptor capping.

Myosin from fetal hearts contains the skeletal muscle embryonic light chain

Robert G. Whalen & Susan M. Sell

Département de Biologie Moléculaire, Institut Pasteur,
25 rue du Dr Roux, 75724 Paris, France

The contractile proteins of adult skeletal and cardiac muscle tissue are very similar. Some of these proteins are identical in amino acid sequence[1,2] or differ only slightly[3]. Various structural studies have shown that the heavy and light chains of myosin are also homologous in skeletal and cardiac muscles[4–11]. In developing skeletal muscles, certain myosin subunits are present which are not found in the corresponding adult muscle[7,10–13]. Whether fetal cardiac muscle also contains myosin subunits homologous to these early forms is not known. We now report that ventricular myosin of fetal rats has a light chain polypeptide corresponding to the skeletal muscle embryonic light chain[11]. This result provides further evidence that a form of myosin light chain, not detectable in adult skeletal or ventricular myosin, is characteristic of the early stages of striated muscle development[14].

Myosin purified from 20-day embryonic rat ventricles by Sepharose or DEAE-cellulose chromatography[11] contains three components of the same molecular weight as adult myosin (Fig. 1*a*), but also has a band of approximate molecular weight (MW) 26,000 (Fig. 1*b*). Two-dimensional gel analysis of adult

0028–0836/80/330731—03$01.00

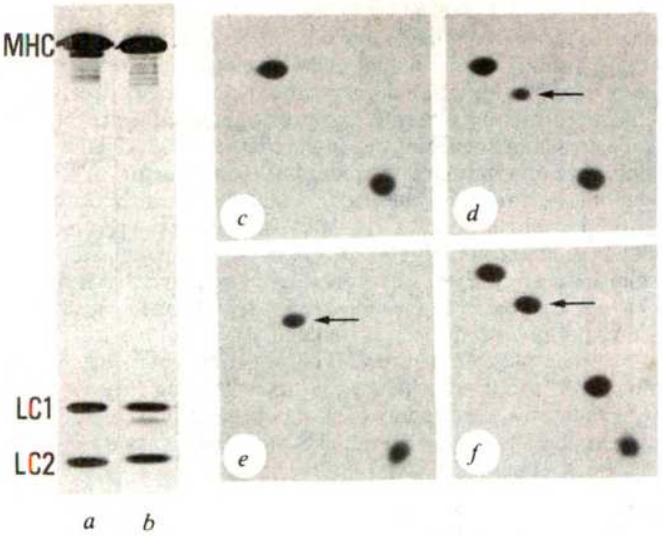

Fig. 1 Gel electrophoresis of various myosin samples. Myosins were extracted and purified from adult rat heart ventricles, 20-day fetal rat heart ventricles and fused L6 myotube cultures as previously described[11]. The final step in the purification procedure for the preparations shown here was chromatography on Sepharose 2B in the presence of 1 mM ATP[11]. *a*, Adult cardiac myosin and *b*, embryonic cardiac myosin were analysed on one-dimensional SDS gels. The positions of light chains (LC1 and LC2) and heavy chain (MHC) are indicated. Two-dimensional gel analysis of myosin light chains[11] was performed on *c*, adult cardiac myosin, *d*, embryo cardiac myosin, *e*, L6 myosin and *f*, a mixture of L6 and embryo cardiac myosin. Only the light chain region is shown. About 15 μg of each myosin were loaded on the gels. The arrows in *d–f* indicate the $\mathrm{LC1_{emb}}$ protein.

and embryonic cardiac myosin light chains (Fig. 1*c*,*d*) clearly revealed two and three components respectively. Myosin from the myogenic rat cell line L6 is composed of two light chains, an LC2 protein of the fast skeletal type plus the embryonic light chain $\mathrm{LC1_{emb}}$ described previously[11]. Co-electrophoresis of embryonic cardiac myosin with L6 myosin showed that the third light chain component in the cardiac preparation corresponded to $\mathrm{LC1_{emb}}$ as determined by their co-migration (Fig. 1*e*,*f*). No fast-type light chains were detected in the embryonic cardiac myosin, as suggested previously[15]. The earlier result may have been due to contamination of the embryonic myofibrillar preparations by histones, as shown elsewhere[16,17].

The possibility that cardiac and L6 embryonic light chain are identical is supported by the following results. During partial proteolysis of SDS-denatured myosin using *Staphylococcus aureus* protease, $\mathrm{LC1_{emb}}$ is converted to a polypeptide of approximately 23,000 MW, whereas LC1 light chains of adult fast, slow and cardiac myosin are relatively resistant[7]. We have verified that this 23,000-MW species is not derived from the heavy chain at these levels of degradation by comparing the cleavage pattern of isolated L6 myosin heavy chain with that of the whole molecule (heavy and light chains; not shown). As Fig. 2 shows, cardiac $\mathrm{LC1_{emb}}$ is degraded to a polypeptide of the same molecular weight as that derived from the L6 embryonic light chain (Fig. 2*a*,*b*). The resistance of the adult cardiac LC1 to *S. aureus* protease (Fig. 2*c*) also suggests that it is not directly related to $\mathrm{LC1_{emb}}$.

The ratios of the various cardiac myosin light chains were determined by densitometry of the stained bands on one-dimensional SDS gels. Adult myosin contains LC1 and LC2 in a ratio of $1.16 \pm 0.08:1 (n = 5)$, which after correction for their respective molecular weights (22,000 and 20,000 (ref. 9)) is close to the expected 1:1 stoichiometry. Densitometry of embryonic cardiac myosin reveals that the ratio of $\mathrm{LC1} + \mathrm{LC1_{emb}}$ to LC2 is $1.19 \pm 0.08 : 1 (n = 4)$. $\mathrm{LC1_{emb}}$ represents about 25% of the total LC1-type light chain in this myosin.

The myosin heavy chain of embryonic cardiac myosin was examined by partial proteolytic cleavage after denaturation by SDS[7,18]. The pattern of degradation is very similar to that of adult cardiac myosin after treatment with *S. aureus* protease (Fig. 2*b*,*c*). The one-dimensional analysis of patterns obtained after cleavage by chymotrypsin or papain also reveals extensive similarity (results not shown). However, two-dimensional analysis after chymotryptic degradation reveals several quantitative differences. For example, some minor polypeptides in the adult myosin pattern (Fig. 3*a*) are major species in the embryonic pattern (Fig. 3*c*); they are indicated in Fig. 3*b* by arrows in the gel containing a mixture of the two reactions. Other polypeptides are major in the adult and minor in the embryonic preparation. No detectable amounts of any adult fast or embryonic skeletal myosin heavy chain isozymes are seen in the cleavage patterns of embryonic cardiac myosin (Fig. 2*a*,*b*, and ref. 7). The quantitative differences seen in the embryonic and adult patterns may mean that these preparations are mixtures of two or more isozymes, the ratios of which are different. This possibility is consistent with results of electrophoresis of native intact myosins[19] which reveals three rat ventricular myosin isozymes (V_1, V_2 and V_3). V_3 is predominant in 18-day embryos (J. F. Y. Hoh, personal communication) while V_1 is the major form in the adult[19]. It is therefore possible that the heavy chain isozyme we find in embryonic heart tissue corresponds to that of V_3 myosin. Interestingly, a V_3 isozyme reappears in large amounts in hypertrophic hearts[20].

We have demonstrated a novel form of myosin light chain in embryonic skeletal muscle[11], and the results presented here reveal an identical, or at least very similar, protein in embryonic rat ventricular myosin. Because the two-dimensional gel technique is capable of high resolution, co-migration of these two proteins is suggestive of identity. The presence of a cleavage site

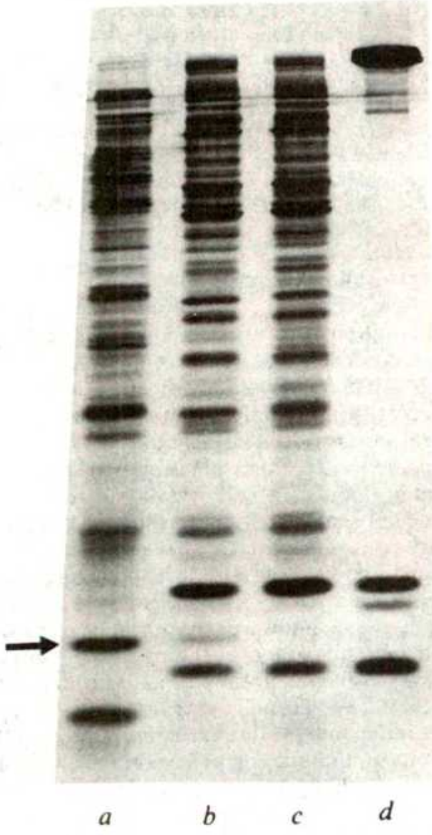

Fig. 2 Partial proteolysis of skeletal and cardiac $\mathrm{LC1_{emb}}$ by *S. aureus* protease. About 16 μg of myosin was treated with *S. aureus* protease in the presence of SDS as described previously[7] and then analysed on a one-dimensional SDS gel. Results are shown for the treatment of *a*, L6 myosin, *b*, embryo cardiac myosin and *c*, adult cardiac myosin. *d*, Untreated embryo cardiac myosin shows the positions of various intact light chains. The $\mathrm{LC1_{emb}}$-derived fragment is indicated by an arrow.

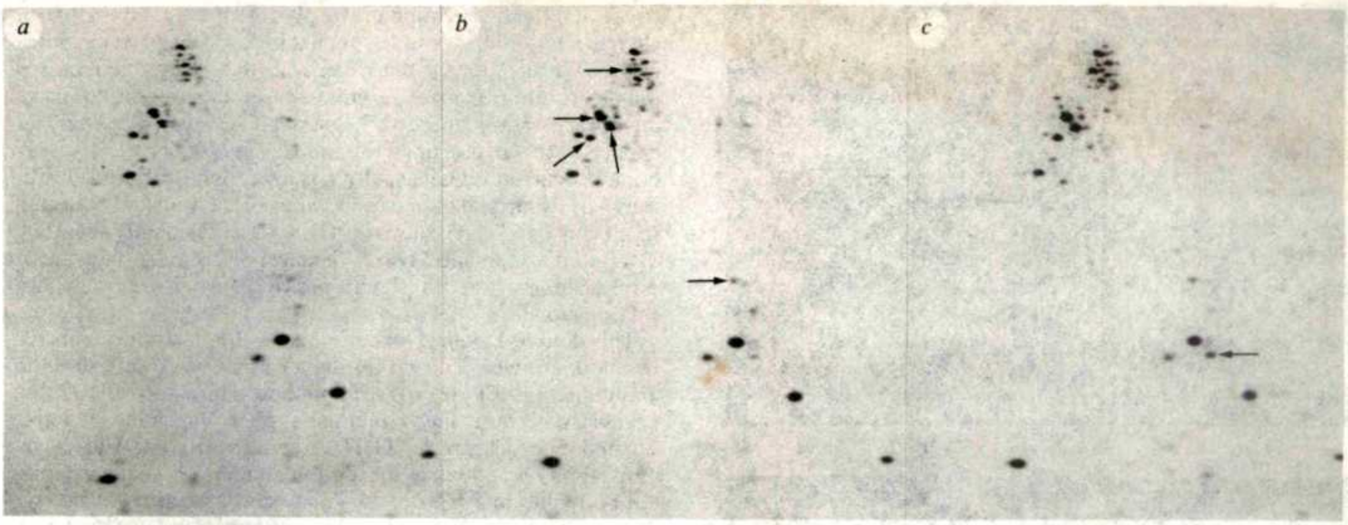

Fig. 3 Polypeptide maps of adult and embryo cardiac myosin heavy chains. The partial chymotryptic cleavage reactions were carried out as described for two-dimensional gel analysis[7] except that the final myosin concentration was only 1 mg ml^{-1}. About 60 μg were loaded on the gels containing *a*, adult and *c*, embryonic myosin cleavage products. Gel *b*, contained about 30 μg of each of the adult and embryonic cleavage products. The arrows in *b*, indicate polypeptides that are major in the embryonic myosin map *c*, and minor in the adult map *a*. The arrow in *c* indicates the intact LC1_{emb} protein. Two-dimensional gels were run as described[11] except that the isoelectric focusing gel was 21 cm long and the second dimension slab gel was 19 cm high, composed of a 4-cm stacking gel and 15-cm separation gel. The gels are presented with the basic *p*H range to the left.

for *S. aureus* protease in both the skeletal and cardiac proteins is also consistent with this possibility. The LC1_{emb} light chain is not found in adult ventricular myosin (shown here) nor in adult skeletal muscle[11]. While we cannot rule out that LC1_{emb} might be a major component of some adult myosin, it seems to be present in skeletal and ventricular myosin only at the early stages of development. The relative stoichiometry of the LC1 and LC2 components in fetal cardiac myosin is the same as in adult myosin, although LC1_{emb} partially replaces the adult cardiac LC1 at the early stages.

The similarity of the ventricular heavy chain isozymes found at 20 days *in utero* with those of the adult could be interpreted in several ways. Conceivably a distinct embryonic form is never present in developing myocytes. Alternatively, cardiac tissue could be much more developed biochemically at this stage than skeletal muscle, and an embryonic form may already have been replaced by the adult forms. Even though myocytes are still proliferating in the perinatal period, these dividing cells are biochemically differentiated[21]. In contrast to the heavy chain, the light chains have not attained the adult phenotype by 20 days of gestation. If the absence of a distinct embryonic heavy chain at this time is simply due to rapid turnover of such a form, then the situation is the inverse of developing skeletal muscle in which LC1_{emb} disappears more rapidly than embryonic heavy chain[7,14,22].

We thank Dr K. Schwartz for helpful discussions and Professor F. Gros for support and encouragement. This laboratory is supported by the CNRS, DGRST, INSERM, CEA and the Muscular Dystrophy Association of America.

Coexistence of α-fetoprotein, albumin and transferrin immunoreactivity in neurones of the developing mouse brain

C. Dominique Toran-Allerand

Center for Reproductive Sciences (IISHR) and Department of Neurology, Columbia University, College of Physicians & Surgeons, 630 West 168th Street, New York, New York 10032

α-Fetoprotein (AFP), a major fetal plasma protein, is present at high levels (mg ml^{-1}) throughout development and at extremely low levels (ng ml^{-1}) in the normal adult (see refs 1,2). Unlike that of most other species, rat and mouse AFP bind oestrogens with a high afinity[3]. This aroused speculation regarding its involvement in the growth and differentiation of oestrogen target tissues[4]. Extracellular sequestration of maternal oestrogens through binding to AFP is generally assumed to protect the female rodent brain from excessive oestrogenization (masculinization) from the high oestrogen levels present during the critical period for sexual differentiation[5]. There is an intracellular pool of AFP of unknown function in brain cytosol of fetal and neonatal rats[6] and mice[7]. Its intraneuronal localization has been confirmed within the central and peripheral nervous systems of the developing rat[8,9] and human fetus[10] by immunoperoxidase cytochemistry. Other major plasma binding proteins such as albumin[9,10] and prealbumin[10] but not transferrin[9,10] have also been localized within neurones of the developing rat and human brain. As part of a continuing ontogenetic study, I present here the first evidence, derived by single- and double-label immunofluorescence, for the intraneuronal localization and coexistence of immunoreactive AFP, albumin and transferrin within the same neurones of the late fetal and postnatal mouse brain. These observations may be relevant to the process of sexual differentiation of the brain, and the mechanism of transport of hormones and other growth-promoting substances into neurones during development.

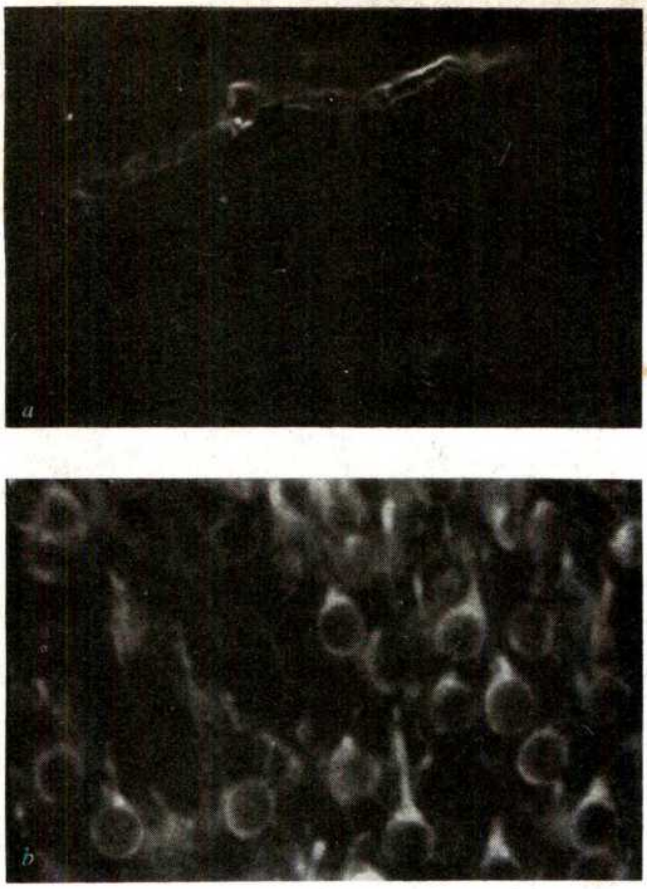

Fig. 1 *a*, Immunofluorescent staining of the newborn male mouse hypothalamus with the non-immune IgG control. Note the total absence of cellular fluorescence and the localization of the staining to a blood vessel only. This section was adjacent to the one in Fig. 2*b* × 100. Detailed methods for Figs 1 and 2 are given in the text. *b*, Immunofluorescent localization of mouse AFP in immature neurones of the 18-day fetal female mouse cerebral cortex. Note the cytoplasmic immunoreactivity with extension into the primary neuronal processes. × 175.

Brains from sexed 18-day fetal, newborn, 8-day post-natal and adult mice were immersed in ice-cold ethanol/acetic acid[11] without stirring for 24 h, dehydrated, cleared and embedded according to the method of Sainte-Marie[12], and processed for single- or double-label immunofluorescence. Demonstration of antigen localization was carried out by incubations of 3–4-μm serial coronal sections with purified goat antibodies to mouse AFP, the γ-globulin (IgG) fraction of rabbit antiserum to mouse albumin either unlabelled or conjugated to fluorescein isothiocyanate (FITC) (Cappel), or goat antiserum to mouse transferrin (Cappel) for 48 h at 4 °C. After washing in phosphate-buffered saline (PBS) (*p*H 7.4), antibody binding was visualized either by the direct method (FITC-conjugated anti-mouse albumin) or indirectly by adding goat anti-rabbit or rabbit anti-goat IgG conjugated to either (FITC) (green) or tetramethyl rhodamine isothiocyanate (TRITC) (red) (Cappel) for 24 h at 4 °C. The sections were then washed in PBS (*p*H 7.6), mounted in Gelvatol and examined with a Zeiss microscope equipped with both fluorescein and rhodamine optics, and epi-illumination.

Controls included: (1) non-immune goat and rabbit sera; (2) absorption (neutralization) of AFP antibodies by newborn mouse serum (high AFP levels); (3) absorption with purified mouse albumin or mouse transferrin (Cappel); (4) the fluorochrome conjugates alone, and (5) newborn mouse liver, a site of AFP, albumin and transferrin synthesis, as a positive control. These showed no fluorescence except for the liver, which confirmed the localization of the plasma proteins to the parenchymal cells. Furthermore, to distinguish the specific intracellular localization of the plasma proteins from their passive uptake, resulting from experimentally induced alterations in cell membrane permeability[13,14], parallel sections were always exposed to antiserum to mouse IgG (Cappel)[13]. IgG immunoreactivity was usually localized only to blood vessels (Fig. 1*a*). Neuronal fluorescence was generally absent, although small clusters of IgG-staining cells were occasionally seen only in regions of obvious tissue damage. Cells were considered AFP-, albumin- or transferrin-positive only if they were also IgG-negative.

The double-labelling experiments (AFP–albumin; transferrin-albumin) were carried out by a combined direct (albumin) and indirect (AFP; transferrin) method. This approach became necessary because the sequential application of the two conjugated fluorochromes (TRITC–rabbit anti-goat; FITC–goat anti-rabbit) resulted in the double staining of each primary antibody due to apparent conjugate cross-reactivity. The conjugated fluorochromes themselves, however, did not detect the inappropriate antibody nor did they stain the tissue in the absence of antibody. The double labelling experiments consisted of sequential applications on the same tissue section of the goat antibodies (AFP or transferrin), TRITC–rabbit anti-goat IgG and FITC–rabbit anti-mouse albumin IgG, each for the time periods described above. Double-label detection of AFP and transferrin was not possible because of their shared species of origin (goat).

Intracellular localization of all three plasma proteins was observed only in the brains of the 18-day fetal, newborn and 8-day postnatal mice. The adult brains exhibited no fluorescence. Specific fluorescence was observed in cell groups throughout the developing brains of both sexes and seemed to be localized to neurones only. Large numbers of post-mitotic neuroblasts and immature neurones exhibited bright, specific intracytoplasmic fluorescence which often extended into primary processes, initial dendritic segments and axons (Figs 1, 2). Neuronal nuclei did not fluoresce. AFP-, albumin- and transferrin-containing neurones were widely distributed in diverse regions, including the cerebral cortex (Fig. 1*b*), septum, basal ganglia, hippocampus, brain stem (Fig. 2*a*), hypothalamus (Fig. 2*b*), cerebellum and medulla. The numbers of fluorescing neurones in any given region increased with its developmental stage. This was exemplified quite strikingly in the cerebral cortex, where the numbers and topographic distribution of fluorescing neurones were closely correlated with differentiation of the cortical layers. In the hypothalamus, preoptic area and the amygdala, however, certain nuclear regions known from ^{3}H-oestradiol autoradiography to contain oestradiol receptors were rendered anatomically distinctive by the complete or almost complete and bilaterally symmetrical absence of fluorescence. These regions include the medial preoptic area, the suprachiasmatic, arcuate, ventromedial and ventral premamillary nuclei of the hypothalamus, and the medial and cortical amygdaloid nuclei and will be described elsewhere (in preparation). Specific fluorescence was also seen in the epithelial cells of the choroid plexus, in the meninges, in blood vessels, to varying degrees in the apical portions of ependymal cells, and in the extracellular space of the developing brains. Fluorescence of the extracellular space, however, decreased significantly between birth and the 8th postnatal day and was totally absent from the adult brain.

Double-labelling experiments demonstrated that all neurones which exhibited fluorescence for either AFP or transferrin (red) also contained albumin (green). Although the lack of suitable antibodies precluded any direct comparisons of AFP and transferrin localization, the topographic distribution of albumin-containing cells in serial sections suggests that all three proteins are in the same neurone.

This is the first demonstration of AFP, albumin and transferrin immunoreactivity in the developing mouse brain and of their coexistence within the same neurones. These observations also confirm that the AFP in mouse brain cytosol is intraneuronal[7].

Furthermore, transferrin has not previously been localized intraneuronally, its specific absence, rather, being noted[9,10]. Because of the inadequacy of the blood-brain barrier at the ages studied, the intraneuronal coexistence of the three plasma proteins makes it seem more likely that they have been taken up by endocytosis from the cerebrospinal fluid and blood[10] than synthesized locally. This hypothesis is supported by the observed immunoreactivity of blood vessels, choroid plexus epithelium and the extracellular space. To investigate the alternative possibility, however, we are now determining whether or not AFP is synthesized in developing neurones by carrying out *in situ* and solution hybridizations to the messenger RNA with a cloned chromosomal DNA probe specific for AFP.

The discrete intracytoplasmic localization of AFP, albumin and transferrin raises questions regarding their possible active and essential role in neuronal differentiation and development. As binders of a variety of hormones and other biologically active substances, these three plasma proteins may mediate or modulate their intraneuronal transport. It has been proposed, for example, that at low steroid concentrations cellular entry of oestrogen into the immature rat uterus may be a carrier-mediated event in contrast to the diffusion seen with high levels[15]. Moreover, the essential role of albumin in the active transport of thyroid hormones into rat hepatocytes in culture has been demonstrated[16]. Incorporation of albumin (but not of other proteins) into the nutrient medium of cultured chick sensory ganglia, furthermore, significantly enhanced the biological activity of nerve growth factor (NGF) by doing more than merely preventing its adsorption to glassware[17].

The intraneuronal localization of the oestrophilic AFP has important implications for the process of sexual differentiation of the rodent brain. Its intracellular presence forces one to reconsider the generally held concept that the female rodent brain is protected from exposure to maternal oestrogens by the extracellular AFP[5]. On the contrary, neuronal uptake (perhaps by endocytosis) of such oestrogen-binding proteins as AFP and albumin must bring oestradiol into the cell. Intracellular dissociation of the protein–oestradiol complex, resulting from the greater affinity of oestradiol for its receptor, could liberate the steroid for subsequent association with its cytoplasmic receptors. Such a mechanism might thus provide certain neurones of both sexes with the intracellular source of oestradiol of non-androgen origin previously postulated as necessary for the induction of both male and female patterns of neural differentiation[18,19].

This phenomenon, however, need not be limited to the particular proteins described here. In those species (birds, humans) whose AFP has little or no oestrogenic affinity[1,2], other binding proteins, including albumin, may serve the same functions by similar mechanisms. Its possible active role in the transport of thyroid hormones and NGF-like substances, among others, as well as its capacity to bind oestrogens, renders albumin also of considerable potential importance to the development of the central nervous system. Furthermore, the intraneuronal localization of albumin makes it imperative that antisera raised to bovine serum albumin-conjugated antigens be pre-absorbed with albumin before use in immunocytochemical studies of developing central nervous system tissue both *in situ* and in cultures exposed to serum-containing medium.

The significance of the intraneuronal localization of transferrin is unknown. That transferrin *per se* may mediate important developmental functions, however, is suggested by recent *in vitro* observations[20] that transferrin (90% iron-free) is essential for neuronal differentiation and survival in serum-free medium.

The cellular uptake of plasma proteins during development may not be unique to the brain. Preliminary studies (unpublished observations) suggest that immunoreactive AFP, albumin and transferrin are also localized within cells of the neonatal adenohypophysis. Their presence in other hormonal target tissues remains to be determined.

I thank Dr E. Ruoslahti (La Jolla Cancer Research Foundation) for the gift of the antibodies to mouse AFP, Dr G. Godman for the Gelvatol, Drs H. Jalanko (City of Hope), A. Etgen and A.-J. Silverman for helpful discussions, Dr C. Paden for photographic assistance and Mrs G. Katzauer for sectioning the tissues. This study was supported in part by grants from NIH (HD-08364), NSF (BNS 77-0859), the WT Grant Foundation, and the March of Dimes Birth Defects Foundation. C.D.T.-A. is in receipt of a NIMH Research Scientist Development Award (MH-00192).

Glial cells in the enteric nervous system contain glial fibrillary acidic protein

Kristjan R. Jessen & Rhona Mirsky

Department of Anatomy and MRC Neuroimmunology Project, Department of Zoology, University College London, Gower Street, London, WC1E 6BT, UK

The complex nervous networks found throughout the mammalian gut—the enteric nervous system—are histologically, ultrastructurally, and, to some extent, functionally—similar to the central nervous system[1-3]. The glial cells of the small enteric ganglia are generally classified as Schwann or satellite cells, since they are found in the peripheral nervous system, possess nuclei which ultrastructurally resemble those of Schwann cells and are derived from the neural crest[4,5]. However, it has been argued that these cells resemble astrocytes of the central nervous system with respect to gross and fine structure, and their relationship with the enteric neurones and their processes[1,6]. In immunohistochemical studies of these cells, both in frozen sections of gut wall and in tissue culture preparations of the enteric plexuses, we found evidence that the enteric glial cells are rich in glial fibrillary acidic protein (GFAP), a protein associated with the 100 Å glial intermediate filaments[7], and hitherto believed to be specific to astrocytes of the central nervous system only[8,9].

Figure 1 illustrates the immunofluorescence seen when frozen sections through ganglia of the rat myenteric plexus, cerebellum and sympathetic ganglia were treated with antisera raised against human GFAP; similar results were obtained with three different antisera[9,10]. As shown in Fig. 1*b*, the antisera reacted strongly with the glial cells in the myenteric ganglia, the immunofluorescence characteristically surrounding the neuronal cell bodies, which were always unstained. The glial staining was of similar intensity to that of astrocytes in frozen sections from the central nervous system (Fig. 1*b*, *d*). No staining was found in the Schwann cells, satellite cells, neurones or axons in sections from other autonomic ganglia with any of the three antisera (Fig. 1*c*). However, Yen and Fields have recently found evidence that a minority of peripheral glial cells in adult rat sciatic nerve sections also contain GFAP immunoreactivity using the same antisera as we used here (personal communication).

It has been demonstrated that astrocytes of the central nervous system maintain their glial filaments when grown in tissue culture and show striking, filamentous GFAP immunofluorescence on treatment with GFAP antisera[11]. It was therefore interesting to see whether enteric glial cells in culture also exhibited GFAP immunoreactivity. Explant cultures of the myenteric plexus were obtained from the proximal colon of 7–14-day-old rats as described elsewhere[12]. We have suggested that one of the cell types in such cultures, identifiable on the basis of occurrence, morphology and interaction with other cells, may be the enteric glial cells[12]. When cultures of the plexus, maintained *in vitro* for 7–10 days, were treated with the GFAP antisera, it was found that most of these putative glial cells showed bright, filamentous immunofluorescence, very similar to that seen in astrocytes in tissue culture (Fig. 2). Other flat cells, fibroblast-like in morphology, were unstained, as were the neuronal cell bodies and their processes. As with astrocytes in culture[13], the morphology of the cells showing GFAP immunofluorescence was quite varied. Many, however, had tapering processes and in most cells part of the cell body flattened out, forming often extensive, thin membraneous expansions.

To establish conclusively that the glial cells in the enteric plexuses contained GFAP, we compared the distribution of GFAP immunofluorescence with that of neurofilament (NF)

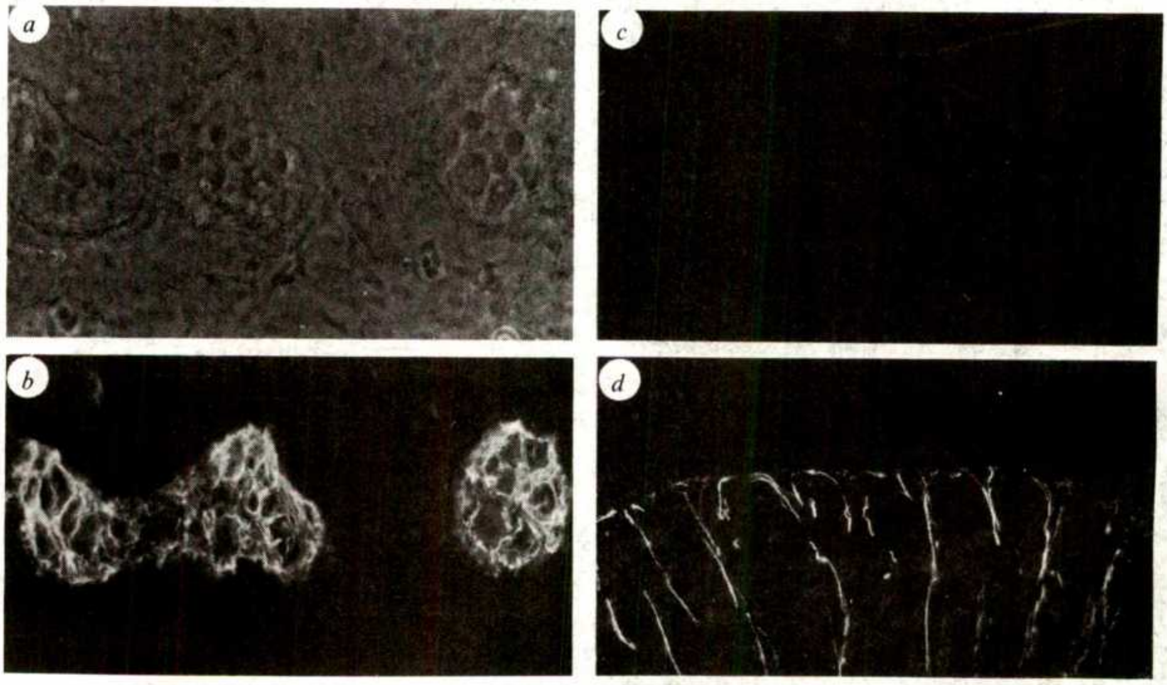

Fig. 1 GFAP immunofluorescence in frozen sections of *a* and *b*, rat colon, *c*, dorsal root ganglion, and *d*, cerebellum. 10 μm sections were left overnight at 4 °C, then incubated overnight at 4 °C with rabbit anti-human GFAP serum (1 : 1000), followed by goat anti-rabbit IgG conjugated to rhodamine (G anti-RIg-Rd) for 30 min at room temperature. They were viewed with *a*, phase contrast or (*b*–*d*), fluorescence optics, using a Zeiss Universal microscope. Only the glial cells in the myenteric plexus are labelled in *b*; the neurones in the plexus and the circular and longitudinal muscle are all unlabelled. No immunofluorescence is seen in any of the dorsal root ganglion cells *c* while the cerebellum shows typical GFAP labelling in processes of Bergmann astrocytes *d* (*a*, *b*, *c* ×300; *d* ×200). The antiserum donated by Drs D. Dahl and A. Bignami has been extensively characterized in a number of studies, which have shown that it specifically stains astrocytes both in tissue sections and cultures and does not stain other cells in nervous or non-nervous tissues[8,9,11,13,16]. The antisera donated by Dr R. Pruss were prepared from human GFAP as described by Drs D. Dahl and A. Bignami[9]. Extensive testing of these antisera on tissue sections and cultures revealed that the staining properties of both antisera are identical to those of the Dahl and Bignami antiserum (R. Pruss, personal communication).

0028-0836/80/330736—02$01.00

immunofluorescence. The NF antiserum was prepared against the 155,000 molecular weight subunit of neurofilament protein[14]. The distribution of NF immunofluorescence in the rat myenteric plexus and sympathetic ganglia is illustrated in Fig. 3. In ganglia of the plexus (Fig. 3*a*) the NF antiserum typically revealed the neuronal cell bodies. No fluorescence was present in the glial cells surrounding the neurones, so that the NF staining pattern was the converse of that seen with the GFAP antisera. In the superior cervical ganglion (Fig. 3*b*) the most prominent sites of NF immunoreactivity were the axons of transversely cut axon bundles. Staining was also seen in the cell bodies of most neurones although the intensity varied markedly between cells and only a few of them stained as intensely as did the axons. All these structures were completely unstained when treated with GFAP antisera. Thus, the pattern of NF immunofluorescence in both tissues is completely different from that of GFAP immunofluorescence, from which we conclude that the immunoreactivity observed in these tissues following treatment with GFAP antisera resides in glial cells and not in neurones.

GFAP is the major protein of the 100 Å filaments found in astrocytes; the GFAP-containing filaments are one of five different, but related classes of intermediate filaments that can be distinguished both by immunological and biochemical methods. The others are neurofilaments, found in central and peripheral nervous systems, desmin filaments, present in muscle cells, keratin filaments in epithelial cells and vimentin filaments, the only filament type that has a wide distribution among different types of cells[15]. GFAP-containing filaments have so far been found exclusively in astrocytes of the central nervous system and have often been used as a cell-type specific marker for astrocytes[7–9,11,13]. However, our results indicate that under appropriate conditions, GFAP can be expressed by glial cells in the peripheral nervous system. The enteric glial cells, like astrocytes, express GFAP both *in situ* and in culture. It has previously been noted that although the enteric glial cells have some of the morphological characteristics of Schwann cells they also show notable structural similarities with astrocytes[1,5,6]. Like astrocytes, the enteric glial cells carry extensive branching and irregular processes which mingle with neuronal processes in a dense synaptic neuropil, they possess glycogen granules and contain a very large number of glial filaments, arranged in a manner similar to that seen in astrocytes. The results described in this paper demonstrate that these enteric glial cells are different from typical Schwann cells and satellite cells not only in structural but also in some biochemical features. More work is needed to determine whether these cells should be classified as modified Schwann or satellite cells, adapted to suit a complex, integrative nervous system, or whether they are sufficiently different from other peripheral glial cells to warrant consideration as a separate class of glial cells.

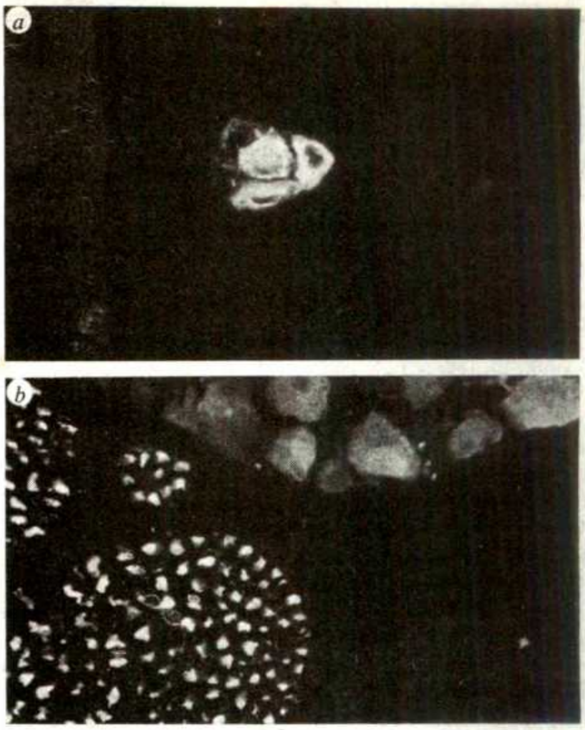

Fig. 3 Neurofilament immunofluorescence in frozen sections of *a*, rat colon and *b*, dorsal root ganglion. 10μm sections were left overnight at 4 °C and then stained overnight with rabbit anti-NF (1:400), followed by G anti-RIg-Rd for 30 min at room temperature. They were then viewed with fluorescence optics as described in Fig. 1. Three neuronal cell bodies in the myenteric plexus are clearly stained with the NF antibodies (*a*). The glial cells surrounding them, in contrast to Fig. 1 *b*, are unlabelled. Neuronal labelling is seen in both cell bodies and axons in the dorsal root ganglion (*b*). In both *a* and *b* there is a clear difference in the pattern of staining between the NF antiserum and the GFAP antiserum staining seen in Fig. 1 (×430).

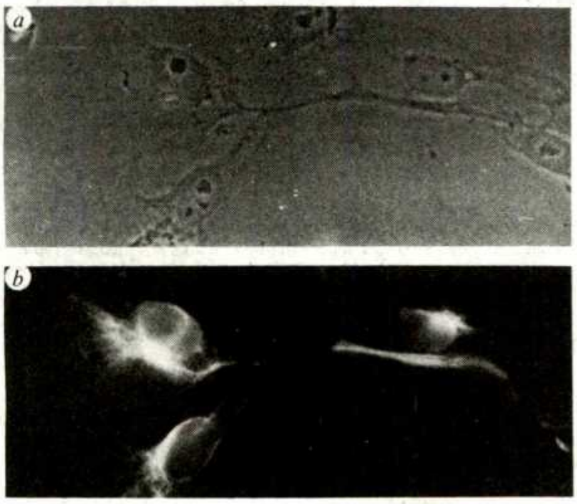

Fig. 2 GFAP immunofluorescence in explant culture from the proximal colon of 15-d-old rat. *a* Represents a phase contrast view of the same field as shown in *b* where fluorescence optics are used (see Fig. 1). Cultures were fixed with 5% acetic acid in ethanol at −20 °C for 10 min, incubated with rabbit anti-human GFAP (1:100) for 30 min at room temperature, followed by G anti-RIg-Rd for 30 min at room temperature. Flat cells in the culture are stained in a filamentous pattern similar to GFAP staining of cultured astrocytes (×640).

We would like to thank Professor Geoffrey Burnstock for generous provision of materials and laboratory facilities, Drs R. Pruss, D. Dahl and A. Bignami for gifts of the three antisera raised against human GFAP, and Dr B. H. Anderton for the NF antiserum. K.R.J. was supported by the Mental Health Foundation.

Monoclonal anti-acetylcholine receptor antibodies can cause experimental myasthenia

David P. Richman*, Christopher M. Gomez*, Phillip W. Berman†, Steven A. Burres*, Frank W. Fitch* & Barry G. W. Arnason*

Myasthenia gravis (MG) is a disease which occurs as a consequence of an autoimmune response directed against the nicotinic acetylcholine receptor (AChR) of the myoneural junction[1-3]. Antisera raised against complex antigens such as AChR comprise a mixture of antibodies reactive with various determinants on the antigen molecule. The antibodies against any single determinant may be of several immunoglobulin classes and idiotypes. Antibodies produced by cloned lymphocyte–myeloma hybridoma cell lines have provided a way of analysing the diverse components making up a polyclonal antiserum[4] and assessing the relative contribution made by each to the overall immune reaction *in vivo*[5,6]. We have applied this technique to the investigation of the autoimmune response in MG. We demonstrate here that certain monoclonal anti-*Torpedo* AChR antibodies, when injected intravenously into normal rats, induce an acute myasthenic syndrome. Thus binding of a single molecular species of antibody reactive with a single antigenic determinant can result in all of the manifestations of an autoimmune disease.

Hybridoma cell lines producing anti-AChR antibody were obtained and partially characterized as described elsewhere[7,8]. A Lewis rat (Microbiological Associates) was immunized with AChR purified from the electroplax of *Torpedo californica*. Spleen cells from this animal were fused with the mouse myeloma cell line P3-X63-Ag8 (provided by Dr C. Milstein). Proliferating hybridomas were screened for production of anti-AChR antibody by a haemagglutination assay (HA) using sheep erythrocytes coated with *Torpedo* AChR (ref. 8).

The binding properties of the hybridoma antibodies have been partially characterized by assessing changes in HA titre when AChR-coated red cells were preincubated with cholinergic ligands. Antibodies from the independently isolated, cloned, hybrid cell lines fall into four groups (1) blockable by α-bungarotoxin; (2) partially blockable by cholinergic ligands; (3) titres increased in the presence of some nicotinic ligands; (4) titres unaffected by any cholinergic ligand or by α-bungarotoxin[8]. The heavy chain class (Table 1) of each antibody was determined by radial immunodiffusion with antisera (provided by Dr Hervé Bazin)[9]. Immunoglobulin-enriched culture supernatant preparations from each hybridoma and from P3-X63-Ag8 were injected intravenously into individual young female Lewis rats (Fig. 1). Animals were examined every 12 h. At either 48 or 72 h the animals underwent *in vivo* measurement of the evoked muscle responses of the gastrocnemius muscle to repetitive sciatic nerve stimulation and *in vitro* measurement of minature endplate potentials (m.e.p.ps) from the diaphragm[10]. All m.e.p.p. amplitudes were corrected to a resting potential of 85 mV. Input resistances ranged from 4 to 15 MΩ. At 48 or 72 h tissues were taken for histological study and blood samples were obtained for serum antibody titre determination by both HA and radioimmunoassay[11].

Two of six antibodies tested (56I and 73G) produced both the clinical and electrophysiological manifestations of myasthenia in injected animals (Fig. 1, Table 1). Injection of similar amounts of antibody (as determined by both antibody titre and immunoglobulin concentration) from the other anti-AChR producing hybridomas or from the myeloma line alone was ineffective. Decrementing evoked muscle responses to repetitive nerve stimulation and diminished amplitude of m.e.p.p. correlated with clinical disease (Table 1). Of five animals tested with clinical signs of myasthenia, four demonstrated decrement of 10% or more. None of 10 animals injected with other antibodies or with the myeloma protein exhibited decrement. The m.e.p.p. amplitudes of 6 of 8 animals injected with antibodies 56I or 73G were lower than any of the values for the 10 animals injected with the other antibodies or myeloma protein. The means of the two groups differed significantly [0.55 ± 0.02 compared with 0.70 ± 0.02 mV (mean ± s.e.m.), $P < 0.001$][12].

Frozen sections of muscle were obtained from several sites. Mononuclear cell infiltrates were located selectively in the regions of endplates of animals injected with antibodies 56I or 73G (Fig. 2*a*). In these areas numerous fibres were undergoing necrosis with frank invasion by mononuclear cells. In sections stained for cholinesterase activity, many cholinesterase-reactive regions were separated from the underlying fibres; the cholinesterase staining was sometimes diffuse and lacked detail (Fig. 2*b*). Frequently mononuclear cells were interposed between the muscle fibres and the cholinesterase-reactive regions (Fig. 2*c*). Serial sections stained for acid phosphatase demonstrated that the infiltrating mononuclear cells were macrophages. No histological abnormalities were found in animals injected with the other antibodies or the myeloma protein.

The syndrome produced here by injection of a hybridoma supernatant fraction containing monoclonal anti–AChR antibody is indistinguishable from the acute phase of rat experimental autoimmune myasthenia gravis (EAMG)[13] or from the disease produced by injection of syngeneic immune serum[14]. The fact that preparations from some anti-AChR producing clones, and from the myeloma line alone, produced no effects suggests that it is not other factors present in the culture supernatants that are responsible for the observed findings. This is the first demonstration, to our knowledge, of the production of

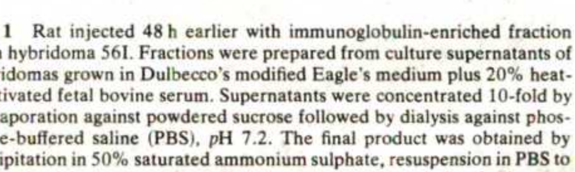

Fig. 1 Rat injected 48 h earlier with immunoglobulin-enriched fraction from hybridoma 56I. Fractions were prepared from culture supernatants of hybridomas grown in Dulbecco's modified Eagle's medium plus 20% heat-inactivated fetal bovine serum. Supernatants were concentrated 10-fold by pervaporation against powdered sucrose followed by dialysis against phosphate-buffered saline (PBS), *p*H 7.2. The final product was obtained by precipitation in 50% saturated ammonium sulphate, resuspension in PBS to ~5% of original volume, and dialysis against PBS. A similar faction was prepared using supernatants from cultures of the myeloma line P3-X63-Ag8. Approximately 1 ml (40–100 mg of protein of 56I and 73G, up to 250 mg of the other antibodies) of each preparation was injected into normal rats. Agar gel electrophoresis followed by densitometric scanning indicated that all preparations consisted of 85–90% albumin and 10–15% immunoglobulin. Isoelectric focusing of the material (performed by David Mattson) revealed 8–12 immunoglobulin bands, 6 of which were those of the myeloma protein. Clinical disease had a similar time course in animals receiving either of the two myasthenia-inducing antibodies and correlated with dose of antibody injected and with serum titre at time of death. Extremity weakness was noted 18–24 h after injection; this worsened over the next 24–36 h. In more severely affected animals susceptibility to fatigue was such that, after one or two steps, the animals lurched to either side. Some showed almost no power in flexion or extension of upper extremity digits so that the front paws remained cupped. Weight loss in these animals, possibly caused by weakness of neck extensors and muscles of mastication, averaged 17 g over the 3-day period of observation. Consistently observed were dried porphyrin secretions crusting the eyelids, nares, and periorbital fur. Weakness was reversed temporarily by intraperitoneal edrophonium chloride.

0028-0836/80/330738—02$01.00

a defined pathological syndrome by an immune reaction mediated by monoclonal antibody. Since the antibody is monoclonal it is presumed to bind to a single determinant on the AChR molecule, to express a single set of idiotypic determinants, and to be of a single immunoglobulin class. It must have, therefore, a single set of effector functions, for example, interaction with complement, interaction with macrophages. These characteristics are sufficient, in the cases of antibodies 56I and 73G, to induce myasthenia.

Data are not yet available to explain the failure of some of the anti-AChR antibodies to induce myasthenia. Since the antibodies were raised against AChR from *Torpedo californica* electroplax, it is most likely that the ineffective antibodies simply do not cross-react with rat junctional AChR (preliminary data seem to support this explanation). Other possible explanations may include a requirement for binding to a particular portion of the AChR molecule.

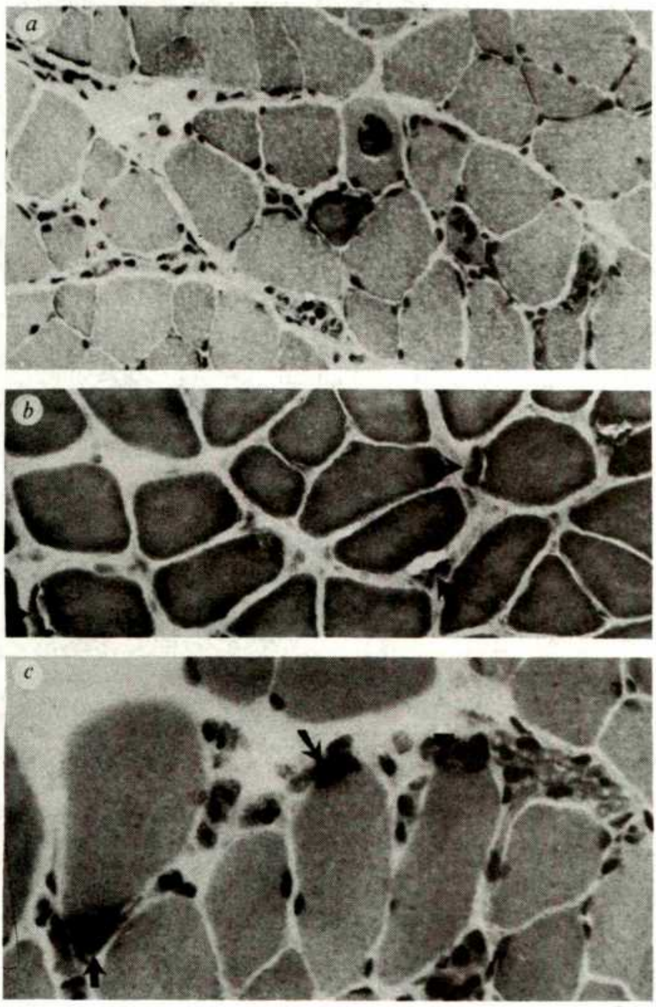

Fig. 2 Forelimb extensor muscle specimens from an animal injected 48 h earlier with antibody 56I. Fresh tissue was quick frozen, sectioned (9-μm), and stained with haematoxylin and eosin (*a*), or for cholinesterase activity by either a modification of the Karnovsky method[22] (*b*) or by α-naphthyl acetate esterase[23] (*c*). Some sections were also stained for acid phosphatase activity[24] (not shown). Mononuclear cell invasion, along with presence of necrotic fibres, is seen in a region shown, on serial section, to contain many end plates (*a*). Several cholinesterase-reactive regions (arrows) are separated from their muscle fibres (*b*). Direct observation identified these regions as cholinesterase-reactive by their distinctive brown gold colour. Invasion of cholinesterase-reactive regions (arrows) by mononuclear cells is seen along with disintegration of one region (arrow head) identified under direct observation by the distinctive dark red colour obtained with this technique (*c*). *a*, ×135, *b*, *c*, ×90.

Table 1 Effects of monoclonal anti-AChR antibodies

Hybridoma antibody (Class) [Specificity pattern]*	Disease score†	Amount injected (nmol)‡	Serum HA titre ($\log_2$)§	% Decrement at 5 Hz‖	m.e.p.p. amplitude (mV)

‖ incr. increment.

ND, not done.

¶ As determined by radioimmunoassay with ^{3}H-AChR (ref. 11), since the binding of this antibody is blocked by α-bungarotoxin.

** $P < 0.01$ when compared with mean of 60D, 62J, 57L, 77F, P3-X63-Ag8.

Mere binding of antibody to AChR is probably not sufficient to induce the syndrome. Various studies have suggested requirements for cross-linking of AChRs by antibody and for complement fixation[15-20]. Such antibody effector functions are primarily determined by heavy chain class or subclass. Both myasthenia-inducing antibodies, 56I and 73G, are of subclass IgG2b and should, therefore, be capable of diffusing into muscle, binding macrophages and fixing complement[21].

The observations reported here establish that a single antibody species, in an otherwise normal organism, can lead to a severe immunologically mediated disorder. Loss of regulation of a single immunocyte clone may be sufficient, therefore, to cause an autoimmune syndrome.

Human chorionic gonadotropin (HCG), or an HCG-like substance (HCG′), has been reported to be produced more widely in human than merely by placental tissue and by certain tumours[1,2]. It has been difficult to detect low levels of HCG in the presence of human luteinizing hormone (LH) because the two are structurally similar and react similarly in most assays. Each is composed of two glycoprotein subunits (α and β), and the major difference between the hormones is an extra 35 amino acid residue at the carboxyl terminal of HCG β-subunit[3]. The availability of a radioimmunoassay using antibodies directed towards this sequence made possible the distinction of HCG′ from LH in extracts of urine from normal postmenopausal women and in pooled human pituitaries[4,5]. Although the existence of HCG′ in either urinary extracts or pituitary fractions has been investigated extensively, on the basis of immunological, biological and physicochemical characteristics typical of HCG, the possibility that some proteases mimic the biological and immunological activities of HCG[6,7] must be carefully considered. We describe here a series of isolation procedures, including a specific immunoaffinity chromatographic step and isoelectrofocusing, which not only separate HCG′ from LH but also eliminate the effect of protease contamination. Furthermore, analyses of our purest HCG′ have revealed that its isoelectric points, molecular size and immunological and biological activities are similar to those of HCG but distinct from those of LH.

Peptides corresponding to the carboxyl terminal sequence of HCG β-subunit are denoted here as s12, s30, s35 and t23 (refs 1, 8, 9). The numbers indicate the number of residues in the peptide (counting back from residue 145, the carboxyl terminal glutamine); s denotes synthetic and t denotes isolation from a tryptic digest of the β-subunit. A specific radioimmunoassay based on an antiserum to s35[9] was used to measure HCG′ in eluents of ion exchange chromatographs. Alternative antisera are specified in Figs 1 and 2 legends. Other assays used were an *in vitro* bioassay based on stimulation of testosterone production by mouse interstitial cells[10] and a radioligand receptor assay using rat testis homogenates[11]. The adsorbent for immunoaffinity column chromatography was prepared as follows. The γ-globulin fraction from a well characterized antiserum (H114)[8] raised in rabbits against s30 was fractionated on a column of Sepharose 4B which had been covalently linked[12] to s12. After washing the column with 0.01 M Na, K-PO_4 and 0.15 M NaCl, *p*H 7.4 (PBS), the adsorbed antibodies were eluted with 0.1 M citrate buffer, *p*H 2.2. After dialysis and concentration by ultrafiltration, they were coupled[12] to Sepharose 4B. This immunoabsorbent preparation was able to bind 102 μg of HCG (lot CR119) per ml of gel sediment.

The starting material for purification of HCG′ was the freeze-dried follicle-stimulating hormone (FSH)-containing fraction CM-1 which had been isolated by a standard procedure from pooled acetone-dried human pituitaries[13]. Specific radioimmunoassay revealed that HCG′ was concentrated in this fraction, from which most of the LH had been removed. Further purification of FSH yielded an FSH-free side-fraction (designated DE-1) which was unadsorbed on DEAE-cellulose chromatography in 0.02 M potassium phosphate buffer at *p*H 7 (ref. 13) and which was eightfold more potent in HCG′ than fraction CM-1. A small portion of fraction DE-1 (in the above phosphate buffer containing 0.2 M NaCl, 0.37 mM $CaCl_2$ and 0.37 mM $MnCl_2$) was fractionated on a column of concanavalin A–Sepharose. Less than 5% of immunoactive HCG′ was unadsorbed. The bulk of the recoverable HCG′ was apparently glycosylated as it could be eluted with 1 M α-methyl-D-glucopyranoside. Chromatography of DE-1 on Sephadex G-100 yielded a fraction (Seph-2B) in which HCG′-specific immunoactivity was increased a further twofold to a potency 1% as active as highly purified HCG (lot CR119). The peak elution volume of the immunoactivity suggested a molecular size larger than that of LH and similar to that of HCG. Fraction Seph-2B was obtained in a yield of about 1.6 mg per 1,000 pituitaries.

Immunoaffinity chromatography was used for further purification of HCG′. Fraction Seph-2B (1.5 mg) was applied to a column (0.9 × 10 cm) of Sepharose 4B linked to purified

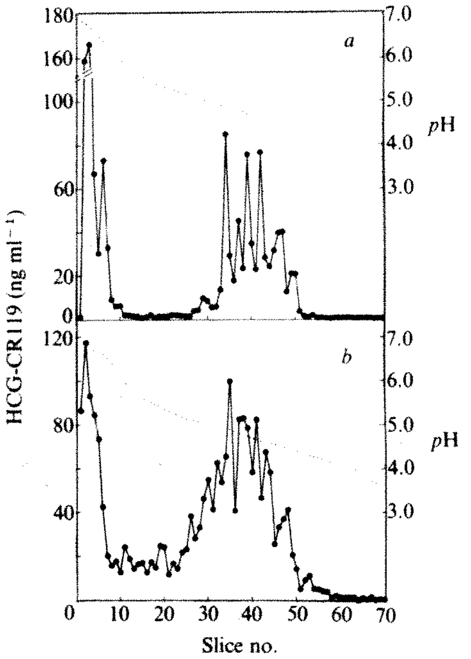

Fig. 1 Isoelectric focusing of fraction Aff-2. This was carried out with cylindrical gels in 6-mm i.d. Pyrex tubes[17]. Carrier ampholytes with *p*I ranges 2–4 (Accurate 42902) and 4–6 (LKB 1809-116) were each diluted to 4% (w/v) in 0.04 M L-histidine buffer, *p*H 7.74. Equal volumes were mixed to make a stock ampholyte solution. Polymerization mixture (2.35 ml per tube) contained 1% ampholytes, 5% acrylamide and 15% *N,N*′-diallyltartardiamide. Polymerization was started by addition of 0.015% (w/v) $K_2S_2O_8$, 5×10^{-4}% (w/v) riboflavin and 0.05% (v/v) *N,N,N*′,*N*′-tetramethylethylenediamine. The catholyte was 0.1 M L-histidine, *p*H 7.74, and the anolyte was 0.1 M formic acid, *p*H 2.29. HCG (CR119), 5.45 μg, (*a*) and pituitary fraction Aff-2, whose immunoactivity approximated to 10 μg of HCG-CR119 (*b*), were each dissolved in 100 μl of 30% sucrose and applied to the gel. The electrofocusing was carried out at 200 V for 18 h. The *p*H gradient along the gels was measured by an automated procedure[17]. Gels were sectioned into 1-mm slices which were each extracted at 4 °C with 1 ml 0.05 M phosphate buffer, *p*H 7.4, containing 0.1% bovine serum albumin (BSA). Each extract was radioimmunoassayed using anti-HCG serum H80[1] (●—●), and major peaks were also bioassayed by measuring testosterone production *in vitro*.

|| To whom reprint requests should be addressed.

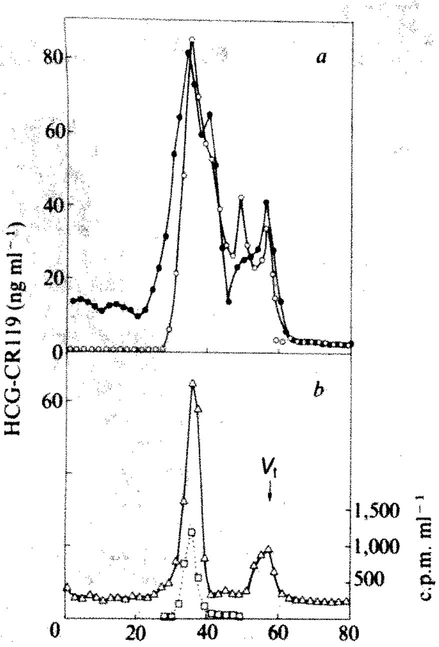

Fig. 2 Gel chromatography on Sephacryl S200 of material in the pooled major peak slices of Fig. 1*b*. A column of Sephacryl S200 (0.9 × 200 cm) was equilibrated with 0.05 M NH_4HCO_3, *p*H 7.8, containing 0.1% BSA. Slices numbered 28–52 were pooled and extracted (as in Fig. 1 legend). The extract was desalted on a column of Sephadex G-25 (equilibrated with the above buffer) and freeze-dried. This material, plus a trace of ^{125}I-iodo-HCG, was dissolved in 2 ml of the buffer and applied to the Sephacryl column. The flow rate was 15 ml h^{-1}; 2-ml fractions were collected. These were tested by radioimmunoassays using anti-HCG serum H80[1] (●—●) and anti-t23 serum H93[1] (○—○), as well as by a radioligand receptor assay (△—△) using rat testis homogenate[11]. The elution of ^{125}I-iodo-HCG was monitored by its radioactivity (□···□). The total column volume is indicated by V_t.

antibodies to s30 and equilibrated with the PBS buffer. The column was washed thoroughly with buffer and water, and adsorbed material (fraction Aff-2) was eluted with 1 M NH_4OH, neutralized with 1 M acetic acid and freeze-dried. This immunoaffinity procedure permits the separation of HCG′ from LH and other substances by binding HCG′ to the purified immunoabsorbent specific to the unique carboxyl terminal peptide of HCG β-subunit. Furthermore, this step should, we believe, eliminate possible pitfalls arising from contaminant proteases which have been reported to simulate HCG activities measuring displacement of ^{125}I-iodo-HCG, stimulation of steroid production or augmentation of adenylate cyclase activity[6,7].

To ascertain whether Aff-2 has physicochemical and immunological characteristics peculiar to HCG and biological activities typical of HCG, the following investigations were carried out. Fraction Aff-2 and purified HCG (batch CR119) were compared in isoelectrofocusing experiments (Fig. 1). Aff-2 contained components within the pI' range 4.4–5.1 (Fig. 1*b*), which is similar to the range for HCG as found by us (Fig. 1*a*) and by others[14]. This is further evidence that human pituitaries contain an HCG-like substance. When immunoreactive peaks were tested by the *in vitro* bioassay[10], all were active in proportion to their immunoactivity. Using a single HCG (CR119) standard we obtained ratios of biological to immunological activities ranging from 0.3 to 0.6. The same range of ratios was obtained for HCG (CR119) in a parallel experiment. Reported pI' values for LH are between *p*H 7 and 9 (ref. 5). The nature of the higher pI' component which appears in both patterns is not known; it was not always detected in separate experiments carried out in the same conditions. If HCG′ is a precursor of LH[4] it is possible that the latter is formed during our experimental procedures and that it appears as the higher pI' component in pattern *b*. Differences in sialic acid content of the various components, which are thought to be responsible for the electrophoretic heterogeneity of HCG[14], may also account for that of HCG′.

To establish whether the acidic components of Aff-2 after electrofocusing had a molecular size similar to that of HCG, the acidic fractions (pI' 4.4–5.1; Fig. 1*b*) were pooled, desalted, freeze-dried, mixed with a trace amount of ^{125}I-iodo-HCG and chromatographed on Sephacryl S200. Chromatogram patterns were revealed by means of two radioimmunoassays and a radioligand receptor assay for HCG (Fig. 2). Each pattern contained a major peak, comprising 73–79% of total activity recovered, and the three peak maxima (corresponding to fractions 34 and 35) were each coincident with the maximum for radioiodinated HCG. Thus, most of the recovered HCG′ with pI' 4.4–5.1 not only exhibited biological activity but also had a molecular size similar to that of intact HCG.

In conclusion, we have demonstrated that the substance purified from human pituitaries by Sephadex G-100 gel filtration followed by immunoaffinity chromatography using purified antibodies specific to the unique carboxyl terminal peptide of the HCG β-subunit, possesses pI' values within the same range as HCG and that the respective acidic components are biologically active in stimulating mouse interstitial cells to produce testosterone. The majority of these acidic components have the molecular size of HCG as revealed by gel chromatography. These data provide further evidence that an HCG-like substance is present in human pituitary extracts which differs from LH in its physicochemical and immunological characteristics. Furthermore, the HCG-like substance found in urinary extracts of postmenopausal women[4] and a patient with Klinefelter's syndrome[1] could originate from the pituitary. Our data also suggest that pituitary HCG′ is glycosylated and thus is different from the non-glycosylated HCG-like substance reported in very low concentrations in many normal tissues[2,15]. However, there was no indication that the gonadotropic activity detected in the latter case was not due to proteases. Although it is possible that pituitaries of pregnant women or patients with neoplasm containing HCG or HCG′ accidentally contaminate the pool of pituitary collection, the detection of HCG′ in pituitary glands and in urinary concentrates[4,5] all from postmenopausal women thought not to secrete HCG, provides strong support that the normal pituitary gland contains HCG′. Larger quantities of highly purified pituitary HCG′ will be required to determine whether it is identical to placental HCG or whether it is an immunologically related substance, possibly a precursor of LH[4] (which is known to have some sequence differences in its β-subunit when compared with the same portion of HCG[16]).

We thank Drs K. J. Catt, E. F. Hartree, G. D. Hodgen and G. T. Ross for helpful suggestions and the MRC for human pituitaries and for a grant in support of this work.

MATTERS ARISING

Does the C-terminal tetrapeptide of gastrin and CCK exist as an entity?

IT was reported by Rehfeld *et al.*[1] that the COOH-terminal tetrapeptide (Trp-Met-Asp-Phe-NH_2, abbreviated to G4 or CCK4), which is common to gastrin and cholecystokinin (CCK), exists in free form in pancreatic nerves, and may control islet hormone release. This report extends previous studies from the same group in which G4 was said to occur in pyloric antral mucosa in concentrations up to twice those of heptadecapeptide gastrin (G17), and in intestine and brain in concentrations considerably higher than those of the 33-residue form of CCK (CCK33) or its COOH-terminal octapeptide (CCK8). In these studies, particular importance was attached to the observation that after gel filtration of tissue extracts, a peak of material eluted in the position of G4 and reacted in radioimmunoassays using antisera specific for the COOH-terminus of gastrin and CCK. However, recent studies in our laboratory cast doubt on the interpretation of these data, and suggest instead that free G4 does not exist in significant amounts in pancreas or gut.

We have raised a rabbit antiserum to G4 conjugated through its NH_2-terminal amino group to thyroglobulin by glutaraldehyde. When used in radioimmunoassays with an ^{125}I-CCK8 label, this antiserum reacts almost equally with G4, G17 and CCK8, and can detect 10–20 pmol l^{-1} of G4. This system offers a clear advantage for the estimation of G4 over the one used by Rehfeld *et al.*, because in the latter system G4 has a 30-fold lower immunochemical potency than CCK8 and CCK33. To estimate the true molar concentration of G4, it was, in effect, necessary for Rehfeld *et al.* to multiply the peak of activity eluting in the position of G4 by 30 compared with the other peaks. There is an obvious disadvantage in this method, for errors are also greatly magnified. Such a correction is unnecessary, of course, when G4, CCK8 and G17 and the other principal forms of CCK and gastrin have equal immunoreactivity. We have found that when hog pancreas is extracted according to the method of Rehfeld *et al.*, the total concentration of immunoreactivity measured with the G4 antiserum was 3.5 ± 0.8 pmol per g (mean, ± s.e., $n = 4$; G4 standard). Closely similar estimates (2.1 ± 0.4 pmol per g) were obtained with a second radioimmunoassay system using an antibody (L48, CCK8 standard) that, like Rehfeld's, reacts about 50 times less well with G4 than with CCK8. Fractionation on Sephadex G-50 indicated that over 80% of immunoreactivity in the extracts had the properties of CCK8. These data indicate that G4 cannot occur in more than trace amounts in pancreas. However, when synthetic G4 was added to the tissue early in the extraction procedure in amounts comparable to those reported by Rehfeld *et al.*, the peptide was recovered in a yield of 73 ± 6%. In parallel studies we have also failed to confirm the presence of G4 in hog, rat or human antral mucosal extracts, which according to Rehfeld *et al.* contain G4 at about 15 nmol per g; instead, we have consistently found a major peak of immunoreactivity corresponding to G17, confirming numerous previous studies.

We conclude from our work that free G4 does not occur in significant amounts in pancreas or gut. The high concentrations of G4 reported by Rehfeld *et al.* reflect the fact that a minor component of gastrin–CCK immunoreactivity is interpreted as G4 and estimates of its molar concentration corrected to allow for the low potency of G4 in the assay system. This correction might conceivably be justified if G4 was proven to exist naturally by isolation and full chemical characterization; this has not been the case. Until the material described by Rehfeld *et al.* in pancreas and elsewhere is isolated and characterized, its true concentration in these tissues cannot be determined. The issues raised here serve to emphasize the very great caution that needs to be exercised in identifying and determining substances by gel filtration and radioimmunoassay, when the material in question has not been isolated.

1. Rehfeld, J. F. *et al. Nature* **284,** 33–38 (1980).

REHFELD *ET AL.* REPLY—First, we note that the total CCK immunoreactivity in pancreatic extracts measured by the G4 antiserum, 3.5 pmol per g, is of the same order of magnitude as that reported by us[1] (6.8 pmol equiv. CCK8 per g). It is interesting also that the L48 antiserum, which reacts less well with G4, measures lower concentrations (2.1 pmol per g) than the G4 antiserum, suggesting that G/CCK4 is indeed present in the pancreas.

Second, Dockray has previously reported[2] that the mammalian brain contains significant amounts of a third immunoreactive component (BP III) with a size corresponding to G/CCK4 or G/CCK6. He measured this BP III peak by four different C-terminal specific antisera (including our ab. 2716). Using CCK8 as standard, the BP III peak constituted 12% of the CCK8-like peak in hog, 31% in dog and 18% in rat cerebral cortex (Table 2 in ref. 2). The BP III peak should be easily measurable by the new G4 antiserum. We are surprised that Dockray has not discussed these earlier results in the light of his new assay findings.

Third, we can only speculate on the reason for the discrepancy between our data (supported by Dockray's earlier data[2]) and those of Dockray and Gregory. (1) Microheterogeneity of the natural tetrapeptide (in analogy with the microheterogeneity of CCK octapeptide[3]) might explain[4,5] the failure of the new assay to measure G/CCK4-like material. (2) Several samples of synthetic G4 received by us from other laboratories have been found to be grossly impure, and even the purest contain minor impurities—might the new G4 antiserum of Dockray and Gregory have specificity for these impurities? (3) In the raising of antibodies, we question the use of G4 conjugates prepared by means of glutaraldehyde. The presence in G4 of N-terminal Trp complicates the normal reaction with aldehydes, and we would anticipate that conjugation would be through a carboline rather than the terminal amino group. If this is so, the specificity of antibodies raised to such conjugates might be abnormal.

In conclusion, we consider the evidence to be in favour of the presence of a tetrapeptide in brain, gut and pancreas, but final confirmation must come from isolation and sequence work.

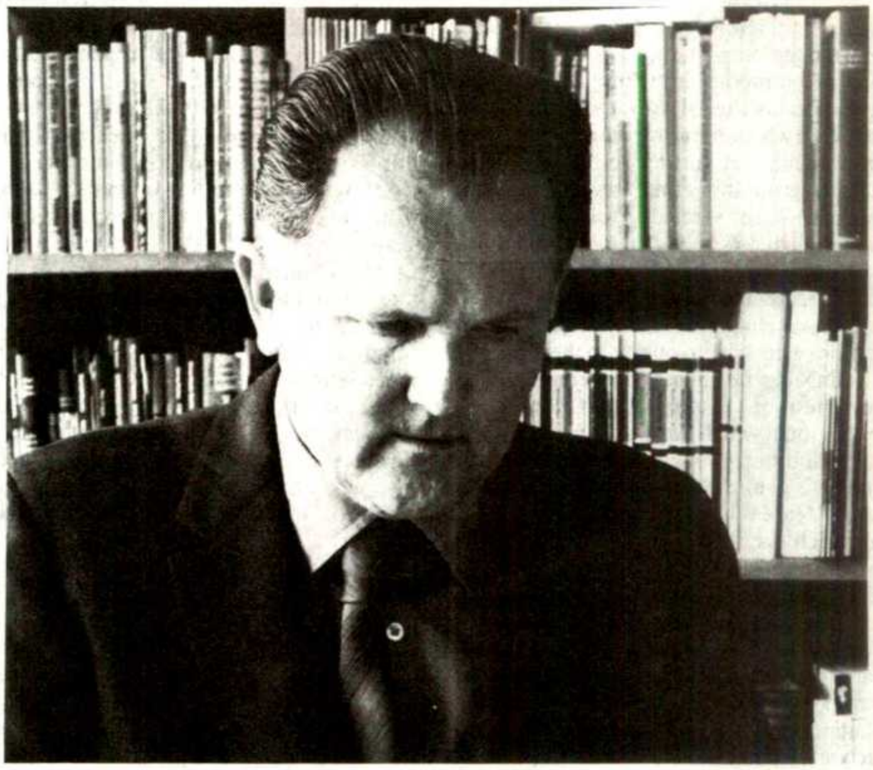
BOOK REVIEWS

Most orthodox heresy: Jensen on IQ myths

Steve Blinkhorn

Bias in Mental Testing. By Arthur R. Jensen. Pp.800. (Methuen: London/Free Press: New York, 1980.) £15, $29.95.

CONSPIRACY theory ranks high in popularity among theories of psychological testing. According to this view, psychometricians, whether wittingly or not, have succeeded in constructing devices which systematically and unwarrantably discriminate against non-whites, lower social classes and possibly females. There is a popular belief that intelligence (mental ability, scholastic aptitude, mental maturity and so on) tests are constructed using scholastic achievement in a white middle-class educational system as a criterion and that devious means are adopted to force scores to a normal distribution. Accordingly, such tests are inappropriate for non-whites, for working, rather than middle-class, individuals and so on. The appropriate action is therefore either not to use them at all or to correct the inherent bias by using lower cut-off scores for, or adding a constant to the scores of, the disadvantaged groups.



Arthur Jensen, "scholarly and dispassionate".

Added impetus to the propagation of this point of view has come in the aftermath of the Burt affair, and phrases such as "the IQ myth" and "the new assault on equality" have gained currency. One of the few topics on which most psychologists (and not only psychologists) seem to feel entitled to pronounce is the validity or otherwise of so-called IQ tests. Sadly, such pronouncements do not always benefit from the technical competence and sense of history which make for an informed judgement. There is a notion abroad that what tests measure and how fairly they discriminate can be determined by inspection, the implication being that psychometricians are peculiarly insensitive to what is patently obvious or deliberately, and for the worst of motives, disingenuous in the pursuit of their craft.

The whole question of inherent bias in mental tests has been brought to a new crisis point by a series of court judgements which have handed down verdicts as to whether or not particular tests are biased. The notorious 15 IQ points difference between mean scores of blacks and whites in the USA gives the topic social, moral and political importance. If this difference is the result of test bias, then something ought to be done about the tests. If, on the other hand, the tests merely reflect a true difference, however caused, then no amount of advanced psychometrics will save an unhappy state of affairs.

Jensen's description of how, as a student, he "came to believe that nearly all standard IQ tests were grossly biased against virtually everyone but the white middle class" is an unexpected entrée to a book which amasses an overwhelming weight of evidence to the contrary. He then proceeds to spend nearly half the book developing the statistical and methodological basis for an examination of test bias. There is implicit in his treatment of classical test theory a criticism of the standard of public debate on test bias. Too many psychologists are either ignorant of, or dismiss as statistical conjuring tricks, elementary procedures such as correcting correlation coefficients for restriction of range or for attenuation by unreliability, or regard predictive validity coefficient of the usual magnitude (0.3 to 0.5) as hopelessly small and indicative of little utility. On the assumption that all interested parties were thoroughly acquainted with basic psychometrics, the book could have been half its actual length.

On the question of bias itself, Jensen is remarkably up to date with the current state of theory and practice. The distinction between bias (a statistical concept and a matter of fact) and unfairness (which involves a value judgement) is well made, and the fact that different definitions of fairness conflict when made operational in terms of the practical use of tests is driven home. The kernel of Jensen's thesis is to be found in Chapters 10 and 11, in which the empirical evidence of test bias (1) in predicting occupational and educational success and (2) in the internal structure of tests, is reviewed. Much of this material is counter-intuitive. It is not the case that for a given test score blacks perform better at work or at school. On the contrary, using prediction equations based on white groups may disadvantage the whites, in that blacks have to do as well or better on the tests to do as well on the task. Nor does the notion that verbal tests yield lower scores for blacks than do non-verbal tests, stand up to scrutiny. Finally, there is no evidence from the internal structure of tests that they are measuring something different in the different racial and social groups.

In short, Jensen provides methods for detecting bias, collates a large amount of empirical evidence and justly concludes that there is no substantial, replicable evidence of inherent bias in commonly used tests where native-born English speakers are concerned. He also disposes of several widespread myths about tests, such as the so-called Pygmalion (teacher expectancy) effect. There is a willingness evident in the psychological community to accept criticisms of psychometric techniques on blatantly *ad hoc* grounds, and a supreme unwillingness to pay attention to the large body of empirical evidence which supports the utility of tests, in particular in cutting across social and ethnic groupings and revealing talent where it is least expected (which, after all, was the original reason for their introduction).

Jensen has neither time nor patience for the overuse and misuse of tests, however. His last chapter is an indictment of malpractice which ought to be required reading for all those who actually enjoy using tests or like to treat IQ as the criterion of personal worth *par excellence*.

Undoubtedly many will feel that by restricting himself to a rather technical brief Jensen is missing the point. The abstractness for which test constructors often strive, they may point out, is itself a cultural variable, highly prized and cultivated in the white middle-class. The format of tests reinforces certain values (accuracy at speed, seeking to generalize, solution of problems in the abstract rather than the concrete) which may be dominant in white middle-class culture.

There follow from this two questions. Is it the case that the kinds of abstract reasoning abilities implicated in, say, Spearman's view of intelligence can be consistently assessed? Is it the case that an individual's capacity to deal effectively with his world depends on such skills? If the answer to the first is affirmative, as Jensen claims and by and large demonstrates, the answer to the second is by no means an obvious yes. Wechsler has defined intelligence as "the capacity of an individual to understand the world about him and his resourcefulness to cope with its challenges". Such a view clearly involves the nature of the world in which an individual exists, and non-intellective characteristics of the individual as important elements in the determination of intelligence.

Now, tests constructed in line with the views of both Spearman and Wechsler intercorrelate highly. This is hardly surprising, given the importance placed in Western society on intellectual skills, for we live in a society where some social security forms demand a higher level of reading skill than the *Times*. But the distinction needs to be maintained, not least because whilst a given level of intelligence in Spearman's terms may imply capacity to cope with the business of living, the reverse need not be true. One wonders whether the high value placed on intelligence in our society is a universal feature, not so much in remote tribes as in ancient Egypt and Rome, or to choose a more immediate instance, in China during the cultural revolution. That is to say, could we choose to organize our society so that differences in intelligence are unimportant, and if so would that kind of society be successful, stable and desirable?

If, as Jensen shows, the accusation of test bias is unfounded, then the truth of the matter is that differences in achievement reflect the extent to which society demands the abilities assessed by the tests. Whether these demands are proper, necessary and fair is entirely open to question, but fiddling test scores to make racial differences vanish is as unworthy as the exaltation of IQ as the sole criterion of personal worth. It neither promotes the interests of those in sympathy with whom it is done nor protects them against the failure it makes more likely. It makes as much sense as subtracting 8 IQ points from the scores of myopics, on the grounds that this is the mean difference between myopics and non-myopics, and clearly myopics are advantaged in that their condition makes them read more books and play less football.

There is a widespread notion that since tests necessarily involve specific tasks, IQ is merely a matter of specific learned skills of a particular kind. Yet such evidence as there is suggests that coaching in specific skills has little transfer value. The point of intelligence testing is not whether an individual can solve problems having a certain logical structure, but whether he can identify the logical structure and find strategies to solve them. Many tasks can be made easier by making their structure more patent and immediately concrete: much of the recent work critical of Piaget has adopted this approach. Such studies point to ways of bringing a wider range of performances within the capacity of the individual, and have immediate relevance to education and training. Their relevance to the study of intelligence, seen as a high-level ability to detect the structure of problems and organize lower-level strategies towards a solution, is however seriously in doubt.

This book is informative, refreshing and a valuable contribution to the literature; its worth as a compendium can hardly be overrated, and it may well find a role as a textbook of psychometrics for the clarity of its exposition of classical test theory. Its scholarly and dispassionate tone will come as a surprise to those who know of Jensen only as a leading figure in anti-test demonology, however out of sympathy they may be with its content.

Steve Blinkhorn is a Senior Lecturer in Psychology at Hatfield Polytechnic, UK.

Understanding nuclear astrophysics

Bernard Pagel

An Introduction to Nuclear Astrophysics. By Jean Audouze and Sylvie Vauclair. Pp.168. (Reidel: 1980.) Hardback Dfl.75, $39.50; paperback Dfl.40, $19.95.

SINCE the 1920s, the development of astrophysics has been closely associated with advances in nuclear physics which have led to our current understanding of stellar energy sources, stellar evolution, nucleosynthesis and nuclear cosmochronology, and to continuing attempts to understand the distribution of the chemical elements in the light of ideas about cosmology and the evolution of galaxies.

These topics are engagingly presented by two well-known French astronomers in this book, which is written at a level suited to first-year undergraduates, but will also be appreciated by graduate students and others desiring an up-to-date introduction to the subject. Succinct descriptions of the basic interactions of physics and of the observable Universe are followed by outlines of big-bang cosmology, stellar evolution and the abundances of the elements in the Solar System, stars and cosmic rays. The remainder of the book gives somewhat more detailed accounts of specific theoretical topics: nuclear reactions and the various nucleosynthesis processes currently considered significant, Solar System and galactic nuclear time-scales and the chemical evolution of galaxies. A brief concluding chapter sketches historical developments and a few outstanding problems.

By far the strongest feature of this book is the nuclear physics, which is carefully and clearly described at the appropriate level. Other aspects are more sketchily treated. This does not matter too much for the observational part, which is adequate as a background to the theory apart from occasional minor infelicities such as a reference to quasars as having "the same optical properties as the stars". A more serious gap is the lack of a coherent account of the non-nuclear aspects of stellar structure and evolution, which makes it difficult for the reader to envisage the context in which the nuclear reactions operate. The chapter on nuclear chronologies and the origin of the Solar System is especially good, but the one on chemical evolution of galaxies shows signs of over-hasty preparation and proof-reading — some equations (including one credited to myself!) are either nonsensical as written or inconsistent with the accompanying text; inconsistent and undefined symbols also occur. (There are also a few minor errors of fact here: the abundance ratio N/O is not as high in the Magellanic Clouds as in the solar neighbourhood and the simple model of galactic chemical evolution does not predict that we should see stars with *literally* zero metal abundance.) The English is generally adequate, though noticeably less than perfect. Finally, prospective purchasers should be warned that I have come across a copy (not my review copy) that is misbound, with several pages in the wrong order.

In short, a curate's egg of a book in which the largely excellent intentions of the authors have been frustrated by insufficient attention to detail at different stages of production. The broad sweep of the subject is well presented, though, the illustrations are good and a useful set of references is given, so that on balance this is a welcome and useful book. ☐

Number 3 in the *Enzymes* dynasty

Athel Cornish-Bowden

Enzymes. Third edition. By Malcolm Dixon and Edwin C. Webb. Pp. 1116. (Longman: London/Academic: New York, 1979.) £25, $49.50.

WHEN THE first edition of this book was reviewed in *Nature* (**182**, 969-970; 1958) it was described as "one of the finest books that has appeared on the topic of enzymes". Two editions and 22 years later this is still true; there have been other excellent books on enzymes, but none with the breadth of this one. Despite the long period since the second edition appeared in 1963, the new edition resembles its predecessors surprisingly closely and has essentially the same organization of material. The authors have included an astonishing amount of useful information in what is still a single volume. This is especially remarkable in view of the amount of space they have devoted, mistakenly in my view, to the Enzyme Commission's classification system for enzymes. More than 300 pages are given over to a description of its principles and a virtually complete list of known enzymes. Surely a better use could have been found for this space.

Another section of questionable usefulness, one that must surely have added substantially to the price of the book, is the "Atlas" of crystalline enzymes, which consists of 25 pages of reproductions of photomicrographs. As this is now relegated to close to the back of the book it would seem that the authors recognize that readers no longer gasp in wonderment at the knowledge that enzymes can be crystallized.

In other respects the authors have displayed an admirable sense of what is worth including and what is not. The early chapters are concerned with practical matters and include much useful advice without becoming enmired in experimental detail of no general interest. The discussion of steady-state enzyme kinetics is especially good and almost justifies purchase of the book by itself. Rather oddly, it is not all in one place but is divided between Chapters 4 and 8, which account for about a quarter of the book. Obviously there are some points of detail where one might quarrel with the treatment, but in general it is balanced and thorough. These two chapters also contain an account of transient-state kinetics, but one senses that this is not a major interest of the authors. The other chapters, concerned with specificity, mechanisms, cofactors, protein structure, protein biosynthesis and enzyme biology, are also of a high standard. Of these, protein biosynthesis is perhaps one topic that might have been omitted, not because of any lack of importance, but because it has developed into a subject rather separate from general enzymology and I doubt whether its devotees will look for an account of it in a book about enzymes.

Finally, a word about production. I was pleased to be sent a copy of the American edition for review, as this is soberly and robustly bound. By contrast, the British publishers should be ashamed of their covers, which are not only ugly but are also far too flimsy for a book of 1100 pages. ☐

Scientific terms by numbers

Alan Isaacs

Longman Dictionary of Scientific Usage. By A. Godman and E.M.F. Payne. Pp.684. (Longman: 1980.) Flexi £4.35, $14.95.

FOR THE casual user of a scientific dictionary — someone who needs to look up the meaning or spelling of a word from time to time — this is not the book to buy. To find the meaning of a word in this dictionary you have first to read the instructions, then you have to look in the index for a two-letter set code that will identify the field of science of the word and for a three-figure number to find the position of the word in the set. Memorizing both the set code and the number, you then search the body of the book for the appropriate set. The alleged advantage of this cumbersome system is that the book is designed specifically for the non-native speaker of English who will benefit from the thesaurus-like arrangement in which terms that are "closely related in meaning or subject area" are grouped together. Even if foreign learners have more patience and perseverance than native speakers, this system has its dangers. If you look up *free electron* in this dictionary you will be directed from the index to the section on radio terms (code NM). There you will be told that it is "an electron in a crystal which [*sic*] is free to move under the influence of an electric field". The user, if he relies on this dictionary, will never know that free electrons also exist in gases. This example highlights the hazards of this kind of coding.

In general, though, the definitions appear to be clear and accurate, and there are plenty of useful collocations and cross-references to help the foreign learner (once he has mastered the meaning of the cross-referencing arrows pointing East, North and South). It is such a shame that most compilers of dictionaries for non-native speakers feel obliged to clutter their books with redundant information (the new *Chambers Universal Learners' Dictionary* is a notable exception). Will a foreign scientist or student really be helped by seeing An or H against a word? Even if he looks in the front matter, where he will learn that the former denotes a non-gradable antonym and the latter a hyponym, will he be any the wiser? If I were a foreign scientist I would want a dictionary that tells me what I want to know simply, by having the information available in its alphabetical place. I am not sure that I would want to be confused with coded answers to questions that I am never likely to ask. Hyponym indeed! □

Alan Isaacs, a former teacher of scientific English to foreign students, is editor of the Penguin Dictionary of Science *and* Longman's New Dictionary of Physics, *and science editor of* Collins English Dictionary.

RNP particles and the virus club

B.S. Cox

Viruses and Plasmids in Fungi. Edited by Paul A. Lemke. Pp.680. (Dekker: 1979.) SFr.110, $55.

MANY fungi harbour ribonucleoprotein particles consisting of a spherical or polyhedral capsid-like structure 35 ± 10 nm in diameter, containing one or more molecules of double-stranded RNA. The particles are rather reminiscent of reovirus.

They are a remarkable group of objects. In the first place, it appears to be quite impossible to infect any fungus with them. The lengths to which numbers of mycovirologists have gone to demonstrate this rather fundamental property of a virus have been extraordinary, both for the man-hours spent and the total lack of success. Secondly, without exception, they are symptomless. Of course it is rather difficult to connect the symptoms of a disease with a virus if one cannot infect the host with it; and the energetically-researched "La France disease" of cultivated mushrooms may indeed be caused by the two or more 'viruses' associated with it. On the other hand, of course, the disease may cause the viruses. 'Virus' is often found, apparently, in healthy mushrooms.

Not all of the *ds*RNAs of fungi are without phenotypic effects. Cytoplasmically inherited *ds*RNAs produce the 'killer' toxins of many species of yeast and of the smut fungus, *Ustilago maydis.* They also apparently cause the fascinating non-pathogenic variant of *Endothia parasitica.* This blight has deprived two generations of Americans of their native chestnuts for the Thanksgiving stuffing. The hypovirulence of the variant is invasive and suppressive, and can be used not only to limit the spread of the cankers caused by virulent strains on *Castanea* but actually to depress the virulence of the pathogen itself.

Cryptic or not, these RNP particles of fungi are curiosities. They are extremely widespread, occurring in all major groups of fungus including water moulds. They form a strikingly homogeneous group of organelles. Homogeneity, universality and non-infectionness suggest a very ancient common origin, but how have they been maintained? Is it possible for a non-essential, wholly cryptic self-replicating particle to survive in such a specialized environment without the means of spreading by infection? The killer (M) *ds*RNA of yeast depends for its maintenance on 30 nuclear genes: one mutation and it's gone. How does it survive? The L-*ds*RNA has not been found to depend on any nuclear genes. Why not? Do the *ds*RNAs do something useful, or is the killer/immunity property a self-selecting mechanism? If so, do all fungi possess it?

Although neither answers to these questions nor, indeed, the questions, are to be found in this book, there are two clear and succinct reviews of the genetics and molecular biology of the RNP particles of yeast, *Ustilago* and *Endothia.* There are also excellent accounts, sometimes commendably brief, of an assortment of non-RNP particles, DNA plasmids, bacterial or rickettsia-like structures and even a couple of cytoplasmically-inherited conditions with no particle to call their own (senescence in *Podospora* and meiotic failure in *Coprinus*). For the rest, there are detailed, rather self-indulgent articles cataloguing biophysical and ultrastructural studies of RNPs, speculations about their life-histories, a methods paper without protocols, many more or less indistinguishable electron micrographs and many a discussion about what these RNPs should be called. The general opinion is that they should be awarded the accolade 'virus', perhaps by broadening the category of admissible members. I can't help feeling that this obsession with joining the club has rather diverted attention and effort away from the problem of what they really are. Much of the repetitive material about functionless particles could have been condensed into a single review article (Chapter II covers all the ground) and perhaps some space given to the many other cytoplasmically-inherited determinants of fungi which have phenotypes but no physical basis yet identified. Visibility in the electron microscope is not the only passport to respectability.

The book is a little out of date but is, nevertheless, for some topics, a very useful source. □

Jewish genetics

Kurt Hirschhorn

Genetic Disorders among the Jewish People. By R.M. Goodman. Pp.493. (Johns Hopkins University Press: 1979.) $32.50, £17.50.

THE genetics of the Jewish people have received a great deal of attention over the past few years. This is primarily due to the virtually unequalled opportunity created by the population dynamics of the state of Israel. Previously isolated groups of Jews have been immigrating to Israel, where they continue a certain degree of inbreeding and are beginning to outbreed with other Jewish groups. Driven by the tradition of Israeli research on human genetics, particularly under the leadership of the late Drs E. Goldschmidt and C. Sheba, a new and large generation of human geneticists has been quick to take advantage of this temporary opportunity.

Three recent publications summarizing these data as well as studies done outside Israel have been *The Genetics of the Jews* by A.E. Mourant, A.C. Kopec and K. Domaniewska-Sobczak (Clarendon: 1978), *Genetic Diseases Among Ashkenazi Jews* edited by R.M. Goodman and A.G. Motulsky (Raven: 1979) and the book reviewed here. The first of these is primarily a tabular accumulation of gene frequencies in various Jewish groups and contains much useful data, while the second represents the proceedings of a symposium with many excellent reviews.

This present book is a *tour de force* which pulls together a mass of reports and develops a comprehensive description of the status of these studies. One could argue with some details such as interpretations of ancient history and the inclusion of a number of genetic diseases found in Jews with "Jewish genetic diseases", and there are occasional lapses in clarity. None of these criticisms should detract from the fact that this is a major and useful book for all human geneticists as well as students of Judaism. This is a field which is applicable to genetic centres wherever Jewish patients may appear and which is certain to grow over the next 20 years. The book also provides a general model for genetic studies in populations, and is therefore recommended for a wide audience. □

21 August 1980

Directive 59 and European defence

The Democratic convention last week was perhaps needlessly enlivened by the curious affair of Mr Edmund Muskie's claimed innocence of the most recent alleged shift in United States strategic policy — the increased emphasis now to be given to military targets in the disposition of American nuclear warheads. Several questions arise, but are unlikely to be answered in the near future, if at all. Did President Carter let slip news of the instruction to the US military on which the new strategy is based — called Directive 59 — in order to impress the impending convention or to take the wind out of Mr Reagan's sails, thus robbing the Secretary of Defense, Dr Harold Brown, of the place in the history books that he might have earned by making a public speech on the subject? (Dr Brown will indeed have made such a speech on 20 August.) Did Mr Muskie have to complain about not knowing of Directive 59 because his officials at the Department of State had not had time to tell him? And did he complain in the terms he used — more sorrow than anger — because of the rumours current earlier in the week that the Secretary rather than the President might end up as the Democratic Party's nominee for the election in November? In this quiet season of the year, these questions will excite attention for weeks to come. There is a danger that the more important question of what Directive 59 really means may be overlooked.

The first thing to say about Directive 59 is that it is not so much an order to the troops as an acknowledgement of what the tropps have been doing, and are prepared to do. Many years have passed since the Department of Defence sought to demonstrate to Congress and the world that the great megatonnage in the warheads of Soviet missiles was more than made up for by the versatility of Multiply-Independent Re-entry Vehicles or independently targeted warheads, MIRVs for short. Since then, both sides of the equation have become larger, and their difference no easier to calculate. For at least a decade, however, the United States has made no secret of its wish to be so well equipped with accurate and separately manoeuvrable warheads that it can reasonably hope to attack crucial military targets, not just cities full of mere people. With the MX missile, and others of the same generation now in prospect, the US military (and their Soviet counterparts) should soon be able to deliver on that promise. Directive 59 is therefore largely an acknowledgement in public of what the Pentagon has been saying about its aspirations since the early 1970s. It should be acknowledged that half a decade has yet to pass before US Strategic Air Commands will be so well equipped that they can do what the US President now says they must do — to be prepared to fight strategic nuclear wars by matching their opponents' strength tit-for-tat while keeping enough in reserve to be able to deliver a final devastating assault. The commanders, however, are not running for election.

For those with long memories — historically, so to speak — there is an ironical circularity in this state of affairs. A quarter of a century ago, when the American Atlas and Titan rockets were still being tested, while the Soviet strategic armoury was dependent on subsonic aircraft for delivery, and when what was called the Cold War was at its height, a number of honest men (the late Sir John Slessor prominent among them) developed the theory of "graduated deterrence". The idea was that the world would be a safer place if the West, at least, was able to match its retaliation more or less exactly with whatever attacks might come its way. The objective was to find some way of managing the escalation of a strategic nuclear war so that it could stop short of the ultimate catastrophe, mutual and virtually total destruction of the two sides in a conflict. The concept was to many people preferable to that of deterrence based on all-out retaliation at the first sign of a strategic attack, but even on paper there were snags. To many Europeans, the most obvious flaw in the theory was that controlled escalation of a strategic conflict would make it possible for the United States to lose its nerve half-way along, with the result that the United States guarantee of Western Europe would be diminished. The most serious argument against the theory of graduated deterrence, at least in the nuclear stages of a strategic conflict, was, however, technical; the missiles of the 1950s were simply not accurate enough to match the need. What has happened now, after a quarter of a century, is that it will soon be technically possible to follow a strategy of graduated deterrence.

What will be the consequences? Again the 1950s are instructive, and it is no surprise that Dr Harold Brown thought it wise to send a message of reassurance to the other NATO governments once Mr Carter had let Directive 59 out of the bag. The new strategic doctrine, Dr Brown said, is but a stage in the evolution of United States strategic policy. This is no more than he said at the meeting of the NATO Nuclear Planning Group at Bodo in Norway last June, and what he is likely to repeat when the same group meets again in November. Other NATO governments appear to have accepted this to be the truth, but they have not yet had time to work out the implications of the new development. The overriding question in their minds will be the question that preoccupied them in the 1950s — will the graduated deterrence strengthen or weaken the United States guarantee of Europe?

The calculation is far from easy, and is best accomplished by successive approximations starting from the assumption that both the American and Soviet strategic forces are capable only of the mass destruction of their opponents' cities. Although the North Atlantic Treaty, like the Warsaw Pact, is a solemn declaration of the superpowers' commitments to their allies, it is only a piece of paper. Nobody supposes that a strategic conflict in Europe would evoke an automatic response in Washington or Warsaw — people pressing buttons without turning over in their minds the prospect that their own people were about to be destroyed. In other words, even with the strategic balance of the 1950s and early 1960s, there was a chance that Europe might be left to its own devices and other people's missiles. The crucial question is whether Directive 59, old hat though it may be, increases or diminishes that chance.

First — this is what Dr Brown has been implying — it will be easier for the United States to honour its commitment to its allies if it can respond to a strategic threat by measures that are more specific than all-out retaliation. If, at the first sign of strategic trouble in Europe, somebody in Washington is faced with the choice of doing nothing or of setting in train an all-out nuclear exchange, he (or she?) is more likely to do nothing than if the choice were between inaction and some more calculated response. In this sense, Directive 59 should be a reassurance to the Western European members of NATO that their powerful ally will be more likely to stir a finger. By the same test, however, the controlled escalation of a nuclear conflict inevitably offers more opportunities for the United States (or, for that matter, the Soviet Union) to lose its resolution. Now, as was apparent in the 1950s, graduated deterrence cuts both ways. The strategic umbrella is broader, but there are more holes in it.

The immediate question (for when the US election has been held) is whether Western European governments will be more conscious of their increased security or of the increased opportunities for the United States to pull out from a European battlefield. Their perceptions will be determined by political and

0028-0836/80/340747-02$01.00

not military calculations. Will a more bellicose president (Mr Reagan) also be more isolationist? Would President Carter, if re-elected, be able to balance his apparently incorrigible unawareness of the European consequences of his domestic pronouncements (such as that about Directive 59) with the flexible and imaginative view of Salt II, Salt III and the other matters at the root of European security to keep the confidence of his NATO allies? Time, no doubt, will tell.

Until that issue is resolved, there are bound to be hankerings in Western Europe after the position adopted by the French a quarter of a century ago, when the Gaullist doctrine of independence was evolving. The French position is quite clear, and has been consistent from the start. In the last resort, the argument goes, even the most solemn guarantees are likely to be abrogated. It makes no sense to think that the people of the United States will knowingly sacrifice themselves for the sake of France. On the other hand, France can safeguard its own future by acquiring an independent nuclear force able to inflict damage on potential adversaries that is more or less proportional to its own potential value as a prize. The British case for the retention of an independent deterrent, much rehearsed when the British government decided three weeks ago to adopt the Trident system of nuclear submarines as its next-generation nuclear deterrent, is subtly different. The objective, that argument runs, is to influence the perceptions not of allies but of adversaries: if it should be thought by others — however mistakenly — that the United States might, in a tight corner, leave Europe to its own devices, the result might be a conflict that would otherwise be deterred. The West German government, denied both these options by its solemn declaration within the Western European Union that it would never become a nuclear power, is understandably (and rightly) more concerned with the threat from Soviet medium-range missiles across the Eastern frontier and would like faster progress with Salt III.

What, in these uncertain circumstances, is to be done? The conventional advice is to wait until after the American election (and then perhaps to wait until a new Administration is installed). That is a counsel of defeat. It is in the best interests of NATO, but would also serve the good cause of diminishing the risk of strategic conflict, if the three principal European states were to use the forthcoming period of uncertainty to decide among themselves what they want for European security. The British and French justifications of their independent nuclear forces are not so different that they could not be reconciled, while both are consistent with a NATO agreement with the Warsaw Pact on medium-range missiles (Salt III). Conventionally, again, it is supposed that an Anglo-French deterrent is unthinkable and that Salt III must wait on Salt II coming out of limbo (which in turn must wait on Afghanistan and, again, the election). But this is not a time for making decisions that must of necessity occupy most of the 1980s. President Carter's announcement of Directive 59, domestically, is an opportunity to begin that process.

What price the price of crude petroleum?

The recession in the industrialized countries of the West is now also beginning to hurt the oil-producing states. In the past few weeks, production in many OPEC states has declined as consumption in many industrialized states has stagnated or even fallen marginally. Some producers are now trimming back the premiuns they have been in the habit of adding to the prices on which they have been settling at the periodic OPEC price fixings, with the result that the prices charged for refined products, especially petrol or gasoline, have themselves fallen by a per cent or so. Meanwhile, the Rotterdam spot market (which is not physically in Rotterdam but rather is the name for a system by which oil traders sell tankerfuls of oil to each other while the ships are still at sea) has seen the price of crude oil fall back and the volume offered for sale by the oil-producing states shrink to a trickle. Understandably, if prices are falling, the oil producers prefer to leave their petroleum in the ground. Only some of the oil producers, Iran most conspicuously, will be embarrassed if, for a time, oil revenues noticeably shrink. But the emerging slump in the demand for oil differs in many important ways from previous occasions in the recent past, 1976 for example, when there seemed to be a surplus of crude oil. It is also an opportunity for the oil-consuming states of the industrialized West to put their own pricing policies for oil in order.

There is some evidence that the present slackening of demand for oil reflects not merely the economic recession in the West but the beginning of an underlying trend towards reduced oil consumption. That this should be happening is merely a sign that increased prices bring lower consumption, the sort of thing that Adam Smith was saying 200 years ago. The only surprise is that it has taken seven years, since the first dramatic increases of the price of oil in the autumn of 1973, for consumers to make arrangements to manage with less. Ironically, in this the first stage of the recession, high interest rates will be a brake on the pace at which new capital developments might help to accelerate the conversion of industrial plant and commercial buildings to more efficient ways of using energy. It may be some small comfort for everybody concerned that, if this recession follows the standard pattern, there will come a time when interest rates are low again. On present form, however, even if present trends persist, it will be a decade or so before the industrialized West's dependence on imported OPEC oil has lessened to the point at which the consumers will be able to look the suppliers in the eye and argue about the price of oil.

In the meantime, there are other steps that could and should be taken, the chief of which is to bring about a greater of harmony between the oil pricing policies of the consumer states. For governments appear still be divided on the objectives of their oil pricing policy: they see higher prices as a means of encouraging conservation, but they differ in the degree to which they wish to protect their electors from reality. The worst offender is the United States, where Congress has stolidly declined to let the Administration take steps to let the price of oil rise towards the international price of crude. (Is that another issue that will be more easily decided when the presidential election has been run?) One result is that the pressures towards conservation are not as strong as they might have been. Another is that energy-intensive industries in the United States are blessed with a commercial advantage over their competitors elsewhere which is widely considered to be unfair. In the past few weeks, there have been rumblings from the European chemical industry that European governments will not be able indefinitely to ignore. Yet they appear to be unwilling to follow the sensible course of harmonizing their systems for taxing oil so as to ensure that, at least within Europe, nobody has an unfair advantage. The European Commission's proposals to this end were given short shrift earlier this year. In Europe, perhaps the worst offender is the British government, which rigidly follows OPEC prices in trading North Sea oil without apparently appreciating the strategic benefits that would flow from a slightly lower price.

Further ahead, the overriding need is for a mechanism resembling a free market that would serve as a means of fixing a realistic price for oil and, ultimately, for other fuels. The notion that oil importers that are also oil producers (chiefly the United Kingdom and the United States) might deliberately use part of their production to increase the volume of crude oil traded on the Rotterdam market (see *Nature*, 3 July) could not fail to have some influence on future OPEC prices. The attempts now being made to organize a future market in crude petroleum, great though the technical difficulties may be, could be an influence of the same kind. The trouble, as always, is that Western oil producers are unwilling to sacrifice any part of their security of supply for the benefits (to them as well as others) of lower prices.

Columbia and Yale at odds about Felig

An unhappy scandal has rocked the departments of medicine at Columbia University and Yale University, has led to the resignation of the newly appointed chairman of the department of medicine at Columbia, Dr Philip Felig and has again raised accusations of plagiarism in the scientific literature.

The trouble, regarded as a tragedy for all concerned by members of the department of medicine at Columbia, was first reported by the *New York Times* last week. What follows is a chronology of the events of the past few years.

In December 1978, Dr Felig, then at the department of internal medicine at Yale, was sent by the *New England Journal of Medicine* a paper which had been submitted by Dr Jesse Roth from the National Institutes of Health with Dr Helena Wachslicht-Rodbard as co-author. The paper, entitled "Insulin binding in *anorexia nervosa*", was sent to Dr Felig as a referee and eventually returned to the *New England Journal of Medicine* where it was published in April 1979.

Early in 1979, Felig and his associate of five or six years, Dr Vijay Soman, submitted to the *American Journal of Medicine* a paper with essentially the same title as that of Roth, which was sent by the Editor to a group of referees which included Dr Roth.

The authors of the original paper recognized that some portions of the text of the Felig-Soman paper were identical with their own original and that an equation which became the basis for their own statistical analysis of their data was similarly identical. Dr Wachslicht-Rodbard protested to the Editor of the *American Journal of Medicine* and later Roth protested to Felig, as a result of which Felig offered to withdraw the abstract of the paper already submitted to that year's FASEB meeting in Atlantic City, to reprimand Dr Soman, to amend his paper so as to acknowledge Roth's priority and to arrange that the paper should not be published until after Roth's had appeared, which was in April 1979 (*New England Journal of Medicine* **300**, 882).

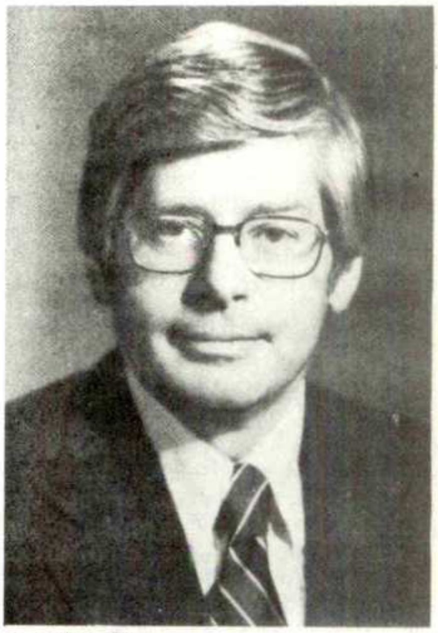
Meanwhile, Roth's colleague at NIH had written to Felig and to the Dean of Medicine at Yale suggesting that much of the data which was the basis for the collaboration between Dr Soman and Dr Felig might be suspect and asking for an audit of the laboratory's work. Even though Dr Felig had at the outset denied the possibility that there might be irregularities in his laboratory, he agreed to an audit and, according to Dr Roth, not to publish his paper until the audit had been completed. In the event, the audit was long delayed and Soman and Felig's paper was published in January 1980 (*American Journal of Medicine* **68**, 66). Only by February 1980 had the independent audit been carried out, revealing discrepancies between raw data and published accounts thereof. Whereupon Dr Soman admitted "fudging" data.

During this period, a Columbia search committee was seeking a new chairman for the department of medicine. In the autumn of 1979, the search committee interviewed Dr Felig, decided to offer him the post and had completed negotiations with him for his removal from Yale to Columbia at the turn of the year. Since then, Dr Felig has been making periodic visits to Columbia, where he began work full-time at the beginning of the academic year in mid-June, having by then moved to New York.

People at Columbia say that they do not dispute Dr Felig's explanation that the alleged plagiarism in the article submitted to the *American Journal of Medicine* may have arisen because Dr Soman had kept a copy of the article sent to Dr Felig for review and passed on to him. Equally, they say, Dr Felig may have submitted his referee's report to the *New England Journal of Medicine* on the basis of a draft prepared by Dr Soman. They emphasize that there are no grounds for disputing Dr Felig's statement that he was unaware of similarities between his paper to the *American Journal of Medicine* and the paper submitted to the *New England Journal of Medicine.*

The audit in February 1980 of the data compiled in Dr Felig's laboratory prompted a second and again external audit by Dr Jerrold Olefsky of the University of Colorado. By then, Dr Felig had asked that Dr Soman should write a letter declaring that he alone was responsible for such similarities as there may have been between the Roth paper and that submitted by Felig and Soman to the *American Journal of Medicine* and Soman was dismissed. The independent audit disclosed that of more than a dozen papers submitted in recent years from Dr Felig's laboratory involving collaboration with Dr Soman at least eight were under a cloud and that six were unsupported by raw data gathered in the usual way in laboratory notebooks.

In February 1980, however, Dr Felig had proposed that Dr Soman should be appointed as assistant professor in the department of medicine at Columbia University without, people at Columbia now say, disclosing that Dr Soman's work was under a cloud. Although the dean of the medical school, Dr Donald F. Tapley, was informed of the outcome of the second independent audit of the Felig paper in March this year, it is now said that Dr Tapley did not inform his colleagues at Columbia until July, when word of the alleged plagiarism had been spread about and when Columbia, with Dr Felig already in post as chairman of the department of medicine, set up an *ad hoc* committee to look into the affair. During the early summer of this year, Dr Felig was at pains to deal with the consequences of the two independent audits.



Dr Philip Felig

One of the papers concerned in the investigation — Soman, V. and Felig, P. "Regulation of the glucagon receptor by physiological hyperglucagonaemia" — was published in *Nature* (**272**, 829; 1978), and Dr Felig wrote to the Editor to say that it had not been possible to find the original data and that "until further data are available, the hormone binding data contained in that publication must be considered questionable". (Dr Felig had also written to the editors of several other journals in similar terms but a retraction in respect of another paper will appear in the current issue of the journal *Diabetes.*) Dr Felig was told by *Nature,* in May, that in Dr Soman's interest it would be best if a retraction in respect of the *Nature* paper appeared only when the position had been cleared up.

In the event, the *ad hoc* committee at Columbia took the view that Dr Felig was at fault in not having been able to recognize similarities between the paper which he signed and submitted to the *American Journal of Medicine* and that which he had, a few weeks earlier, been asked to review; for having delayed for as much as nine months before seeing that an audit of his laboratory's data had been carried out; and for not volunteering to his academic colleagues at Columbia the trouble he had encountered at Yale. Faced with this complaint, Dr Felig resigned from Columbia at the end of last month.

Yale takes a quite different view of what has happened. On the telephone this week,

0028-0836/80/340749-02$01.00

Dr Robert W. Berliner said that Columbia had made a gigantic mistake. He said that the alleged plagiarism consisted of a sentence or two and an equation that is not nearly as special as is claimed. People at Yale, indeed, suspect that Dr Felig is the victim of a misunderstanding. He has been invited to return to Yale and has apparently agreed to do so. This week, Dr Felig was on vacation. Dr Roth, while sympathetic to the predicament in which Dr Felig initially found himself, expressed the view that it was careless of Dr Felig to go ahead with publication before the audit had been completed.

School computing

Money to spend

The British government's £9 million programme to promote the use of computers in schools is getting off to a slow start because of delays in appointing a director. To avoid the possibility of losing some of the money if it is not spent before next March, the Department of Education and Science (DES), which is putting up the funds, has already had to award some grants. About £500,000 of the £1 million set aside for this financial year has been either awarded or earmarked for projects which are as yet planned only in outline. The allocation of larger sums for projects which will define the emphasis of the four-year programme will have to wait for the new director whose appointment is expected to be announced in September.

The present programme has grown out of a plan of the previous Labour government to spend £12 million on developing the educational value of microcomputers. None of that money was spent, however, because of the change of government in April last year. After more than a year of deliberation, the present Conservative government announced last March that it was to renew the programme by spending £9 million over the next four years: £1 million is to be spent before March 1981 and £2.7 million is to be spent in each of the remaining three years. When it is fully underway, the programme is to be administered by the Council for Educational Technology for the United Kingdom.

The DES has yet to decide on the overall objectives of the programme because to do so it needs the advice of the director as well as a recently appointed advisory committee of civil servants, teachers and representatives of educational organizations. The advisory committee gave the matter some thought at its first meeting at the end of July. All members were agreed that the programme should aim to improve the use of computers in schools but there was a difference of opinion on what should be the long-term objectives of computer education. Some members believe that the aim should be to acquaint most school leavers with computers and their uses: others believe that the aim should be to give pupils a grounding in programming and computer technology. Members plan to resolve the issue at the committee's next meeting in September.

Much of the work on computers in schools has been done by the Council for Educational Technology for the United Kingdom, which will administer the current programme when it gets under way. Other groups, which will no doubt be looking for funds, include Micro and Mini Computer Users in Secondary Education, a voluntary organization which is building up a library of software and guidance notes for teachers, and the Schools Council. The Schools Council hopes to receive grants to extend its existing work on compiling software and course notes on several subjects central to the school curriculum. Some of the packages it has already produced are designed to be of use in teaching history, economics, geography and even home heating, as well as chemistry, physics and biology.

Only about one hundred schools in Britain own their own computer and it is unlikely that much of the £9 million will be spent directly on increasing that number. One major constraint on the work funded under the programme will be that it should lead to results or suggestions for computer use which are within the financial limits of local education authorities.

Judy Redfearn

Soviet environment

Old hands back

Environmental protection is now a major feature of Soviet planning, and Moscow radio recently took to task Western newspapers (including the *Guardian*) which, it said, reported only the negative aspects of Soviet ecology. In response, the commentator drew specific attention to a speech of Academician N.P. Dubinin, delivered at this year's plenary meeting of the Soviet Academy of Sciences, and which was later published in the *Vestnik* of the Academy.

Academician Dubinin is a leading Soviet geneticist, whose work, notably his book *Evolutionary Genetics* had been suppressed during the Lysenko period. His address to the academy, entitled *Genetics and its significance for Mankind* covered a whole range of topics from plant-breeding to genetic engineering. Nearly half his speech, however, was devoted specifically to the genetic aspects of pollution, which, he explained, make up an important section of the Soviet Union's "Man and biosphere" programme, which is the responsibility of a special environmental Interdisciplinary Council of the State Committee of the USSR on science and technology.

In his speech, Dubinin stressed that much of the work in this field was taking place within the framework of the United States – USSR collaboration programme. By stressing the collaborative aspect, he was thus able to quote exclusively from US sources on the genetic hazards of pollution by mutagens, or to attribute to American authors the more pessimistic viewpoint that "at the present time science does not have at its disposal the means of solving this exceptionally complex problem". On the other hand he attributes to Soviet authors a "highly promising express test scheme" for studying the frequency of genetic mutation, tests based on leukocyte cultures and a method for determining gene and chromosome mutations in embryo mouse cells. The American J. V. Neel, however, receives due credit for his improved monitoring programme for observing the increase of mutations due to the Hiroshima and Nagasaki bombs.

In a speech intended to review the positive aspects of Soviet genetics, open criticism of past policy would clearly be out of place. There were, however, one or two, interesting allusions to the Lysenko aberration. In speaking of the "adaptive norm", Dubinin specifically cited his own (erstwhile banned) work of 1948, and stressed the importance of establishing whether or not unfavourable genetic changes had occurred over the last 20 to 30 years. Soviet genetics, it should be recalled was effectively restored only in 1963 – 64. In a speech which the Soviet media singled out as the proper and positive way to report environmental genetics, such low-key criticisms, it appears, are quite in order.

Vera Rich

Frogs to eat

The edible frog (*Rana esculenta*), the basis of a number of French recipes for gourmets, is one of the species widespread on the mainland of Europe which have established themselves only with difficulty in the United Kingdom. The photograph is taken from a Nature Conservancy Council booklet, *Wildlife Introductions to Great Britain,* which is the report of a working party of the UK Committee for International Nature Conservation. The edible frog is apparently now established only in the counties of Norfolk and Sussex.

0028-0836/80/340750-02$01.00

Interferon production

Japan now

International agreements for the manufacture of interferon appear to be catching on. Last week, the Wellcome Foundation Limited (whose sole shareholder is the British foundation known as the Wellcome Trust) announced an agreement with the Sumitomo Chemical Company of Japan that will in due course enable the Japanese company to use Wellcome technology for manufacturing lymphoblastoid interferon.

The project, which is thought to be potentially worth several million pounds to the British company, will first of all involve clinical trials in Japan based on interferon supplied by Wellcome. Thereafter, the Japanese company will decide whether or not to go ahead with the building of a plant for producing interferon commercially, using the techniques developed at the Wellcome Foundation over the past few years.

Broadly speaking, the technique is to infect a culture of lymphoblastoid cells with Sendai virus, which stimulates interferon production, and to extract lymphoblastoid interferon on chromatography columns loaded with antibodies against the type of interferon being produced.

So far there has been no opportunity to decide whether the recently announced technique for raising monoclonal antibodies against interferon (Secher, D. S. and Burke, D. C., *Nature,* **285,** 446; 1980) will make this process efficient.

The cost of interferon plants of this kind is likely to be of the order of £5 million. It is thought that the production of interferon by the Wellcome Foundation now exceeds the total production of Finland, hitherto the chief source of interferon. For those drug houses manufacturing interferon from tissue cultures, the overriding question for the future must be whether cloning techniques will lead to more efficient and cheaper manufacture.

If it is possible to obtain as many as a hundred molecules of interferon from a bacterium such as *Escherichia coli* carrying an interferon gene, the capital costs of the manufacturing plants required to produce a given amount of interferon will be reduced at least in proportion to the ratio of the generation times of bacteria and cells in culture — 20 minutes to three days, or a factor of a hundred. Drug houses using tissue culture techniques (which are thought to include Roche and Merck as well as Wellcome) appear however to be counting on the length of the period of clinical investigation of cloned interferon that would be needed before these could be put on the market.

As things are, there is no direct evidence that cloned interferon is equivalent to that from tissue culture and in any case the multiplicity of interferon molecules now being identified will need to be distinguished from each other physiologically and clinically, a process thought by the existing manufacturers to require five years or so.

Although the agreement with the Sumitomo Chemical Company has been formally signed, there are some grounds for anxiety that the arrangement may be frustrated by difficulties in Japan about the widespread use of whatever materials the Wellcome Foundation's Japanese partner eventually seeks to put on the market.

Occupational safety

Cuts ahead

Britain's Health and Safety Executive (HSE) is expecting difficulty in cutting its coat according to its cloth. In its latest annual report, published earlier this week, the HSE says that the government's plan to set its 1981-83 grant at 6% below the grant for 1979-80 will mean a reduction in the amount of work it can carry out.

Most of the savings will be made on staff, probably by reducing numbers from 4200 to 3800, and on internal office costs. But, says the report, some of its work of direct relevance to employers and workers, in particular that of the Factory Inspectorate, is bound to suffer. The research budget is also expected to come off particularly badly, with cuts of 18 per cent or about £2.2 million expected for the main research and development budget.

The main fear of John Locke, Director of the HSE, is that its work will become more reactive, dealing only with problems retrospectively. Such a move would be contrary to the policy of anticipating problems adopted by the executive since its creation in 1974.

Locke regards the anticipation of problems through extensive visits to workplaces and an active research programme a priority, even above some of the daily demands on the executive's time. In the report, he says that longer term work on problems with no immediate obvious effects on employers and workers, especially those of occupational exposure to chemicals, noise and radiation, must continue even if cuts have to be made elsewhere. Such a policy would be in line with the changing emphasis of the executive's work over recent years from accidents at work to longer term health problems.

The plan is to make most of the cuts in the research budget fall in those areas, commonly involving standard testing, where industry could be persuaded to step in with funds. Hence, the HSE hopes that industry will make up for the £1.6 million reduction in the research division's direct support to the inspectorates by arranging for its own tests to be done. Industry is also to be encouraged to pay for and conduct some of the work done under three of the executive's major current research projects; a study on the toxic effects of low levels of isocyanates, a study on mortality in the rubber industry and a project at Porton Down to study the dispersal of heavy gas clouds. To avoid industry totally controlling studies on its own problems, the HSE still intends to be responsible for designing and monitoring research projects. Industry, however, will be encouraged to provide its own data for them or to pay for research that is done independently.

One of the executive's problems in defining a coherent programme of future work is that with the increasing public awareness of health and safety issues, largely fostered by its previous work, increasing demands are constantly being made on its resources and new problems are brought to its attention. One of the major areas in which it will be stepping up its work is nuclear safety to cope with the government's plans to increase the nuclear power programme and to build a pressurized water reactor. Additional resources are to be put into the Nuclear Installations Inspectorate and almost all the work on fast reactor safety is to cease so that resources can be transferred to studies of PWR design. Work will also increase on toxic chemicals and major hazards, both of which are part of EEC programmes of research.

In a plea for kinder cuts by the government, the report argues that a major reduction in its services could lead to increased expenditure elsewhere, especially in the health services and sickness pay. It says that if further cuts, beyond 6% are planned then the Health and Safety Commission, the body to which the executive is responsible, would look to the government for suggestions as to which areas of its work it should reduce.

The executive does have some statistics to support its case. The number of fatal accidents for those industries covered by the executive throughout its five year life, fell from 651 in 1974 to 544 in 1979. Non-fatal accidents have also dropped by about 25% over the period.

Graduate students

Places sought

Demand from new British graduates for research grants is surprisingly buoyant this year. Half-way through the short season during which the research councils make awards, the Science Research Council at least is modestly encouraged by the volume of applications, which is well up on that of last year.

Part of the explanation is the relaxation of the rules for the awards in the gift of the SRC Engineering Board. For the second year, awards of engineering studentships both for research and for advanced study (usually leading to an MSc degree) are being made on the principle of "first come,

0028-0836/80/340751-02$01.00

first served".

Now that word of the new regulations has percolated to the universities, the Engineering Board's objective of increasing the amount of postgraduate study seems well on the way to being achieved. The Engineering Board has set itself a target for this year of 435 research studentships and 535 advanced course studentships, and gives the impression of being prepared to spend more in future years if only it can attract suitable applicants.

In science subjects, where the rules are unchanged, the target for the award-making season is virtually the same as last year — 769 research studentships and 435 advanced course studentships. These awards are made on the nomination of university and polytechnic departments on the basis of quota allocations by the various subject committees of the Science Research Council. Even so, there is some evidence that the volume of applications is greater than in 1979.

The parallel operation of these two systems is likely to throw an interesting light on the workings of the quota system. Although (outside engineering) the quotas are fixed by the SRC subject committees after a necessarily subjective estimate of the capacity of individual departments to provide training in research, many of those who wish to see a further concentration of research support on departments with high reputations have regarded the quota system as an impediment to change. Would-be engineering research students are in the circumstances more free to decide where to settle, for which reason a comparison of the distribution of research students in science and engineering will be of some interest when the award-making process is over.

Applications for postgraduate awards have also increased under the SRC's scheme for Cooperative Awards for Science and Engineering (CASE) although a relaxation of the rules may again have helped. CASE studentships involve research projects worked out in partnership by a university department and an industrial company, which in previous years have had to be approved by the SRC before a student award can be made. For the first time this year, university departments have been allowed to nominate a student while seeking approval for a project, although an award remains conditional on the students' performance in the degree examinations.

The target for CASE studentships this year is 760, but clearly the SRC would again spend more if there were a sustained demand. It is, however, something of a surprise that the council has been able to build up to 700 awards a year in less than a decade of CASE studentships.

The apparent buoyancy of demand for postgraduate awards is somewhat at odds with reports that many new graduates are this year more anxious to find permanent jobs than to remain in research. By the end of the summer, it is also possible that much of the demand may have melted away. One of the hazards of the process is that awards offered are not always taken up, sometimes because applications are made in duplicate. The SRC's record of this kind is that of a husband and wife who each made sixteen separate applications.

NPT review conference

Smooth start

The Second Review Conference of the Non-Proliferation Treaty (NPT) got off to a smooth and predictable start in Geneva last week. From the opening declarations which delegates to the conference were making in the first six working days, it is plain that the non-nuclear weapons states which are parties to the treaty will be urging that the nuclear powers have made too little progress too slowly towards strategic disarmament, and that the restrictions imposed on trade in nuclear materials in recent years are both a violation of the treaty and discriminatory against developing countries.

Delegates from nuclear weapons states are however heartened that these protests have been couched in moderate language. For their part, the nuclear weapons states (the Soviet Union, the United Kingdom and the United States) have been making much of the report on the comprehensive test-ban negotiations submitted to the Committee on Disarmament at the end of July and of the Committee on Assurance of Supply set up under the International Atomic Energy Agency and due to hold its first meeting at the end of September.

Procedural matters appear to have caused so far the few anxieties that have flitted across delegates' minds at Geneva. As planned by the preparatory conferences, however, the Iraqi delegate was in the end appointed charman of the conference. It has been agreed that most of the work will be done by two committees which met for the first time on Tuesday and which are concerned respectively with progress towards disarmament and security of supply.

Work on the drafting of the conference report will begin next week, and although everybody seems reconciled to the notion that the report will refer to the discontents of the non-nuclear powers, it was hoped last week that a consensus document would be agreed.

For the most part the nuclear powers presented a united front in their formal speeches, drawing attention to the need to strengthen the NPT system and to the detailed character of the report on the comprehensive test-ban negotiations. At one point, however, the Soviet delegate did seek to embarrass the United States by pointing out that Salt II would by now have been ratified had it not been for the United States Congress.

The discontents of the non-nuclear powers, expressed in several of the formal statements, were eloquently put by Mr Domingo Siazon, the leader of the Philippine delegation, who argued forcefully that restrictions on the supply of nuclear materials devised in the past few years by nuclear suppliers were a violation of the NPT, and that signatories of the treaty such as the Philippines, having signed in good faith, had every reason to expect that the nuclear powers would honour their undertaking to provide nuclear materials, fuel and equipment, without discrimination.

It is planned that the review conference will end on 5 September.

Windmill power

UK gets wind

Windmills seem to be on the march in Britain. Officials at the Central Electricity Generating Board (CEGB) will embark this summer on the choice of a site for a large windmill which the board plans to order in 1983 and commission by 1985.

The decision to buy a windmill, announced last week, seems to indicate that the board has decided to take wind power seriously. It is the first piece of alternative energy technology to be bought by the board, Britain's sole electricity utility, on a commercial basis. The early announcement of the plan is intended to stimulate British industry to develop an improved machine by 1983.

The CEGB's plan is to choose a site where other windmills could be built later to assess the characteristics of windmill arrays. It is prepared to spend about £10 million on building ten 1-MW machines. The first windmill will be a 1-MW machine, probably of horizontal axis, with a blade span of no less than 200 ft suspended 150 ft above ground. While industry is busy working on new designs to compete for the order, the CEGB will be gaining operating experience on a smaller 100-kW machine which it hopes to buy as soon as possible.

The apparent sudden interest in wind power has been stimulated by recent developments in the United States. Hamilton Standard, an American company which has pioneered wind-turbine technology, has recently claimed to have designed a windmill which could bring down the cost of wind-generated electricity to as little as 1–2 pence per kWh. Previous best estimates of cost have been about 3–4 pence per kWh.

Undoubtedly, these low estimated costs have stimulated interest in wind power within the CEGB. It is too soon to know what part windmills will eventually play in the pattern of the CEGB's electricity generation. Intermittent generation is an obvious problem unless pumped storage is available. The CEGB says that the chief contribution will be in saving fuel.

Costs of generating electricity from

0028-0836/80/340752-02$01.00

power stations now being built range from 2.28 pence per kWh (nuclear) to 3.59 pence per kWh (coal). If, because of intermittent generation, windmills do not reduce the total need for installed capacity, however, the cost of wind-generated power should be compared with the costs of fuel in conventional stations, 0.61 pence per kWh (nuclear) and 2.30 pence per kWh (coal).

Hamilton Standard claims to have applied some of the principles involved in building helicopters to the design of a flexible windmill capable of bending in the wind and responding to wind coming from different directions. Until now, most windmill designs have assumed the need for a large rigid structure capable of standing up in gales and for very strong rigid sails to withstand opposing gravitational forces. Hamilton Standard is now saying that a bendy windmill can withstand considerable forces and can be built more cheaply because less material is needed.

A cheaper windmill could also operate economically in wind speeds of only 6 m s^{-1} to operate effectively. The ability to respond more sensitively to variations in wind direction also suggests that a flexible design of windmill might be successful in relatively low wind speeds.

In the light of these considerations, the CEGB says that it will be looking at flat inland sites, probably in the east of England, as well as hilltop sites for its first big windmills. A low inland site would have the added advantage of causing less environmental trouble than a hilltop in the rural areas of Scotland or Wales.

Judy Redfearn

Nuclear generation costs compared

The report of the Central Electricity Generating Board (CEGB) for the year to the end of March 1980 includes a detailed analysis of the costs of generating electricity from power stations of different types which is likely to be much quoted in the months ahead, when plans are being laid for the further development of the British nuclear power programme. The figures now published represent a departure from previous practice in that the assumptions on which they are based are stated more explicitly than in the past, with allowance being made for elements of cost such as the interest paid during the period of construction and the cost of decommissioning the stations concerned.

During the past year, the cost of nuclear power generated from the first generation of British "Magnox" stations was less than that of electricity from coal or oil. The costs for the past year are shown in the accompanying Table 1.

Part of the reason why the nuclear costs turn out to be so advantageous is that the initial capital costs of the Magnox stations, built between the late 1950s and the late 1960s, are much lower than present-day replacement costs would be. Although the same is true of the capital costs of conventional power stations, the fact that nuclear capital costs represent a greater proportion of the total implies that the figures are not a reliable guide to the costs of building new power stations of the same types.

One surprising feature of the CEGB's operations during 1979–80 is that the load factors of the nuclear stations were more or less the same as those of conventional stations. Electricity generated by the nuclear plant amounted to 70 per cent of net capacity, compared with 69 per cent for coal-fired stations and 77 per cent for oil-fired stations. Originally, it was intended that the nuclear plant in the British generating system should be run at virtually full capacity; the board says that the lower load factors now being obtained from the nuclear power stations reflect their increased age. The costs of electricity generation are obtained by dividing the total cost of operation by the amount of electricity generated and thus increase as load factors decline.

Table 2 Costs for Hinkley B (AGR) and Drax (coal-fired)

	Hinkley Point B p/kW h	Drax first half p/k W h
Capital charges and provision for decommissioning	0.37	0.12
Interest during construction	0.18	0.04
Inclusive fuel costs	0.55	1.25
Other costs of operation	0.16	0.09
Research	0.07	0.01
Training	0.02	0.01
Total	**1.35**	**1.52**

The CEGB's annual report also provides costs on a comparable basis for two of its newest power stations — the Advanced Gas-Cooled Reactor station (the first of its type to be commissioned) and the newly-completed Drax coal-fired power station. The figures are shown in Table 2. The load factors for the AGR station (Hinkley Point B) and Drax were 55 per cent and 74 per cent respectively. The poor availability of the AGR reflects the difficulties in bringing this station into operation. It may seem remarkable that, in the circumstances, the cost of electricity generated is not much greater than that from the older Magnox station.

Mainly because of inflation, the CEGB expects nuclear costs to rise. The net cost of electricity from the three AGR stations soon to be commissioned (Dungeness B, Hartlepool and Heysham I) are estimated at 2.62 pence per kWh, 2.28 pence per kWh and 2.31 pence per kWh respectively. The increase is largely attributable to increased capital costs, three times as great as those for Hinkley Point B. At the same time, the board estimates that the cost of conventional electricity will have increased still further, with oil-fired plant producing electricity at a cost of more than 6 pence per kWh and the second half of the coal-fired Drax station producing electricity at 3.59 pence per kWh.

For the first time, the CEGB also provides figures to show the basis on which future investment decisions are being made. The principle is that of discounted cash flow in which future costs are represented by a present cost using a discount rate of 5 per cent per annum. The board also makes the assumption that the price of coal will increase at an average rate of 2 per cent a year at least until the end of the century and notes that the cost of building generating plants of all kinds has recently been increasing faster than inflation. The calculations now published, and summarized in Table 3, show that a nuclear generating plant has potential advantages over a coal-fired plant both in generating electricity more cheaply and in its effect on the economics of the generating systems as a whole — assuming that nuclear plants would displace less efficient plants, the Net Effective Cost of nuclear generating capacity becomes negative, implying a net saving for each power station built.

Table 3 Overall comparison of costs for nuclear and coal-fired stations

	Nuclear p/k W h	Coal-fired p/kW h
Capital charges at station and provision for decommissioning*	1.39	0.76
Interest during construction*		
Inclusive fuel costs	0.61	2.38
Other costs of operation	0.22	0.21
Generation costs	2.22	3.35
Less fuel saving from displacing less efficient plant	2.68	3.02
	—0.46	+0.33

Table 1 Costs of power generation by Magnox, coal-fired and oil-fired stations in 1979-80

	Nuclear (Magnox) p/kW h	Coal-fired p/kW h	Oil-fired p/kW h
Capital charges and provision for decommissioning	0.34	0.09	0.14
Interest during construction	0.06	0.02	0.02
Inclusive fuel costs	0.60	1.29	1.61
Other costs of operation	0.26	0.14	0.14
Research	0.03	0.01	0.01
Training	0.01	0.01	0.01
Total	**1.30**	**1.56**	**1.93**

CORRESPONDENCE

Nuclear facts

SIR — The letter which you published on 10th July under the heading "Nuclear Protest" from three correspondents from Edinburgh Science for People, contains several misleading statements.

It is wrong to claim that trade union rights are "denied" in the nuclear power industry. Many of the staff in the industry who belong to trades union are very active in participating in debates about nuclear issues within their movement and in promoting the case for nuclear power development. They are presumably best able to judge their own conditions of employment; your correspondents should take account of their views and of those of the trade union leaders who speak for them.

It is incorrect to describe the UKAEA Constabulary as "an armed secret police force". There is nothing secret about them. They are sworn in as special constables. They are individually responsible for their actions and their powers are more circumscribed than those of the ordinary civil police. The AEA Constabulary are responsible to the Secretary of State for Energy through the Chairman of the Authority, and their functions have been reported to and debated by Parliament.

It is impossible to claim that the civil application of nuclear energy to commercial electricity generation has led to weapons proliferation; all of the existing nuclear weapons states found ways of implementing their political decision to have such weapons which did not start from a nuclear power programme.

This exchange of letters seems to me to substantiate the need identified in your editorial (19 June) for professional people, in universities, industry and government, to resolve their points of disagreement. We should at least be able to start with a correct statement of the facts before debating the political aspects of nuclear power development.

L. E. J. ROBERTS

AERE Harwell,
Oxon, UK

Geological sport

SIR— The Geological Olympics are over for another four years. The 26th International Geological Congress held on 7–17 July in Paris had the feel of an Olympic Marathon, with well over 2,500 talks in nine working days. Anybody attending each day deserved an Olympic medal for endurance, for on some days they had to make an agonizing choice between eighteen simultaneous sessions on such diverse topics as Ophiolites, Cambrian Stratigraphy, Geophysics of the Lithosphere and Upper Mantle, Applied Geochemistry, History of Tectonics pre 1922, Coal and Magnetic Stratigraphy and Ocean Floor Reconstruction.

What was the delegate likely to encounter? There was always the chance of "meeting old friends and hearing old papers" but in fact there was plenty of new research "on display". The problem was the way in which it was displayed. Having sat through approximately 2,000 slides (16 papers/day × 6.5 days × 20 slides/paper = 2,080 slides), I can honestly say that probably only one half of them were legible. The rest might well have not been shown — indeed, some speakers even apologized with the standard "If you could see the relevant points, you would notice. . .".

Why are some slides so atrocious at conferences? Admittedly some were superb — large lettering, good use of colours. Others, regrettably, were just unintelligible. The slide of a table photographed directly from a journal, itself produced by offset-litho techniques is a good example. In these cases, the printing has probably been reproduced three or four times with an inevitable reduction in definition each time. The result is a blur from row 1, a sigh from the back and another author loses his audience's concentration. Maybe the time has come for "pre-talk screening" of slides to take place and rejection of those considered of dubious quality.

Apart from poor visual aids, the conference was a tremendous success. The sight of two German scientists actively discussing manganese nodules in English at a conference in France under a session chairman from Hawaii confirms that the occasion had an international flavour. But I wonder how many tribal groups (geochemists, geophysicists, petrologists, etc.) actually strayed outside their own compounds during the fortnight and how many merely "flew in" for the relevant day's papers.

Those who took this second course will have undoubtedly missed some of the more worthwhile aspects of the gathering — although no doubt pressing commitments elsewhere are partly to blame for brief visits. Maybe the Earth Scientists of today are becoming too specialized and hence, as chemists become geochemists, physicists geophysicists etc., the ability to understand broad based geology is declining.

2,4,5-T dispute

SIR—Now that I have returned to the UK I have seen your editorial of 17 July and without complaining about the snide reference to me (no doubt prompted by your reluctance to publish the piece you requested me to write on the cancer issues) you have still got the 2,4,5-T issue wrong. I have no idea where you got the figure of 100 tons for the quantity of herbicide-based materials imported. As far as I know it is nearer 160 tons. *Nature* should (as in the back part of the magazine) abandon prejudice and support quite reasonable and sane crusades to protect people.

CLIVE JENKINS

Association of Scientific Technical
and Managerial Staffs, London, UK

The source of the figures quoted in the leading article to which Mr Jenkins refers is as follows. Customs and Excise give imports of 2,4,5-T into the United Kingdom in 1979 as 116 tonnes. Use of the material in the United Kingdom in 1979 was given as 58 tonnes in an answer to a Parliamentary Question on 20 June. The difference is accounted for by re-exports. Mr Jenkins has been informed of the source of the figures used but insists that his letter should be published. The article of his own to which Mr Jenkins refers was invited in March but not published because, in the judgement of the editorial staff of *Nature*, it dealt with a different aspect of the problem from that originally defined.

Editor, *Nature*

Misciting latest

SIR—In their News and Views article "*Just so stories and cautionary tales*" *(Nature,* 31 July)[1], Robert May and Miranda Robertson quote our study[2] where we point out that W. D. Hamilton's paper *The genetical evolution of social behaviour*[3] is frequently miscited as *The genetical theory of social behaviour.* Although the recent trend to miscite the paper can be traced back to E. O. Wilson's *Sociobiology, the New Synthesis*[4], the mutation has occurred independently at least three times and is an easy one to make for those familiar with Sir Ronald Fisher's *The Genetical Theory of Natural Selection*[5].

Similarly, misciting Wilson's book as *Sociobiology, the Modern Synthesis,* as May and Robertson did, is easy to do for anyone who has read Sir Julian Huxley's *Evolution, the Modern Synthesis*[6].

Distance measured

SIR, — Bougault and Treuil in their *Nature* article (17 July) fail to inform us whether their distances are nautical or statute "mille passum" — there is a difference of 11.5 chains between these units, equivalent to 10,000 yr of seafloor spreading. Confusion could be avoided, and precision improved, by quoting distances in the traditional leagues of Columbus, Champlain and the imperturbable Captain Nemo.

Filter tips

SIR—Dr Zeki's red filter described in your article (*Nature,* 31 July, p.435) is really excellent for use in photographing fluorescent DNA bands on agarose gels. One of the most important factors for a contrast filter is the absence of fluorescence of the filter itself. Conventional red filters usually emit fairly strong fluorescence when hit by a strong UV ray from a transilluminator, and this fluorescence makes for a somewhat bright background and an unclear photograph. We have been using a UV filter in front of a conventional red filter, to cut UV light and thus to minimize the self-fluorescence of the red filter. In this manner a satisfactory photograph can be obtained. It is important to use a good UV filter, however, because some emit a weak fluorescence.

Comparison of Dr Zeki's filter with our double filter showed the former to be superior. Dr Zeki's filter is completely free of intrinsic fluorescence. My thanks to Dr Owen for his helpful observation.

NEWS AND VIEWS

Neutrino weight watching

from A. De Rújula and S.L. Glashow

IN the past few months, there has been a great deal of excitement about neutrinos, chiefly because of two sets of experiments which have been reported. One experiment, due to F.W. Reines and his group at the University of California (Irvine), based on measurements of neutrinos from a nuclear reactor, has been interpreted as evidence for neutrinos whose mass is not identical with zero. The same conclusion is suggested by very preliminary results from a neutrino experiment at CERN. To the extent that both these experiments suggest that there may be interconversion between the three known species of neutrinos, the conclusions would help to account for the measured deficit of neutrinos from the sun. The interpretation of the experiments so far reported is however both uncertain and controversial. Plainly we are in for a period of lively argument; the hope must be that people will now design the experiments that must and should be carried out to settle this intriguing issue.

Pauli, in 1932, postulated the existence of neutrinos (and antineutrinos) in order to explain why beta rays, unlike alpha and gamma rays, are not monoenergetic. Nuclear beta decay releases a fixed amount of energy shared between two light particles, an electron and an antineutrino (so that $n \rightarrow p + e^- + \bar{\nu}$). Pauli's particles were not however 'seen' until 1957, when Cowan and Reines showed that antineutrinos emitted by a nuclear reactor produce positrons in a remote detector ($\bar{\nu} + p \rightarrow e^+ + n$).

The muon (μ) is a charged particle much like the electron, but heavier. It is produced together with a neutrino in the decay of a pion by a process much like nuclear beta decay. In 1962, we learned that neutrinos produced with muons (ν_μ) are distinct from those produced with electrons (ν_e) for a beam of 'muon neutrinos' arising from decaying pions was seen to produce muons in a detector, but never electrons. Today, the electron is known to have an even heavier charged sibling called tau (τ). It, too, seems to have its own kind of neutrino (ν_τ).

Experimental study of tritium beta decay a decade ago demonstrated that the mass of the electron neutrino may be zero and must be very small, less than 60 eV/c^2 or 10^{-31} grams[1]. The mass is at least four orders of magnitude less than that of the electron. Perhaps all three kinds of neutrinos are exactly massless — what could be simpler and more elegant? The trouble is that this kind of reasoning once led us astray with space reflection, time inversion and charge conjugation, which have turned out not to be symmetries at all. Nature will find her own way to elegance. We dare not frame laws of nature that have no logical necessity. Conservation of energy and of electric charge are well founded. Many other 'laws' are suspect. Protons may not live forever, and neutrino masses may be merely very small.

Indeed a recent report from the Institute for Theoretical and Experimental Physics in Moscow suggests that the mass of the electron neutrino is not zero[2]. Again, the beta decay of tritium was studied, because it is the least energetic of all beta decays and hence the one most sensitive to neutrino masses. According to the authors, "the results perhaps give an evidence for the existence of the non-zero neutrino mass" in the range 14 to 40 eV/c^2. This cautious conclusion reflects the great difficulty of the analysis of the experimental results, for the effects of such neutrino masses on the observed energy of the electrons are of the same order of magnitude as the atomic or molecular corrections that must be made. Astrophysicists must nevertheless be delighted by the Soviet result, since they have a problem that neutrino masses of a few eV or tens of eV may solve. There is more mass in our universe, it seems[3], than can be accounted for in known forms of matter. This 'missing mass problem' recurs at various scales of length — the universe as a whole; in the dynamics of clusters, groups and pairs of galaxies; and in the massive, extended and non-luminous halos that most galaxies are known to have. May this missing mass be in the form of neutrinos?

Cosmological black-body radiation is interpreted as a relic of and evidence for the primordial big bang. As well as the observed electromagnetic radiation, it must include neutrinos. Hundreds of neutrinos, on the average, must inhabit each cubic centimeter of the universe. Should the heaviest neutrino have a mass of between 5 to 50 eV/c^2, these relic neutrinos would *in toto* outweigh the stars. They would provide the missing mass, and they could bind to galaxies to form their halos. The mass in our universe would consist mostly of neutrinos, which are so weakly interacting that they may be detected only by their collective gravitational effects.

Non-zero neutrino masses imply a new phenomenon called neutrino oscillation, or neutrino mixing. Bruno Pontecorvo[4], in 1968, showed that massive neutrinos might change their identities in flight. A particle which is born as an electron neutrino in a beta decay may periodically behave as if it were a muon neutrino or a tau neutrino. Suppose that there are three kinds of neutrinos and that they are not massless. Call them ν_H, ν_M, and ν_L: the heaviest, the middleweight, and the lightweight. The crucial point is that ν_e need not be one of *these* neutrinos. Its wave function may be a linear combination of the three, with the muon neutrino and the tau neutrino being orthogonal combinations of the same three. On this picture, neutrinos arising from nuclear beta decay are born as electron neutrinos but, as time passes, their ν_H, ν_M, and ν_L components evolve differently. As the linear combination changes, the beam becomes a mixture of electron neutrinos, muon neutrinos and tau neutrinos. There will be oscillations of neutrino identity with frequencies that are determined by the differences between the masses of the neutrinos. These oscillations can lead to a variety of novel observable effects.

Electron neutrinos should be copiously

produced by the mechanisms that power the sun.[5] These solar neutrinos have been detected on Earth when they transmute chlorine atoms to argon atoms. The observed flux of solar neutrinos appears to be too small by a factor of about three when compared with theoretical expectations. There are two popular explanations for this 'solar neutrino problem'. One stems from the observation that the chlorine experiment is sensitive to only a small minority of the solar neutrinos, the most energetic. These arise from a rare solar nuclear reaction, for which the calculation of the solar flux may be wrong. Accordingly, it is necessary to repeat the experiment with a detector sensitive to a broader range of neutrino energies. Many tons of such exotic and costly materials as gallium or indium are needed for this. But the phenomenon of neutrino oscillations could provide a more intriguing resolution of the solar neutrino problem. With maximal neutrino mixing, the solar neutrinos may have become an equal mix of the three neutrino species by the time they have reached the Earth. Since the method of detection of solar neutrinos is sensitive only to electron neutrinos, the apparent flux is thereby reduced to one-third. This explanation of the solar neutrino deficit requires neutrinos to have masses of at least 10^{-6} eV and to mix to a considerable extent.

Several recent ground-based experiments point in the direction (but do not amount to a compelling proof) of neutrino oscillations. Two of these tentative sets of results must be regarded as teasers for the more precise experiments that can and must be done.

Electron antineutrinos ($\bar{\nu}_e$) from a reactor were observed in a deuterium (d) detector eleven meters away[6]. Two reactions induced by the antineutrinos were studied, $\bar{\nu}_e + d \rightarrow n + n + e^+$ and $\bar{\nu} + d \rightarrow n + p + \bar{\nu}$. The first is a conventional 'charged current' weak interaction to which only electron antineutrinos can contribute. Other antineutrinos can make only μ^+ or τ^+, for which there is not enough energy. Thus, the first reaction would be inhibited by neutrino oscillations. The second reaction is a 'neutral current' weak interaction characteristic of the now accepted electroweak theory. It is unaffected by neutrino oscillations because the neutral currents involve all neutrino species equally. The ratio of the number of charged-current events to the number of neutral-current events is therefore sensitive to the existence of neutrino oscillations but relatively insensitive to the poorly-known flux of antineutrinos from the reactor.

Reines *et al.*[6] measured this ratio and find that it is about half of what one would expect with no neutrino oscillations. This suggests considerable neutrino mixing and neutrino mass splittings of at least 0.5 eV. The statistics of the effect are not yet convincing, however, and the authors cautiously conclude "... that further experimentation with $\bar{\nu}_e$ at reactors ... would be helpful in elucidating the effect here observed, as well as experiments at accelerators and with cosmic rays." The interpretation of this experiment has been criticized by Feynman and Vogel[7], who have pointed out a possible inconsistency between the deuterium experiment and an earlier hydrogen experiment by the same group done under similar experimental conditions. When this inconsistency is taken into account, the evidence for neutrino oscillations becomes less than convincing. The controversy is alive, and a revised version of the Reines *et al.* manuscript is in circulation.

The second set of data comes from an accelerator experiment at CERN with a beam of neutrinos expected to consist of equal numbers of electron and muon neutrinos. These neutrinos are very energetic, so that the muon neutrinos may interact in the detector to make muons just as readily as the electron neutrinos may interact to make electrons. If there are no neutrino oscillations, one should therefore see equal numbers of electrons and muons in the detector. The same should be true if there are oscillations connecting electron and muon neutrinos, since as many ν_e become ν_μ as ν_μ become ν_e. The Big European Bubble Chamber, sitting in this neutrino beam, has so far observed about 20 neutrino-induced events[8]. Only half as many electrons as muons were seen, but the statistics are clearly limited. If the observations are significant, however, a possible explanation is that electron neutrinos mix with tau neutrinos. This could explain the apparent systematic deficit of the electron neutrino component in the CERN experiment, in that of Reines *et al.* and in the solar neutrino experiment.

There are thus several suggestive experimental indications that neutrinos have mass and do oscillate. None of the experiments is beyond question. Yet, such results would fit quite well into current theoretical developments concerning the synthesis of the strong, weak and electromagnetic interactions. All of these 'grand unified theories' *predict* that baryon number is violated, so that all nuclear matter ultimately decays. Many of than also *demand* that neutrinos have mass, but say nothing of what these masses are. Particle theorists may not know quite what they are doing, but they do feel they are on the right track. Positive results from proton-decay experiments and from neutrino-oscillation experiments will tell us much about the nature of the underlying theory. For example, a model with neutrino masses involves seven more measurable parameters than a model with massless neutrinos. We need these hints. Moreover, proton-decay and neutrino-oscillation experiments do not depend upon the construction of ever larger accelerators. The high-energy frontier is certainly of fundamental importance, but there is still much to be learned at lesser energies. □

Esoteric DNA?

from Mervyn J. Turner and John S. Cordingley

ONE of the more esoteric areas within the field of mitochondrial DNA research has been the study of kinetoplast DNA (kDNA). Protozoa of the order Kinetoplastida, which includes the causative agents of the leishmaniases and trypanosomiases, characteristically contain a single large mitochondrion within which is found the kinetoplast, a disc-shaped mass of tightly packed DNA spatially associated with the basal body of the flagellum. Electron microscopy of spread kDNA shows a complex network of two kinds of interconnected DNA circles. The size of the smaller 'minicircle' component is species specific, varying between 700 and 2,300 base pairs, with each network containing about 10,000 minicircles. Each network also contains up to 50 copies of a larger 'maxicircle' component of up to 35 kilobase pairs. RNA transcripts of the maxicircle can be readily detected and this is one of several pieces of evidence suggesting that maxicircle DNA is equivalent to the mitochondrial DNA of other eukaryotes.

There is no similar consensus on the function (if any) of the minicircles. A number of laboratories have suggested from hybridisation kinetics and restriction endonuclease digestion that the minicircles within each network are heterogeneous with respect to sequence. Using cloned minicircles from *Trypanosoma brucei*, Donelson *et al.* (*Plasmid* **2**, 572; 1979) extended these data to show about 25% sequence homology between *T. brucei* minicircles. Chen and Donelson (*Proc. natn. Acad. Sci. U.S.A.* 77, 2445; 1980) now report the complete sequences of two cloned *T. brucei* minicircles, each of about 1,000 base pairs. The two molecules share about 12% homology within a nearly continuous stretch, and another 15% scattered randomly throughout the rest of the two sequences, thus confirming the prediction of about 25% homology.

Does this bring us any closer to an understanding of the function of the

0028-0836/80/340756-02$01.00

minicircle? Fouts and Wolstenholme (*Nucl. Acids Res.* **6**, 3785; 1979) found an RNA transcript of 240 bases from minicircles of *Crithidia acanthocephali*, but as yet no such transcript has been found in *T. brucei*. Intriguingly, there are potential coding transcripts of comparable size in each minicircle sequence, and in each case such potential transcripts begin within the 12% of continuous sequence homology. Circumstantial evidence suggests that this 12% homology is conserved within all minicircles of *T. brucei*, since it has been reported that the restriction endonulease Taq 1 cleaves all *T. brucei* minicircles and a recognition sequence for this enzyme is found within the 12% homology (the only Taq 1 site in one of the kDNA sequences). There are no obvious origins of replication in the kDNA sequences, which are characterised by a distinct lack of palindromes and inverted repeats. Outside the 12% continuous homology, the sequences are remarkably A-T rich (77%), perhaps analogous to the high A-T content in non-coding regions of other mitochondrial genomes.

These data leave open the question of minicircle function. Possible suggested functions for the kinetoplast, some more far-fetched than others, have included a structural role at the base of the flagellum; a means of segregating maxicircles equally at division; a repository of transposons; and an involvement in the control of antigenic variation or other gene expression.

Minicircles have many features in common with satellite and repetitive DNA in other systems. In addition to the presence of multiple copies, they possess a buoyant density distinct from the nuclear DNA and show internal repeats and sequence divergence. This feature is particularly obvious in *T. cruzi* minicircles, which appear to comprise four tandem repeats of a related sequence (Leon *et al. Biochem. Biophys. Acta* **607**, 221;1980). Thus, having no demonstrated phenotypic effect, one may speculate that minicircles are an example of mitochondrial parasitic DNA! □

Can genes choose habitats?

from J.S. Jones

ALTHOUGH the history of evolutionary genetics is largely a tale of attempts to explain genetic variation there is no consensus of opinion as to the evolutionary forces involved. One possibility is that variation is promoted by the complexity of the environment; if one allele is favoured in one microhabitat and its alternatives in others, then natural selection within the population could maintain genetic variation.

There are a number of convincing instances of an association between the genetic diversity of a population and the ecological complexity of its habitat. In the genus *Drosophila*, for example, species living in the complex environment of a tropical forest have up to ten times as many chromosome inversions as those living in simpler habitats such as deserts or offshore islands[1]. Again, studies of populations of *Drosophila willistoni* show there is a clear relationship between the extent of chromosome polymorphism and the floral diversity of the environment[2].

Since the first attempts to provide a theoretical basis for these effects were made by Levene[3], many mathematical models of natural selection in heterogenous environments[4] have been put forward. In a recent paper, however, Maynard Smith and Hoekstra[5] show that most of these models are limited in their usefulness; only under certain very specific conditions of the relative fitness of each allele in each ecological riche can they maintain polymorphism. They therefore have little more value as a general explanation of genetic variation than do the older theories in which heterozygotes have an overall advantage over homozygotes[6].

However, models of natural selection in complex environments become much more powerful if individuals of different genotypes are able to select the niche in which they are most fit[7]. Habitat choices linked to genetic differences have now been found for a variety of genetic polymorphisms.

The early experiments of Kettlewell in which melanic and non-melanic *Biston betularia* were released into a barrel painted with black and white stripes showed that the moths chose resting sites against which they were best camouflaged. This kind of experiment has now been extended to other species and to natural populations[8]. *Anolis* lizards in the Caribbean show a polymorphism related to camouflage in which the different morphs choose the appropriate habitat; unstriped individuals spend most of their time on the ground, while those with stripes prefer to live in the bushes in which they are best concealed[9]. Taylor and Powell[10], working in the Sierra Nevada mountains of California in a locality which has a mosaic of woodland and open habitats, marked *D. persimilis* captured from the various habitats with fluorescent dusts. When they released them into the wild the flies showed a strong tendency to return to a habitat similar to the one in which they were first captured. This behaviour is associated with local differences in the frequencies of chromosome inversions.

Habitat selection is also involved in the chromosomal variation of the mosquito *Anopheles arabiensis*[11]; in Nigeria mosquitos possessing certain inversions are more likely to rest indoors (and hence to bite humans) than are others from the same population with a different chromosome constitution. However, not all inversion polymorphisms involve habitat selection. Atkinson and Miller[12] find no evidence that *D. subobscura* from particular habitats tend to return to them. This contrasts with *D. persimilis* but may be related to the evolutionary inflexibility of *subobscura*'s inversion polymorphism, which shows few geographic or temporal trends.

Nearly all animals are highly variable for the genes controlling soluble enzymes. Remarkably, there is now evidence that individuals with different genotypes for certain enzymes may select a habitat which increases their fitness. The freshwater isopod *Asellus aquaticus* lives on decaying leaves and is polymorphic at an amylase locus. Homozygotes for one of the amylase alleles select willow when given a choice between willow and beech in the laboratory to a much greater extent than do the other genotypes[13]. This is reflected in local differences in gene frequency in ponds containing both types of leaf. The alcohol dehydrogenase polymorphism of *D. melanogaster* is the most extensively studied of all enzyme polymorphisms. When larvae are placed at a junction between medium containing 17% ethanol and medium without ethanol, those homozygous for the Adh^{F} allele tend to move onto the alcohol medium; Adh^{S} homozygotes show no habitat preference[14]. This behaviour is related to the higher activity of Adh^{F} in metabolising ethanol and to the selective advantage conferred on flies bearing this allele when faced with an alcohol stress[15]. Clearly, a general tendency for animals of different enzyme genotype to select the ecological niche to which they are biochemically most suited might help to answer the vexed question of why there is so much molecular polymorphism in natural populations.

The theory of sympatric speciation — that a single species may split into two reproductively isolated populations

without complete geographic isolation — has been put forward and discredited so often that Mayr has compared it to the Hydra which grew nine heads whenever one was struck off. Habitat selection might, nevertheless, lead to the genetic division of a population if the different genotypes mate within the micro-habitats which they have chosen. The most convincing examples of this are found in insects which parasitise plants and which have strong host-plant fidelity[16]. In Wisconsin the introduced hawthorn fly *Rhagoletis pomonella* showed a sudden — and presumably genetic — habitat extension to apples in 1864 and to cherries in 1960. These populations are now partially reproductively isolated from each other so that at least the early stages of speciation have been completed. How widespread this mechanism is remains to be seen.

Most new ideas in evolutionary biology can be traced directly to the writings of Charles Darwin and habitat selection is no exception. In the *Origin of Species* he wrote: "The more diversified the descendents from any one species become . . ., by so much will they be better able to seize on many and widely diversified places in the polity of nature and so be enabled to increase in numbers." With evidence that choice behaviour may play a part even in molecular evolution, Darwin's suggestion is at last receiving the attention which it deserves. □

Switching on the muscle genes

from Harriet Harris

THE differentiation of muscle fibres from precursor myoblasts is accompanied by particularly striking changes in cellular morphology and function. Myoblasts are developmentally committed cells, but mononucleate and lacking the biochemical and structural attributes of muscle. Myofibre differentiation proceeds by fusion of myoblasts into long, multinucleate myotubes, and this is accompanied by pronounced changes in the pattern of protein synthesis, most notably a several hundred-fold increase (Devlin & Emerson *Cell* **13**, 599; 1978) in the synthesis of actin, myosin and other myofilament proteins which assemble into sarcomeres. After some days, cultured myotubes are contractile and resemble terminally differentiated muscle fibres.

A central question concerning the mechanism of differentiation in this, or any, system, is how, and at what level are changes in gene expression regulated? Are the changes in protein synthesis a direct reflection of changes in the transcription of genomic DNA into RNA, or are there additional controls at the post-transcriptional level, that is, the processing of nuclear RNA into cytoplasmic messenger and its translation into protein? The answer may not be simple: multiple modes of regulation are indicated for muscle by a quantitative study by Devling and Emerson (*op. cit.*) on the pattern of post-fusion protein synthesis. Interestingly, expression of the major muscle proteins myosin (heavy and light chains), troponin and tropomyosin appears to be coordinately regulated, but a number of other muscle-specific, but mainly unidentified polypeptides exhibit different patterns of expression. Actin and myosin synthesis have, however, attracted the most attention and in the past, both transcriptional and post-transcriptional control mechanisms have been invoked to account for the immense proliferation of muscle myosin on cell fusion. More recent biochemical work (Strohman *et al. Cell* **10**, 265; 1977) and *in situ* hybridization experiments (John *et al. Cell* **12**, 501; 1977) on myosin mRNA show that, although some myosin message is present in prefusion myoblasts, the amount is greatly amplified in myotubes. This argues against the existance of a pool of stored message, but is consistent with either an increase in transcription on fusion, or an increase in the stability of message, as proposed by Buckingham *et al.* (*Proc. natn. Acad. Sci. U.S.A.* **71**, 1466; 1974).

An account of a much broader attack on the whole area of gene expression in muscle differentiation is given in two recent papers from Gros' laboratory at the Institut Pasteur (Affara *et al. J. mol. Biol.* **141**, 441; 1980; Affara *et al. J. mol. Biol.* **141**, 459; 1980). These describe experiments to monitor changes occurring during differentiation in the widest possible range of gene products, at three levels: in the nuclear RNA (nRNA), that is, at the level of transcription, in the cytoplasmic mRNA population and in the pattern of polypeptides synthesized. Cultured cells representing three different stages in mammalian myogenesis were employed in this study: an undifferentiated mouse embryonal carcinoma cell line, a mouse teratocarcinoma-derived myoblast cell line and myotubes formed *in vitro*. To compare the complexity of transcribed sequences at each stage of differentiation, Affara *et al.* hybridized excess total nRNA from each type of cell (undifferentiated, myoblast and myotube) to single-copy mouse DNA. The committed cells (myoblast and myotube) showed a 30% increase in the extent of hybridization over the carcinoma cells, implying that new DNA sequences are transcribed at this stage. The cytoplasmic mRNA (polysomal, poly A-containing mRNA) populations at each stage of differentiation were compared by hybridization experiments using complementary DNA (cDNA) probes for the mRNA from each cell type. It was thus shown that, although most mRNA sequences found in undifferentiated cells are still present in myoblasts and myotubes, at each stage in differentiation a new set of mRNAs enters the polysomes. Is the appearance of these messages under transcriptional control? cDNA probes enriched for myotube-specific sequences, or those common only to myoblasts and myotubes, were used to search for these sequences in nRNA. The results suggest that RNA found specifically in the polysomes of differentiated cells is absent from the nRNA of undifferentiated cells, implying that, in these cells, the corresponding genes are not transcribed. This conclusion was supported by testing the susceptibility of common and myotube mRNA-specific sequences in chromatin to nuclease attack; unexpressed genes are expected to show greater resistance than those transcribed (Weintraub & Groudine *Science* **193**, 848; 1976). Such an increased resistance was indeed found for myotube-specific genes in carcinoma cell chromatin, but not in myotube chromatin. It thus appears that the presence of new messages in the polysomes of myoblasts and myotubes is regulated at the level of trascription. However, because some RNA sequences common to myoblasts and myotubes, and present in similar amounts in the nuclei of both show increased abundance in myotube cytoplasm, the authors suggest that post-transcriptional factors may modulate the quantities of some polysomal mRNAs.

The next question addressed by Affara *et al.* is whether the new group of mRNAs which appear in the cytoplasm of myotubes are indeed translated, and whether they code for identifiable, muscle-specific proteins. The set of myotube-specific messages was purified by a hybridization technique and translated *in vitro*. Many of the polypeptides produced correspond to new proteins synthesized by myotubes *in vivo*. These included, most rewardingly, myosin light chains, muscle actin and troponin as major components, thus confirming that the expression of these proteins is regulated by the appearance of specific, new messages at cell fusion.

There are still some flaws in the experimental system of Affara and colleagues. Limitations in analytical

technique (the cDNA probes are not pure; certain messages may not be efficiently translated *in vitro*) make it difficult to trace the expression of any particular gene from transcription to translation with any confidence. An increase in experimental resolution will be required to distinguish the relative contributions of transcription and message stability to the rate of synthesis of specific proteins. A further criticism concerns the validity of the teratocarcinoma cell line as a model for normal muscle development. Although most of the identified muscle-specific polypeptides produced by the myotubes were characteristic of fast skeletal muscle, the authors also noted production of embryonic myosin light chain and slow muscle troponin C, which implies that there are aberrations in the regulatory mechanisms of these cells. However, it is to be hoped that the experimental approach outlined in these papers will lay the foundations for a more detailed understanding of the mechanisms of myogenesis. ☐

Multiphoton ionization interference effects

from Peter Knight

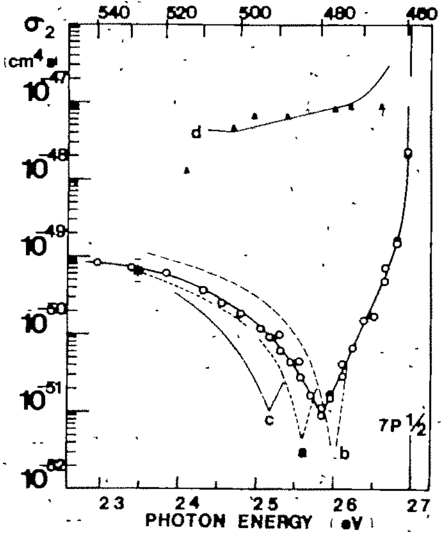
DIFFERENCES between results and theory in multiphoton ionization experiments seem to have been resolved by a recent experiment of the Saclay group (Morellec *et al. Phys Rev. Lett.* **44**, 1394; 1980).

The ionization of atoms by the simultaneous absorption of several photons from an intense laser field has been the subject of intensive investigation recently, spurred on in part by the potential application to isotope separation. However, experiments and theory have been disagreeing by up to four orders of magnitude (*Nature* **270**, 561; 1977) even for the simplest example of non-resonant two-photon ionization of a simple alkali such as caesium. Calculations employing second-order perturbation theory all agree in predicting a deep interference minimum in the two-photon ionization cross-section of caesium at photon energies between 2.3 and 2.6 eV arising from cancellations of 6p and 7p intermediate state contributions. Experiments of Van der Wiel and colleagues (*J. Phys.* **B 8**, 1617; 1975) saw no such minimum, and their observed cross-sections were four orders of magnitude greater than expected from theory. Several attempts have since been made to explain this anomaly and the experiment of Morellec *et al.* seem to have resolved the problem by using a very much more intense laser than that of Van der Wiel.

Most workers in the field have suspected that an explanation of the discrepancy between theory and experiment was connected with the presence of a small number of alkali dimer molecules in the atomic beam target. To find the interference minimum is difficult experimentally: the atomic cross-section is (obviously) very small. On the other hand caesium molecules can ionize and produce a detector signal very easily in the wavelength range where the predicted atomic minimum should occur, since they possess many intermediate levels at the appropriate energies and can be reasonantly ionized. The molecules are in fact so easy to ionize that they can dominate the ionization rate even if their concentration is very low (a few percent) of the atomic concentration. Van der Wiel and his coworker did attempt to isolate and eliminate molecular contributions yet still found their anomalously high cross-sections survived.

The Saclay group have now attacked the dimer problem in two ways. First, they work at much higher intensities than Van der Wiel using a three-stage oscillator-amplifier dye laser pumped by the second-harmonic of a ruby laser. Their experiments could then be carried out using laser intensities of 10^{10} W/cm^2 compared with 10^5 W/cm^2 of Van der Wiel. Under such circumstances the resonant molecular ionization signal is saturated and is proportional to the intensity whereas the unsaturated atomic signal depends quadratically on the laser intensity and is easily distinguished from the molecular background. Secondly, the Saclay group performed their experiment with and without a caesium atomic beam superheater which efficiently dissociates dimers, and clearly see a reduction in the molecular component by more than an order of magnitude when the superheater is used. Using these two improvements together results in the atomic signal dominating the unwanted molecular signal in the 10-20 GW/cm^2 laser intensity range.

Two-photon ionization cross-section of Cs atoms as a function of photon energy and laser wavelength (from Morellec *et al. Phys Rev. Lett.* **44**, 1396; 1980). Triangles: experimental points of Van der Wiel normalized to new photoionization cross-sections; circles: experimental points of Morellec *et al.*; curves *a*, *b* and *c* are perturbative calculations noted in the text; curve *d* is a theoretical result incorporating laser bandwidths in a simple model of Armstrong and Eberly.



The Saclay results for the ionization count are converted into a value for the two-photon generalized cross-section σ_2 taking into account well-known multimode coherence effects. Their results for σ_2 are shown in the figure and compared with earlier results of Van der Wiel and various theroetical values. It is clear that the expected ionization minimum has been observed, with a reduction by two orders of magnitude in σ_2 in going from photon energies of 2.3 to 2.58 eV, and then a huge increase as the photon energy approaches the 7p$_{1/2}$ intermediate-state resonance. Curves *a*, *b* and *c* are all derived from second-order perturbation theory using different atomic calculational methods: curve *a* is due to Bebb (*Phys. Rev.* **149**, 26; 1966), curve *b* to Teague *et al.* (*Phys. Rev.* **A14**, 1057; 1976) and *c* to Rachman *et al.* (*Phys. Lett.* **68A**, 433; 1978). These second-order perturbative theories are in quite good agreement with each other and with the Saclay data, and disagree with the data of Van der Wiel *et al.* Curve *d* in the figure, due to Armstrong and Eberly (*J. Phys.* **B12**, L291; 1979), although agreeing with Van der Wiel's data, disagrees with the new results and the second-order theoretical results. Curve *d* is obtained by incorporating laser fluctuations into the ionization dynamics in a first approximation using a phase-diffusion model of the laser bandwidth. This clearly exaggerates the laser bandwidth in the wings of the laser line and over-emphasises fluctuations in a way anticipated by Armstrong and Eberly who are currently working on improved laser-bandwidth models. The conclusion is that for the system studied by the Saclay group, second-order perturbation theory is adequate, that the interference minimum is observed once precautions are taken to eliminate molecular background, and that the earlier experiments at lower intensity were probably limited by this molecular background. It looks as if the non-resonant multiphoton ionization of simple atoms is now fairly well understood. ☐

The source of cells for regeneration

from J.M.W. Slack

A solution to the long standing problem of the source of cells for regeneration has been brought nearer by recent studies on planaria and the amphibian limb. The experiments use two techniques: X radiation doses which can inhibit cell division and regeneration without killing the tissues, and markers which allow the fate of cell populations to be followed.

Both planaria and the limb undergo 'epimorphic' regeneration in which a blastema consisting of cells which are visibly undifferentiated and indistinguishable from one another is formed at the wound site. The blastema cells first proliferate and then differentiate to reform the missing body part containing several different cell types.

The key questions are:— (1) Is the blastema formed (a) from cells drawn from all parts of the body, or (b) from tissues local to the wound? (2) Is the regenerate formed (a) by the *de novo* differentiation of reserve cells, or (b) by dedifferentiation and redifferentiation of functional tissue cells? (3) Is the blastema (a) a mixture of cells pre-committed to differentiate into particular cell types, or (b) composed of similar pluripotent cells able to become any of the cell types in the regenerate?

Although the questions are logically independent the discussion usually becomes polarised into an argument of 'neoblasts *versus* metaplasia'. 'Neoblast' is a term often used to indicate small basophilic cells present in planaria and other organisms, or sometimes in a special sense to indicate mobile pluripotential cells reserved for regeneration. 'Metaplasia' is the dedifferentiation of functional cells followed by redifferentiation of the cells or their progeny into a different histological type — for example transformation from myotube to chondrocyte. The 'neoblast *versus* metaplasia' argument thus corresponds to options 1a, 2a and 3b *versus* options 1b, 2b and 3b. Although the controversy has become fixed in this dichotomy, it must be remembered that other combinations of answers to the three questions are also possible.

J.M.W. Slack is in the Imperial Cancer Research Fund Laboratories, Mill Hill, London.

Planaria can regenerate from either an anterior or a posterior cut surface and contain scattered small basophilic cells which have been called neoblasts by many authors. Early experiments[1] showed that regeneration could be prevented by X-irradiation, but if the worm contained an unirradiated portion (either a shielded region or an unirradiated graft) then it could regenerate fully, even when the healthy portion was some distance from the level of amputation. The time taken for regeneration to begin increases with this distance and correlates with migration of the neoblasts through the intervening tissue.

This showed that a blastema can be formed from migratory cells and is capable of forming all the tissues of the regenerate. However, it did not exclude the possibility that the migratory cells were formed by dedifferentiation, or that in unirradiated worms differentiated tissues local to the wound can also contribute to the blastema. Indeed, histological and electron microscopic studies suggest that local dedifferentiation does occur[2].

Now studies have been published[3–6] on the regeneration of a strain of planaria which are naturally occurring mosaics: the somatic cells are triploid, the cells of the male germ line are diploid and the cells of the female germ line are hexaploid. Regeneration from the gonadless regions gives rise to worms whose somatic tissues consist wholly of triploid cells, whilst regeneration from a cut surface through the gonadal region gives rise to blastemas and regenererates containing some diploid and/or hexaploid cells. Of particular significance is that myotubes with diploid nuclei were found in the muscle of the regerated pharynx[6]. If germ cells and their precursors are accepted as *bona fide* differentiated cells then metaplasia has clearly occurred by the sequence: germ cell→ blastema cell→ muscle cell. However, it could be argued that the germ cells are a special case because in other circumstances they may exhibit pluripotency without passing through a sexual cycle, for example in mammalian teratocarcinoma. This objection might be overcome by building up stocks of worms whose somatic tissues are of an unusual ploidy so that metaplasia between different somatic tissues can be looked for.

Many species of urodele amphibia will regenerate limbs after amputation. The limb contains no small basophilic cells and the histology of the blastema suggests formation by dedifferentiation of muscle, cartilage and connective tissue. Amputation through a small X-irradiated region does not result in regeneration even when the remainder of the limb and the rest of the animal is unirradiated[7] so, in contrast to the planaria, it seems that a blastema cannot be formed without the participation of tissues local to the wound.

Recently studies on metaplasia have been carried out using axolotl tissues labelled by tritiated thymidine and triploidy[8–10] or pigmentation and allogenic differences leading to graft rejection[11,12]. Grafts of a particular marked tissue into an X-irradiated limb followed by amputation of the limb through the graft leads to the formation of a regenerate wholly composed of graft-derived cells, confirmed by the retention of the marker in the various cell types. The irradiated background tissue is necessary because although it does not contribute any cells to the regenerate it does contribute pattern information without which few structures are formed from a small graft[13].

The results are summarised in the Table below. It is clear that there is extensive metaplasia between the different internal tissues, which are all derived from the mesoderm of the embryo. However, epidermis never contributes to the internal tissues and vice versa, indicating the existence of a lineage restriction between tissues of different embryological origin.

So although there may be some restrictions on the possible interconversions, there is now good evidence from both planaria and the amphibian limb that some functional cell types can dedifferentiate and that their progeny can appear in the regenerate as different histological types. These results should be taken seriously by those who advocate theories of cellular differentiation based on irreversible events such as the chemical modification or rearrangement of DNA. □

Cell types found in regenerates formed from grafts of particular tissues.

	Grafted Tissue

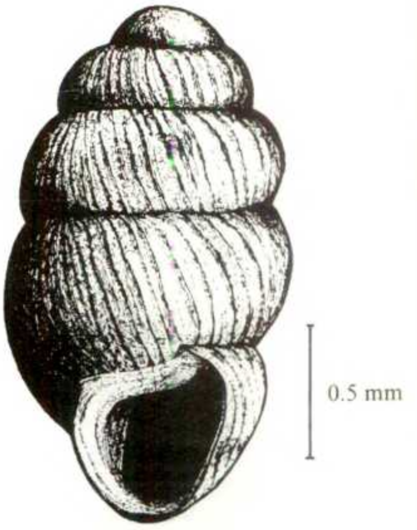
A glacial relict mollusc

from B. Coles and B. Colville*

THE mollusc *Vertigo genesii* (Gredler), thought to be extinct in Britain, has been found living in the Upper Teesdale National Reserve. *V. genesii* has a scattered distribution in Boreal and Arctic Europe where it lives in base-rich flushes of montane character[3,4] and is common in British deposits of late-glacial age (12,500 — 10,000 BP)[5,6].

The Upper Teesdale National Nature Reserve, UK, is well known for its exceptional flora, including a relict arctic-alpine element.[1] A similar faunal element has not been recognised although the Reserve contains invertebrates of rare occurrence in Britain.[2] The specimens were found, alive, in tufts of *Carex demissa* Hornem. (agg.) in the open parts of base-rich flushes on Widdybank Fell (450 m) in May 1979; their presence was confirmed in July of the same year. Mollusca associated with *V. genesii* were:— *Lymnaea truncatula* L., *Succinea pfeifferi* (Rossmässler) and *Nesovitrea hammonis* (Ström). Plants present were:— *Armeria maritima* Willd., *Plantago maritima* L., *Juncus triglumis L., Kobresia simpliciuscula* (Wahlen.), *Carex demissa* Hornem. (agg.), *C. panicea* L. and *Equisetum variegatum* Web. & Mohr. *Minuartia stricta* Hiern (which is probably the most notable plant of the Teesdale flushes, Teesdale being its only station outside the arctic circle) was not found at this site but the flush is otherwise typical of areas in Upper Teesdale where an arctic-alpine flora occurs. The occurrence of *V. genesii* in Upper Teesdale and its association with the relict arctic-alpine flora agrees well with the European distribution of the species. It is noteworthy that the associated Mollusca in Upper Teesdale were also common associates of *V. genesii* in the late-glacial.



Vertigo genesii

Sign, symbol and syntax in the language of apes

from Brendan O. McGonigle

TERRACE'S[1] recent criticism of evidence suggesting that apes can master "the conversational, semantic, or syntactic organization of language" has intensified a controversy spanning a century of speculation by primatologists. In the 19th century, several determined attempts were made to teach apes to talk but they were largely unsuccessful, only a few words being mastered by some animals. Later, Yerkes[2] identified part of the problem as the medium of communication. Apes would not mimic what they heard; instead their powers of imitation were heavily dependent on vision. Impressed by their intelligence, especially as a result of Köhler's now classic studies of insightful behaviour by chimpanzees[3], Yerkes suggested that apes "might be taught to use their fingers, somewhat as does the deaf and dumb person, and thus helped to acquire a simple, non-vocal 'sign language' ".

More than 40 years later this suggestion was put to the test[4] when a young chimpanzee, Washoe, was trained by the Gardners on a form of manual-visual communication claimed to be a version of American sign language (ASL). By the third year of the project, Washoe had acquired a stable repertoire of some 85 signs of which a number were used in two sign combinations in a manner compatible with that reported for children[5]. In addition, Washoe invented a number of signs of her own. A striking case was *bib* whose ASL equivalent was not known to her trainers when it was first introduced (appropriately) by the chimp. In later tests the Gardners monitored Washoe's capacity to answer 'wh' questions (who, what, where, whose) the production of which constitutes the first evidence that children have grammatical competence[5]. With various simplification procedures for analysing their data (now contentious) the Gardners found that the question frames exerted a very high control over the replies as indexed by the grammatical appropriateness of the answers. In carrying out the tests the Gardners relied on productive (making the chimp formulate a reply in terms not given in the question) rather than comprehension tests which "effectively eliminates the problem of clever Hans cueing".

Despite its apparent scientific rigour, the work has had its critics. In a recent attack, Seidenberg and Petitto[6] claim that Washoe's signing does not resemble signing in ASL in any important way. Instead, they allege that a large proportion of ape signs can be interpreted without any special knowledge of apes or ASL and form part of a repertoire of unlearnt gestures. These authors also challenge the Gardners' method of simplifying or reducing the replies of Washoe to 'wh' questions before reporting them. Amongst those deleted were signs which were repetitious of those in a question and signs which were repeated during a reply. The effect is to trim a response such as *you me you out me* to *you me* thus giving the utterance a more humanlike form — a possibly serious distortion in their view. By contrast, children in the early stages of language acquisition "typically produce utterances which are reduced relative to the corresponding adult forms, leading to the characterization of their speech as telegraphic".

Terrace and his associates have also found evidence for redundancy in the signing of their chimpanzee Nim, trained like Washoe in what is in fact Pidgin Sign English (PSE). Some utterances contained as many as 16 signs issued in "a striking, redundant, recursive string". In analysing the relationship between 2, 3, and 4 sign combinations, moreover, Terrace has found a major difference between Nim and children. When making longer utterances the child deletes repeated elements and expands on the information given in the shorter utterance. By contrast Nim's additions to the two sign utterances tended to be redundant, for example, "play me", "play me Nim" or repetitious, for example, "eat Nim eat". Terrace suggests that the purpose of three sign combinations by Nim is to add emphasis rather than convey new information.

The really significant findings in the report by Terrace *et al.* which

Brendan O. McGonigle is in the Department of Psychology, University of Edinburgh, Scotland.

0028-0836/80/340761-02$01.00

indicate that Nim has little language ability are the following. (i) An increase in vocabulary to 125 signs during the course of the training programme did not result in a related expansion in the mean length of utterance (MLU). This remained fairly stable over the course of the programme. (ii) There was little originality in Nim's utterances. A high percentage (87%) were classifiable as 'adjacent' (i.e. following the teacher's utterance without a definite pause) and a large percentage of these (~ 40%) were either imitations or 'reductions' (containing some of the utterances of the teacher and nothing else). (iii) Nim showed little evidence of the 'turn-taking' strategy which characterizes human conversation. Instead a large majority of his signs overlapped with those of his teachers — most of them interruptions which could not be construed as attempts to 'take the floor'.

To check that Nim was not an atypical case, Terrace *et al.* have analysed two films of Washoe which also include signing behaviour by Ally (Nim's full brother) and Koko, a gorilla[7]. Their analysis shows they claim that "Washoe's utterances were adjacent and imitative of her teachers' utterances . . . ninety-two percent of Ally's, and all of Koko's, signs were signed by the teacher immediately before Ally and Koko signed".

The Gardners hotly deny that Terrace's analysis is accurate, claiming instead that single frame and slow-play analyses misrepresent and distort the record. They also draw attention to the fact that Washoe frequently signed to herself when she was unaware of an observer, or when looking at pictures in magazines[4]. As things stand it will be some time before the technical and the statistical issues raised by Terrace's analysis can be resolved.

One conclusion which does emerge, however, is that where there is suspicion that some of an ape's signs are merely imitative of an earlier use in the same test by the teacher, the use of syntactic criteria including word order may reduce the danger of 'over-attribution' by the experimenter. To use these criteria it would be necessary to establish that the constituents of any utterance had particular meanings when presented in isolation, that signs in different linear combinations had different meanings, and that each order structure is not specific to a unique combination of signs. So far none of the chimpanzee language projects appear to have met all of these criteria — at least within the same study. Premack[8], who trained a chimp, Sarah, using an artificial language based on plastic symbols claims that "chimps can be taught word order but only with explicit training . . . ". He found no evidence that Sarah could produce structural innovations, although he claims she converted the trainer's (production) order of symbols and "produced sentences by systematic rearrangement . . .". On this latter point, however, he offers no evidence. As for word understanding, the use of too few alternatives in the tests employed frequently leads to ambiguity as to what the chimp has understood. (For instance, the preposition *on* was taught in isolation such that word order was always a simple clue to the subject-object relationship specified. It would not have been had this preposition been contrasted with *under*).

Stronger evidence for grammatical competence comes from Project Lana[9] where chimps have been trained to use lexigrams from a language called Yerkish. A computer monitors the productions of the subject — achieved by depressing keys — which must conform to the rules of a correlational grammar before any requests can be honoured, e.g. *Please machine give chow period*. The words *please* and *period* are fixed features of the sentence frame to enable the computer to determine the beginning and the end of an utterance. Examination of the performance of the subject Lana over one month of training revealed that she composed on her keyboard "76 strings of 6 lexigrams that were grammatical sentences and that did not figure in any training programme, whereas during the same period she produced only 71, 6-lexigram strings that were ungrammatical"[10]. Clearly there is evidence here of innovation. However, the analysis did not include consideration of the communicative or the contextual appropriateness of these grammatical strings and it seems likely that not all of the constituent lexigrams in the strings carried an independent meaning for Lana. For example, *please* is an invariant feature of a sentence frame necessary to get the computer to accept a message. It is improbable, as Seidenberg and Petitto[6] point out, that the appropriate depression of this key suggests that the ape has a sense of politesse. More recent work on this project has shown, furthermore, that apes begin to use individual lexigrams as referents for objects and actions after they are able to produce ordered sequences of them to produce food. The apparent ordering of signs must be rigorously analysed to determine the extent to which the sequences are controlled simply by lexical order rules independent of their (constituent) meaning.

Issues of syntax apart, it seems pertinent to ask what apes tutored in these various 'languages' have revealed about their mentation which could not be inferred from other aspects of their behaviour. The results thus far are ambivalent. On the one hand the content of ape language merely reaffirms the narrow incentive range within which the chimp seems to operate in laboratory situations. His favourite words seem to be those which invite the listener to donate food or drink, or which command attention (although this pattern may change when more work is carried out with mature subjects). On the other hand, the restrictions on semantic role which Terrace describes in the case of Nim (indexed by a marked restriction on the range of agents and beneficiaries, e.g. NIM, me, you and the names of other animates) are symptomatic perhaps of an egocentric form of thought — a characteristic of early stages of child development according to Piaget — not easily revealed by non-verbal tests. The response of apes to attempts to teach them the spatio-temporal conventions for reference to objects and events outside the immediate context of utterance should provide further important clues to the cognitive resources available to these enigmatic primates. □

100 years ago

HUMAN HYBERNATION

In the *Transactions* of the Royal Society Dr. W. Oliver has recorded the history of an extraordinary sleeping person named Samuel Chilton of Tinsbury, near Bath, who on May 13 1694, being then 'of robust habit of body, not fat, but fleshy, and a dark brown hair," happened, without any visible cause or evident sign, to fall into a very profound sleep, out of which no art used by those who were near him could rouse him until after a month's time; then he rose of himself, put on his clothes, and went about his business of husbandry as usual; slept, could eat and drink as before, but spoke not one word till about a month after. In 1696, on the 9th of April, this youth fell off to sleep again, and although a heroic apothecary, Mr. Gibbs, bled him, blistered him, and scarified him, he slept on for seventeen weeks, waking up on August 7, not knowing he had slept above a night, and unable to be persuaded he had lain so long, until going out into the fields he found everybody busy getting in the harvest, and then remembered very well that when he fell asleep they were sowing of the barley and oats which he now saw ripe and ready to be cut down. For six weeks of this sleep he had fasted, but after he awoke he went to work in his ordinary way, and continued to work until August 17, 1697, when, after complaining of shivering and cold in his back, and vomiting once or twice, he fell into one of his long sleeps once more. So he lay sleeping until November 19, when he awoke, said he "felt very well, thank God," ate some bread and cheese, and dropping off still another time, slept on until the end of January, 1698, and "then waked perfectly well, not remembering anything that happened all this while."

REVIEW ARTICLE

Nucleosome assembly

Ronald A. Laskey & William C. Earnshaw
MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

Histones and DNA can spontaneously associate to form the nucleosome subunits of eukaryotic chromatin, but two proteins which occur in the eukaryotic nucleus can facilitate nucleosome assembly and greatly extend the conditions which permit assembly to occur. Recently several laboratories have reported new experimental systems which help to analyse, reconstruct and exploit the cellular mechanisms of chromatin assembly.

IN eukaryotic nuclei DNA is packaged into regularly repeating nucleoprotein units called nucleosomes. The structure of the nucleosome has been reviewed extensively[1–4] and the major features of the prevailing model[5] are summarized in Fig. 1. Two structural domains have been distinguished by nuclease digestion, a protected nucleosome core and an exposed linker DNA segment of variable length. The nucleosome core consists of 146 base pairs of DNA coiled around a central histone octamer containing two each of the histones H2A, H2B, H3 and H4. Histone H1 associates with a further 20 base pairs of DNA adjoining the core, to complete two full superhelical turns of 80 base pairs each around the histone octamer[6,7]. In addition to this simple repeating structure chromatin possesses a complex range of local variations in the distribution of nonhistone proteins[8,9].

Studies of chromatin assembly have been directed both at determining the pathway of nucleosome assembly and also at analysing the functional significance of variations in chromatin structure. Chromatin assembly by dialysis against gradients of salt under nonphysiological conditions (starting at >1 M NaCl) has produced information about nucleosome structure, but attempts to attach biological significance to the assembled structures have been repeatedly confused by artefacts (reviewed in refs. 2–4).

Recently several new experimental systems for assembling nucleosome cores or nucleosomes at physiological ionic strength have been described. They fall into three classes: (1) self-assembly systems[10,11] in which histones and DNA associate without assembly factors; (2) factor mediated assembly systems in which assembly is facilitated by purified assembly factors[12,13]; and (3) unfractionated cell homogenates[14–16] which attempt to mimic the cellular processes and which can be fractionated further to elucidate the cellular mechanisms of chromatin assembly. All three classes will be considered here, together with investigations of assembly of replicating chromatin in intact cells. At present only the unfractionated cell homogenates have been able to reconstitute the physiological spacing between adjacent nucleosomes.

Self-assembly of the nucleosome core

Histones and DNA contain the morphogenetic information required to assemble a nucleosome core. This has been clearly demonstrated by the reconstitution of nucleosome cores by salt gradient dialysis from approximately 1 M NaCl (refs 17–21).

Although the capacity for self assembly was readily demonstrated at unphysiological salt concentrations, it has only recently been observed at ionic strengths close to physiological. Ruiz-Carrillo *et al.*[10] renatured core histones into H3/H4 tetramers and H2A/H2B dimers by prolonged dialysis and slowly pumped the histones into an excess of DNA at 0.2 M NaCl. The product was shown to be authentic nucleosome cores[10] (Fig. 2). If histone H1 was included a precipitate formed. This could be redissolved by dialysing the precipitate to lower salt concentrations (10–30 mM). In a second study by Stein *et al.*[11] the core histones and DNA were mixed more abruptly. A precipitate formed, but redissolved during 16 h at 37 °C, to reveal substantial formation of nucleosome cores. In both cases excess histones caused irreversible precipitation.

Although these two assembly procedures[10,11] are limited in the conditions which yield soluble products rather than insoluble precipitates, they clearly establish the principle that nucleosome cores can self-assemble from histones and DNA in the absence of other factors.

Nuclear proteins which facilitate nucleosome core assembly *in vitro*

Two proteins from the eukaryotic nucleus allow nucleosome core assembly to proceed rapidly *in vitro* without precipitation. One appears to interact with DNA and the other with histones. They are respectively DNA topoisomerase I (nicking-closing enzyme)[13] and nucleoplasmin, an acidic thermostable protein which was originally isolated from *Xenopus* eggs[12].

The assembly pathway mediated by DNA topoisomerase I involves making a complex between topoisomerase I and DNA and then adding histones[13]. Approximately one topoisomerase I molecule is required for each nucleosome assembled, corresponding to 20 times more of the enzyme than would relax the same weight of supercoiled DNA. Assembly is inhibited when the weight of histones exceeds the weight of DNA. It is not clear yet if topoisomerase I acts by decreasing the electrostatic attraction between DNA and histones (see below) or by performing some additional function such as providing a swivel. DNA topoisomerase I occurs at substantial concentrations in the chromatin of a wide range of eukaryotes. Its properties and distribution have been reviewed elsewhere[22].

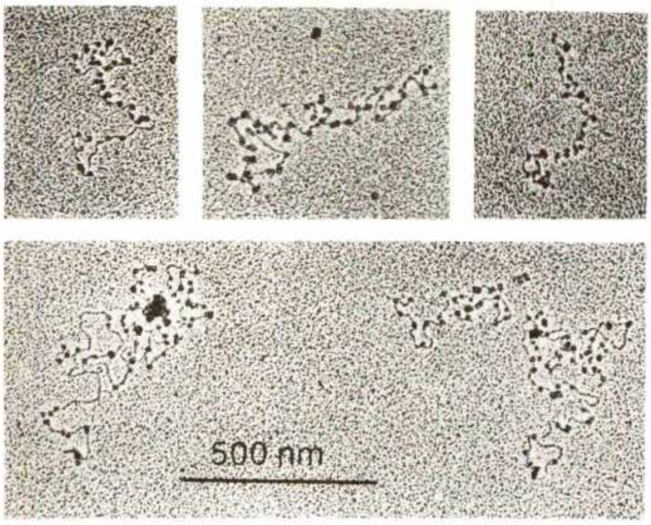

Fig. 2 Electron micrograph of nucleosome cores assembled by very slowly pumping core histones (without H1) into excess DNA at physiological ionic strength. Reproduced with permission from ref. 10.

Fractionation of a cell-free nucleosome assembly system[14] from eggs of *Xenopus laevis* led to the identification and purification of an acidic, thermostable protein which facilitates nucleosome core assembly *in vitro* when histones and DNA are rapidly mixed[12]. The protein is rich in potentially charged amino acids (notably 30% Asx + Glx)[23]. It is phosphorylated[24,25] and it has an isoelectric point of 5 (ref. 26). In solution it is an unusual multimer, a pentamer of the $M_r = 29{,}000$–$30{,}000$ subunits, and this pentamer is active in nucleosome core assembly[27]. The protein does not bind detectably to DNA or nucleohistone[27] but it does bind histones *in vitro*[12,27]. Its activity is independent of DNA topoisomerase[12,23,27], and the properties of the protein, which itself has no associated topoisomerase activity, are strikingly different from known DNA topoisomerases[22]. Unlike DNA topoisomerase I it can mediate nucleosome core assembly in the presence of excess histones[12,27].

Recently this protein has been shown to be the most abundant protein in the *Xenopus* oocyte nucleus, occurring at about 5 mg ml^{-1} and representing 7.5–10% of the total nuclear protein[24–26]. It is localized in the nucleoplasm[24–26] and using a combination of immunofluorescence and immunoprecipitation, Krohne and Franke have shown that this, or a conserved, antigenetically related protein, occurs at substantial concentrations in the nucleoplasm of a wide range of vertebrate cell types[25] (Fig. 3). The probable reason why it had not been observed in nuclei previously is rapid leakage from nuclei in aqueous isolation buffers[24–26]. Thus it was first discovered in total homogenates of cells in meiotic metaphase[12]. With the agreement of Krohne and Franke we propose to call this protein 'nucleoplasmin' reflecting its unusual intracellular location.

Although it is not clear if nucleoplasmin is tightly bound to the histone pool of *Xenopus* oocytes[24,25] its ability to bind histones *in vitro* led to the suggestion that it assembles nucleosomes *in vitro* both by neutralizing electrostatic repulsion between histones thus promoting histone:histone interactions, and also by acting as a 'molecular chaperone' which competes against the strong electrostatic attraction between histones and DNA, thus minimizing nonspecific insoluble aggregates[12,27].

These interpretations are consistent with the observations of Stein *et al.*[11] that polyglutamic and polyaspartic acids can also greatly facilitate nucleosome core assembly when used in the conditions described for nucleoplasmin. In additon Stein *et al.*[11] showed that polyglutamic acid causes histones to associate to form stable octamers in the absence of DNA and at physiological ionic strength. These observations may partly explain the mechanism of nucleosome core assembly by nucleoplasmin *in vitro*.

Although nucleoplasmin assembles nucleosome cores *in vitro*, the possibility that *in vivo* it performs a wider role of mediating between the many highly charged components of the nucleus deserves investigation.

The methods for assembling nucleosome cores *in vitro* at physiological ionic strength are summarized in Table 1. From a comparison of the methods the following principles emerge. First the steric information for self-assembling a nucleosome core resides in histones and DNA themselves. Second nonspecific electrostatic interactions between histones and DNA or between histones and nucleosomes[28,29] can result in insolubility of the product. This problem can be minimized by careful control of the experimental conditions, but it is accentuated by the presence of histone H1 or excess free histones. Third, the problem of solubility can be avoided by using 'assembly factors'. Fourth, these may act in different ways. Thus DNA topoisomerase interacts with DNA permitting subsequent ordered interaction with histones while nucleoplasmin and polyglutamic acid or polyaspartic acid appear to promote histone:histone interactions and do not interact directly with DNA. The simplest unifying hypothesis appears to be that the assembly factors described so far act *in vitro* by competing against or masking the strong electrostatic interaction between histones and DNA thus allowing self assembly to occur without aggregation and precipitation. Although it is possible that the assembly factors are recycled there is no evidence that they act truly catalytically or that they contribute steric specificity to the assembly pathways.

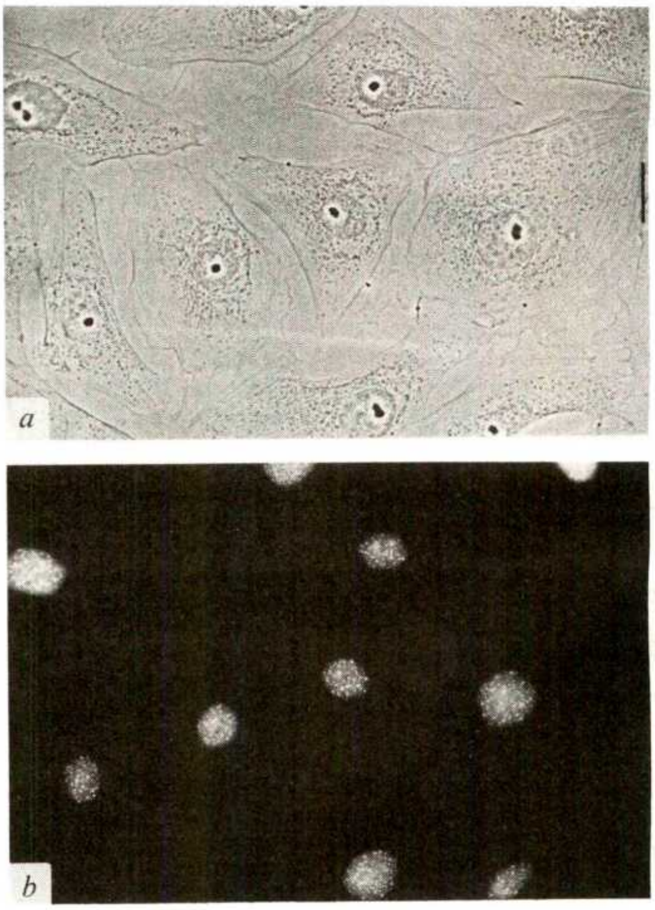

Fig. 3 Phase contrast (*a*) and immunofluorescence microscopy (*b*) of rat kangaroo cells incubated with antiserum raised against nucleoplasmin from oocyte nuclei of *Xenopus laevis*. The cells all show a strong and specific staining of their nuclei. Scale bars, 20 μm. Photograph supplied by G. Krohne and W. Franke (see refs 24 and 25).

Table 1 Methods for assembling nucleosome cores *in vitro* using purified reagents at physiological ionic strength

Method	Normal location	Approximate weight ratios	Time to completion	Product characterization†	Reference to method
Without assembly factors:					
(1) slow pumped addition of histones to excess DNA		1 DNA ≤1 core histones	2–5 h*	*A–E*	10
(2) rapid mixing		1 DNA ≤1 core histones	16 h (precipitates and redissolves slowly)	*A–C*	11
With assembly factors:					
Factor	Normal location				
(1) DNA topoisomerase I	Chromatin (eukaryotes)	1 DNA ≤1 core histones 0.4 topoisomerase I	<1 h	*A–D*	13
(2) Nucleoplasmin	Nucleoplasm (amphibians, birds, mammals, possibly elsewhere)	1 DNA 2 core histones 3–4 nucleoplasmin	<1 h	*A–C*	12
				D–E	27
(3) Polyglutamic acid	Synthetic	1 DNA 2 core histones 3–4 polyglutamic acid	~5 min	*A* and *F*	11

* Precipitates when histone H 1 is present.

† Key to product characterisation: *A*, Electron microscopy; *B*, supercoiling; *C*, sedimentation; *D*, digestion by micrococcal nuclease; *E*, digestion by DNase I; *F*, protein cross-linking

Cellular mechanism of nucleosome assembly

There is no direct evidence yet that either DNA topoisomerase I or nucleoplasmin is involved in the cellular mechanism of nucleosome assembly. However, the following observations are consistent with their involvement. First, both proteins occur in the nucleus at concentrations sufficient to assemble nucleosome cores *in vitro*. Second, when naked DNA is introduced into *Xenopus* oocyte nuclei or into eggs which are in meiotic metaphase it is rapidly relaxed by high concentrations of topoisomerase before it is assembled into nucleosomes[14,30]. Third, eggs of *Xenopus laevis* contain a large histone pool, sufficient for 20,000 diploid nuclei[31,32] and of the assembly methods described above only nucleoplasmin (or polyglutamic and aspartic acid) allows nucleosome assembly and chromatin solubility in the presence of excess histones[10,11]. Fourth, the endogenous histones in *Xenopus* egg homogenates exhibit anomalous charge properties, adsorbing to positively charged but not negatively charged resins at neutral *p*H suggesting that they are bound in a complex with a net negative charge. Purified nucleoplasmin mimics this effect when mixed with histones[27]. Finally, the rate of nucleosome core assembly by purified nucleoplasmin is similar to the rate in unfractionated homogenates and is sufficient to account for the rapid rate of nucleosome assembly in the early *Xenopus* embryo[27].

Recent work of Nelson *et al.*[16] suggests that *Drosophila* embryos may contain yet another nucleosome assembly factor. Although it has not yet been characterized, it seems to differ in some of its properties from either nucleoplasmin or DNA topoisomerase I. It will be interesting to see if it is related to a polypeptide, 'X', which Worcel *et al.*[33] observed associated with nascent nucleosomes in cultured *Drosophila* cells. In the same study[33] newly replicated DNA was observed to associate stably with H3 and H4 2–10 min before it associated stably with H2A and H2B and 10–20 min before it associated with H-1. A similar sequence of events has been deduced for mouse hepatoma cells[34] and replicating SV40 chromatin[35]. Ruiz-Carrillo *et al.*[10] have shown that a similar sequence of additions can be used to assemble nucleosomes *in vitro*. While this sequence of histone depositions may be widespread, it is not clear if it is essential *in vivo*. Thus the time course of histone depositions described by Worcel *et al.* is unlikely in early *Drosophila* embryos where the entire interphase of the cell cycle lasts only 3.4 min[36,37] shorter than the lag between depositions of different histones observed by Worcel *et al.* From *in vitro* studies there is evidence that nucleosomes can be assembled by interaction of DNA with either preformed histone octamers[11,29] or dissociated dimers and tetramers[10]. It is possible that the multiple nucleosome assembly pathways *in vitro* reflect multiple alternative pathways in the cell, which would not be surprising if the problem of assembling nucleosome cores correctly involves simply limiting electrostatic interactions between histones and DNA to localized regions, nucleosomes, and preventing indiscriminate electrostatic cross-linking leading to precipitation.

An aspect of nucleosome assembly *in vivo* which we have not considered above is the role of transient post-translational histone modifications seen in newly synthesized histones[38–40]. Since nucleosome cores can be assembled efficiently *in vitro* from unmodified histones (Table 1) it is tempting to speculate that the modifications might have an alternative role such as specifying the periodicity between adjacent nucleosomes in chromatin.

Assembly of regularly spaced chains of nucleosomes

Nucleosome cores are not distributed randomly along DNA, but are spaced at regular intervals of approximately 200 base pairs[41,42]. The average length of the linker DNA varies between different cell types so that the nucleosome repeat length ranges from about 160 base pairs in fungi and rabbit cortical neurones to 241 in sea urchin sperm[43–47].

However none of the purified *in vitro* assembly systems listed in Table 1 has reproduced the native spacing. They either space nucleosomes randomly or at intervals which are shorter than those from the parent native chromatin[10,13,27]. In contrast, as seen in Fig. 4, the unfractionated cell-free assembly system from *Xenopus* eggs spaces nucleosomes regularly at about 195 base pairs[14] and the same has recently been shown for an unfractionated assembly system from *Drosophila* embryos[16]. The mechanism which specifies the length of the internucleosome linker is unexplained but some models can be firmly eliminated. First, the correct spacing does not arise by copying the spacing on a parental molecule. It can arise *de novo* on naked DNA[14,16] (Fig. 4). Second, it does not require DNA replication or the discontinuous synthesis of Okazaki fragments since it can occur in the absence of DNA replication[14]. Third, it is unlikely to arise from a conserved periodic signal in DNA since spacing is observed on reconstituted prokaryotic templates (ref. 16 and W.C.E. unpublished observation) which are not naturally assembled into nucleosomes. On the other hand, it seems possible that it may be mediated by transient nucleosome sliding since it occurs in circumstances where assembly appears to be non-cooperative[14], suggesting that a mechanism must exist for correctly aligning randomly deposited nucleosomes. So far correct inter-nucleosome spacing has only been observed in assembly systems which use an endogenous stored histone pool, namely egg extracts from *Xenopus* and *Drosophila*[14,16]. Woodland[48] has shown that the stored histones of *Xenopus* eggs have secondary modifications characteristic of newly-synthesized histones in somatic cells, which raises the possibility that the transient histone modifications may be the missing ingredient required to achieve correct spacing in purified assembly systems. This hypothesis can be tested, and with the emergence of evidence suggesting that nucleosomes have specific phase-relationships with some DNA sequences[49–55] there is an obvious need to develop purified assembly systems which position nucleosomes precisely on DNA.

Relationship of nucleosome assembly to DNA replication

Nucleosomes persist in the region of replication forks and both daughter DNA duplexes are rapidly converted to nucleosomes[56–60]. By labelling nascent histones with dense amino acids and ^{3}H-lysine, Leffak *et al.*[61] have shown that parental histone octamers segregate conservatively to one of the daughter duplexes and that groups of parental nucleosomes segregate together. There is disagreement, however, over the site of assembly of new nucleosomes. Studies in which newly replicated chromatin is density-labelled by dense thymidine analogues, then fixed in formaldehyde and separated from bulk chromatin on the basis of its greater density have repeatedly suggested that new histones associate with unreplicated DNA[62–64]. In contrast, studies which have fractionated nascent chromatin from bulk chromatin by sedimentation avoiding the use of dense thymidine analogues or formaldehyde fixation have suggested that new histones are deposited at or near the replication fork[33,35]. Additional support for the view that new nucleosomes form on newly replicated DNA comes from experiments in which protein synthesis is inhibited by cycloheximide[65]. Here putative replication forks can be observed in which one of the daughter duplexes is fully assembled into nucleosomes while the other appears to be naked DNA. This suggests that parental nucleosomes pass to one of the daughter duplexes leaving the other as the site for new nucleosome formation. One of the two newly synthesized strands (the lagging strand) at a replication fork is synthesized discontinuously in Okazaki fragments (reviewed in ref. 66), and Seidman, Levine and Weintraub[67] have argued that this strand is probably the site of new nucleosome formation (Fig. 5). Although the discontinuous synthesis of DNA is not necessary to specify the spacing between adjacent nucleosomes (see above), a more attractive possibility is that the repeating nucleosome structure of chromatin may specify the periodicity of Okazaki fragments with replication proceeding by unfolding one parental nucleosome at a time[68].

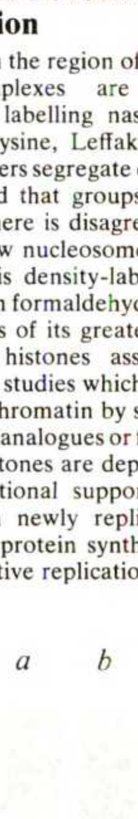

Fig. 4 Assembly of regularly spaced chains of nucleosomes by incubating ^{32}P DNA in homogenized eggs of *Xenopus laevis* (as in ref. 14). *a*, The chromatin assembled *in vitro* was cleaved with micrococcal nuclease deproteinized and electrophoresed in a 1.7% agarose gel. *b*, DNA fragments cleaved from rat-liver nuclei by micrococcal nuclease and ^{32}P-labelled by nick translation were electrophoresed on the same gel to show nucleosome spacing at 195 base pairs.

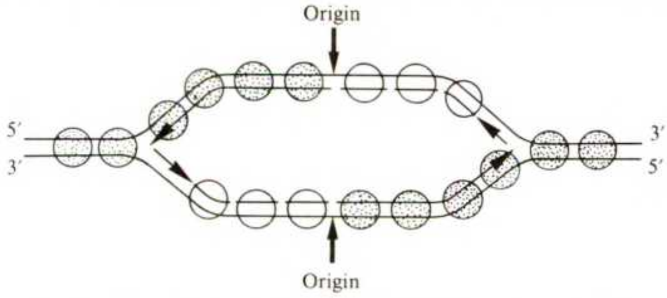

Fig. 5 A model for segregation of nucleosomes at replication forks proposed in ref. 67. Parental nucleosomes (stippled) segregate conservatively to the daughter DNA duplex containing the continuously synthesized strand, while new nucleosomes (unstippled) are assembled on the daughter duplex which is synthesized discontinuously in Okazaki fragments. Arrows indicate the direction of DNA strand growth. While this model is attractive, it is still opposed by some studies (see text).

Assembly of transcriptionally active nucleosomes

Digestion with nucleases indicates that transcriptionally active regions of chromatin are organized into nucleosome-like structures but that these have a different conformation from bulk chromatin (reviewed in refs 2–4). Regions of chromatin which code for RNA in a particular cell type are selectively sensitive to digestion by DNase I[69,70] or DNase II[71]. The degree of DNase I sensitivity is the same whether the gene is transcribed occasionally or frequently[72] suggesting that this altered conformation is a property of all genes which are competent to be transcribed. The boundaries of DNase I sensitive regions are precise[54,73] and the active conformation appears to correspond to elevated levels of two non-histone proteins HMG 14 and HMG 17[74,75] of the 'high mobility group'[76]. Furthermore Weisbrod and Weintraub[75] have shown that these two proteins can restore DNase I sensitivity to salt-washed chromatin or nucleosome cores[77], indicating that the nucleosomes from which they were eluted contain an additional structural peculiarity apart from HMG 14 and 17. This could either be the presence of an additional modification or factor specifying the sites to which HMG 14 and 17 should bind, or alternatively the lack of a normal nucleosome component which competes with HMG 14 and 17 for occupation of a site within the nucleosome.

How does such a structure originate? Weintraub has shown that the DNase I sensitive structure arises within 3 min of replication of that region of DNA, suggesting that the decision to assemble potentially active or inactive chromatin occurs at the time of DNA replication[60]. Therefore our understanding of the differentiation of somatic cells would be substantially enhanced by a knowledge of the mechanisms which assemble newly replicated DNA into transcriptionally competent nucleosomes and of the regulatory mechanisms which rigorously select specific regions of the genome for assembly into the active conformation. The *in vitro* nucleosome assembly systems which have been reviewed here are ideally suited for investigating these questions.

An Archaean sub-seafloor geothermal system, 'calc-alkali' trends, and massive sulphide genesis

P. J. MacGeehan* & W. H. MacLean

Abitibi Project, Department of Geological Sciences, McGill University, 3450 University Street, Montreal, Quebec, Canada H3A 2A7

Archaean Noranda-type exhalative massive sulphide ores were formed by sub-seafloor geothermal activity which leached mafic constituents and ore metals from iron-rich bimodal (basalt–rhyolite) tholeiites and converted them to hydrothermally altered greenschist facies 'intermediate' rocks of apparent calc-alkaline affinity.

A MAJOR problem in the study of Archaean and younger greenstone belts is the identification of the primary geochemistry of volcanic rocks that have been subjected to extensive rock–water interaction. The rocks, mostly fine grained basalts exhibiting greenschist facies mineralogy, are normally classified on the basis of chemical composition and normative mineralogy on the assumption that rock–water interaction was largely an isochemical process. This hypothesis apparently succeeds in large parts of the greenstone belts where the volcanic rocks were only weakly hydrated during halmyrolysis and burial metamorphism, but, in some areas, sub-seafloor geothermal activity contemporaneous with volcanism produced more intense rock–water interaction with higher water-to-rock ratios. It is in these areas of intense hydrothermal alteration, seafloor exhalative activity and associated massive sulphide mineralization, that the primary petrological and chemical identity of the volcanic rocks has been radically changed, causing them to be incorrectly identified using standard geochemical rock classification schemes.

The nature of this problem became evident during research in the Matagami, Quebec Archaean volcanic centre and mining district in the Abitibi greenstone belt, where sulphide ores are associated with several thick domal accumulations of rhyolite

interbedded with iron-rich pillowed basalt flows. These rocks were formerly described as 'calc-alkaline'[1] owing to the predominance of rocks of 'intermediate' chemical composition (andesite–dacite–rhyolite). These show a large scatter rather than a systematic alkali-enrichment on an AFM plot, a feature characteristic of many mineralized Archaean volcanic centres[2–5]. However, they are now known to constitute a hydrothermally altered bimodal basalt–rhyolite suite of clear tholeiitic affinity[6]. Their apparent 'calc-alkaline' traits reflect a hydrothermal overprint caused by rock–water interaction during sub-sea floor geothermal activity as a modified seawater brine intensely spilitized, silicified and leached metals from large volumes of iron-rich tholeiitic basalt before discharging through overlying rhyolite to deposit massive sulphides on the sea floor.

In this article we examine the petrography and geochemistry of the rock–water interaction in the Garon Lake geothermal system at Matagami, and compare and contrast the trends produced with recognized igneous fractionation trends.

The Garon Lake geothermal system

The Garon Lake geothermal system developed within a 500-m thick sequence of tholeiitic pillowed basalt (units B_2–B_4) after extrusion of the Garon Lake rhyolite (Fig. 1). The basalts are underlain by the Bell Channel rhyolite, thus the reservoir rocks of the system are confined to a narrow, well-defined stratigraphic interval in which the individual flow-units have been mapped in detail and followed along strike for several kilometres. The basalts are intruded by contemporaneous gabbro sills of very similar mineralogical and chemical composition, several of which may have been lateral feeders to the pillowed flows. The geological setting, petrology and primary geochemistry of the units have been discussed elsewhere[6,7], where they were shown to form part of a bimodal basalt–rhyolite suite of tholeiitic affinity.

Most of the volcanic rocks have been hydrothermally altered to some degree: the basalts are intensely spilitized and silicified, whereas the domal parts of the Garon Lake rhyolite are pervasively chloritized and transected by zones of disseminated sulphide mineralization. Earlier studies have shown that this alteration accompanied sub-seafloor geothermal activity which began while the volcanic rocks and contemporaneous intrusions were still hot, and terminated before the extrusion of volcanic rocks overlying the Garon Lake rhyolite[7,8]. At the time when the geothermal system was active, seawater was convected through basalt from intake zones at the periphery of the rhyolite and then discharged through permeable zones (now alteration pipes) in the rhyolite dome. The exhalative massive sulphide lenses at the Garon Lake mine formed down slope from the western alteration pipe[9]. The geothermal system had a lateral extent >5 km (Fig. 1), indicating that >10 km^3 of volcanic rock were subjected to hydrothermal alteration.

Rock–water interaction

The reservoir rocks are bleached and mottled pillowed basalts that would almost invariably be called 'andesite' in the field. Two main stages of hydrothermal alteration can be recognized petrographically: (1) an early and minor stage of dominantly destructive (argillic) alteration that accompanied localized convective fluid movement in water-bearing basalt bordering some of the contemporaneous gabbro sills[8]; and (2) a later and

widespread stage of intense spilitization that accompanied large-scale convective circulation of fluid after the reservoir rocks were sealed from above by the Garon Lake rhyolite (Fig. 1).

Spilitization is localized around pervasive quartz–epidote-filled veinlets and cylindrical pipes (alteration patches[10]) which transect the basalt section. These structures form an interconnecting network interpreted as conduits of concentrated fluid flow at the time the geothermal system was active. Whereas the smaller veinlets have a random orientation, the larger veinlets and pipes are invariably orientated parallel to stratigraphy, indicating a dominantly horizontal vector of fluid movement within the reservoir rocks (Fig. 1).

The basalt around the quartz–epidote structures has been intensely bleached and silicified to light grey and grey-green domains up to one or several metres in diameter. Although the igneous fabric was almost entirely preserved in these domains the mineral assemblages were drastically changed: plagioclase phenocrysts and laths were replaced by single crystals of inclusion-free albite that commonly retain original twin planes, pyroxene was replaced by actinolite (twin planes, exsolution lamellae and subophitic textures partly preserved), and ulvospinel first crystallized ilmenite in trelliswork patterns but was then partly replaced by actinolite and sphene. With advanced spilitization, epidote, magnetite, ilmenite and sphene were replaced by quartz, albite, minor chlorite and rutile, the latter as needles preserving the outline of former ilmenite grains. This intense spilitization grades outward to a zone of weak but pervasive hydration where basalt has a uniformly dark green colour and a more or less constant chemical composition. Here, the pyroxene is pseudomorphed by dark green actinolite, plagioclase is saussuritized, and the groundmass consists of ulvospinel granules and sodic plagioclase crystallites in a chloritic, devitrified glass matrix.

Overall, the mineralogical changes in the basalts were accompanied by significant decreases in colour index and increases in hardness so that they now frequently resemble andesites and dacites in the field. The role of quartz is particularly important. While not a primary phase or a product of isochemical devitrification of basaltic glass, quartz increases significantly with increasing degree of alteration.

The Garon Lake rhyolite (dacite in some classification schemes[6,11,15]) is devitrified quartzo-feldspathic and generally spherulitic acid glass that contains up to 20% inverted β-quartz and sodic plagioclase phenocrysts and rare granophyre fragments[6–8]. Zones of intense chloritization that constitute the alteration pipes are mineralized with chalcopyrite and pyrite (Fig. 1). The direct replacement of rhyolite glass (~75% SiO_2) by massive chlorite (~35% SiO_2) proceeded without obvious volume change; β-quartz phenocrysts were corroded and plagioclase grains were either partly corroded or entirely replaced by granulose quartz plus chlorite or massive chlorite.

Geochemical changes

Intense spilitization of the reservoir rocks was accompanied by major chemical adjustments, the most important being the significantly higher SiO_2 content of altered samples. Unaltered or least altered samples of the chilled rims and cores

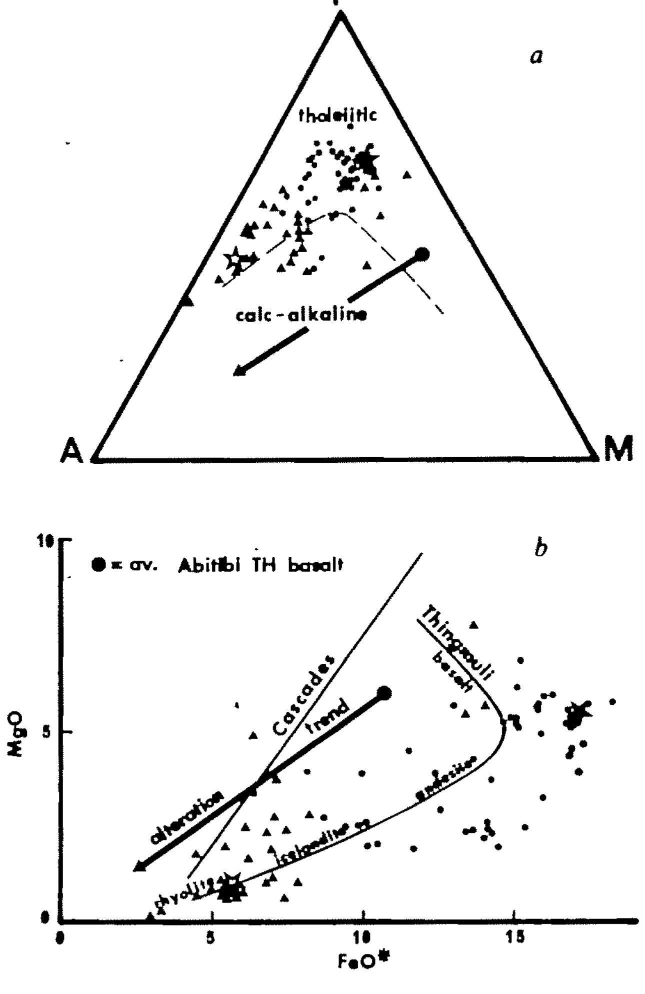

Fig. 4 *a*, AFM plot. The dividing line is after Irvine and Baragar[15]. *b*, MgO against FeO* (total iron as FeO) The Thingmuli[17] (tholeiitic) and Cascades (calc-alkaline) trends are shown. of pillows lie in the compositional range 48–52% SiO_2, but hydrothermally altered samples show a progressive increase in SiO_2 to 65% in the B_3 unit and up to 75% in B_4 (ref. 8). Increases in SiO_2 in B_3 (Fig. 2) are accompanied by: (1) a linear depletion in FeO*, MgO, CaO, TiO_2, P_2O_5, V, Cr, Mn, Co, Ni, Cu, Zn and Cd, reflecting their dissolution during breakdown and reconstitution of the mafic minerals and plagioclase; (2) a significant increase in Na accompanying the albitization of plagioclase; and (3) comparable increases in Zr, Y and REE by factors of up to three. K_2O, which probably had a very low initial content, remains low in the altered rocks. Although scatter is considerable, the ratios of depleted elements (FeO*/MgO, FeO*/TiO_2, and so on) remained essentially constant and identical to the igneous ratios, indicating that their dissolution was a congruent, non-selective process. Hydrothermal alteration in the remaining basalt flows (units B_2 and B_4) was very similar, although changes in the intensity of silicification, in the Na_2O/SiO_2 enrichment, and in the behaviour of P_2O_5 and Al_2O_3 did occur with stratigraphic height within the geothermal system[7,8].

Two lines of evidence, the petrographic observation of the pseudomorphic replacement of the igneous rock fabric and the immobile behaviour of Al_2O_3 (Fig. 2), indicate that rock–water interaction was essentially a constant volume process. The incremental enrichment in SiO_2 and Na_2O was therefore accompanied by the active congruent dissolution and transport of FeO*, MgO, CaO, TiO_2 and the trace elements listed above, because only SiO_2, CaO and Al_2O_3 (quartz and epidote) were later precipitated in the hydrothermal conduits[10]. This alteration accompanied an increase in the temperature of the fluid. The precipitation of silica in the central part of the geothermal system occurred around the critical point of the brine ($T \sim 400\,°C$; $P < 0.75$ kbar)[12–14], where SiO_2 solubility decreases rapidly with rising temperatures while that of most other components continues to increase. Similarly, as the metal-charged brine rose through the rhyolite to the sea floor it cooled, leached silica from rhyolite, and precipitated most of the elements dissolved from the underlying reservoir rocks as minerals in the alteration pipe and massive sulphides on the sea floor (Fig. 2).

Significance of the alteration trends

Rock–water interaction during sub-seafloor geothermal activity caused the congruent dissolution of many major and trace elements from basalt, their transport by fluid, and their later precipitation in similar ratios in rhyolite approaching the discharge points of the system. Cumulatively, this resulted in the compositional gap of the bimodal basalt–rhyolite suite being spanned by a continuum of altered rock compositions (Fig. 2). Using as an example only one basalt flow from the reservoir and the overlying Garon Lake rhyolite (Figs 2–6), the geochemistry of the hydrothermally altered rocks seems to be indistinguishable from the spectrum of intermediate igneous rock compositions. Hydrothermally altered basalt and rhyolite samples span the field through andesite and dacite on a normative colour index versus normative plagioclase composition diagram (Fig. 3a) used to classify volcanic rock types[15], and classification systems based on SiO_2 content[3,4,16] (see Fig. 3b).

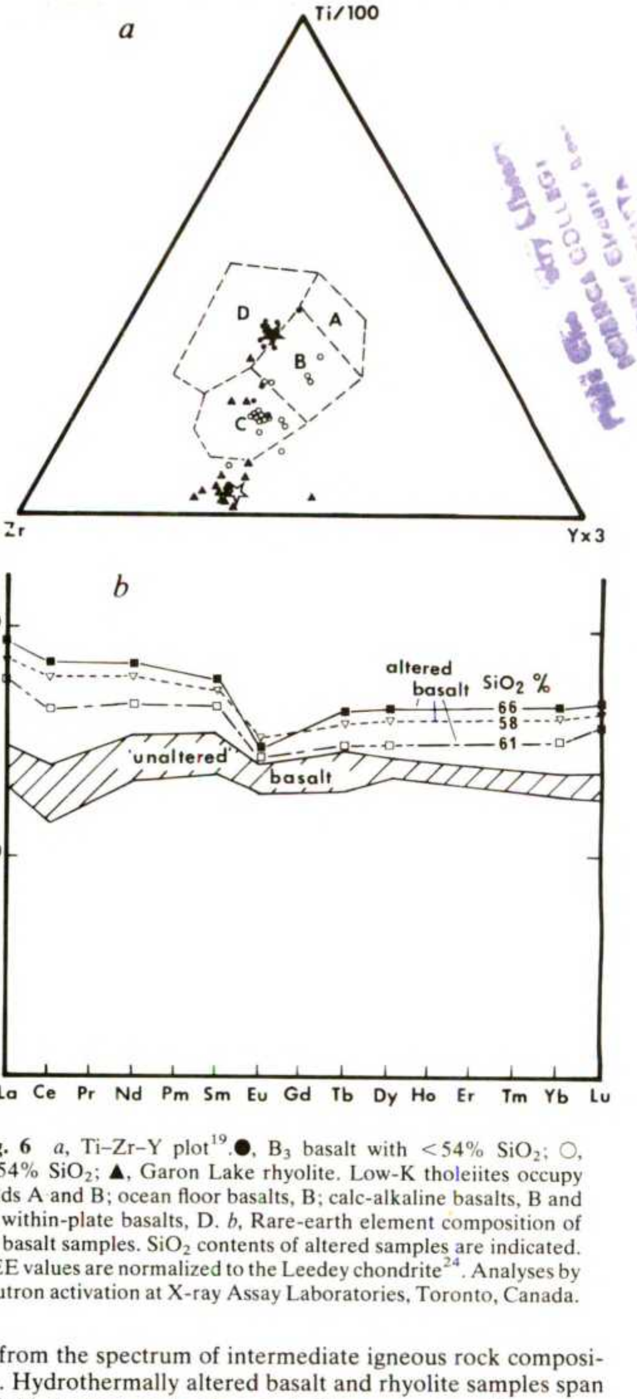

Fig. 6 *a*, Ti–Zr–Y plot[19]. ●, B_3 basalt with <54% SiO_2; ○, >54% SiO_2; ▲, Garon Lake rhyolite. Fig. 5 Comparision of Al_2O_3 with normative An[15].

Furthermore, as rock–water interaction involved the net substitution of salic (SiO_2, Na_2O, and so on) for basic (FeO*, MgO, CaO, TiO_2, and so on) components, the resulting chemical alteration patterns resemble igneous fractionation trends. For example, most major and trace elements show a variation typical of volcanic rock suites when plotted against a fractionation index (for example, SiO_2, Fig. 2; differentiation index and solidification index plots show similar patterns). However, despite Na metasomatism during spilitization of basalt, altered samples remain in the sub-alkaline field on an alkali–silica plot (Fig. 3b). The resemblance with a fractionation trend is also seen on an AFM plot, widely used to distinguish tholeiitic from calc-alkaline rocks; the least altered basalt samples lie close to the FM join and altered samples extend towards the alkali corner (Fig. 4a). The resemblance is maintained in plots not involving the alkalis, for example, FeO* versus MgO (Fig. 4b), where, despite the scatter, the alteration parallels the later stages of the Thingmuli tholeiitic trend[17]. There is no evidence of iron enrichment, however, and the resemblance to a tholeiitic trend is dictated by the high initial FeO*/MgO of this basalt which precludes a calc-alkaline association. This would not have been so in most Archaean centres where the basalts generally have much lower FeO*/MgO ratios (see Fig. 4 for plots of average Abitibi basalt[18]). In its essential characteristics (alkali enrichment with depletion of mafic oxides) the alteration mimics a calc-alkaline fractionation trend, and would easily be confused for one in many mineralized volcanic centres. This apparent calc-alkaline affinity is indicated on many other major element plots except that of Al_2O_3 against normative plagioclase composition (Fig. 5) where the low mobility of Al_2O_3 during alteration confines the data to the tholeiitic field.

The whole trace element suite was also mobile during alteration: V, Cr, Co, Ni, Cu, Zn and Cd decreased, and Zr, Y and REE increased with increasing SiO_2 content (Figs 2–6). A plot of the 'immobile' elements Ti, Zr and Y (Fig. 6*a*) shows how mobile they have been. The negative correlation of Ti for Zr and Y that can be seen in Fig. 2 produces a continuum of points between the original basalt and rhyolite on Fig. 6*a*. This diagram has been used successfully to distinguish the tectonic setting of modern basalts ($<54\%$ SiO_2)[19], and the correlations made there have been frequently used to classify older rocks[20–23]. Most samples from the reservoir rocks of the geothermal system with less than 54% SiO_2 do plot in a small area of Fig. 6*a*, but the tendency of the altered rocks to move to the calc-alkaline field is apparent. Plots with Cr, Co and Ni yield similar results. The REE are also mobile but retain the flat profile (Fig. 6*b*) typical of fractionated tholeiites, lacking the characteristic strong LREE enrichment and high La/Yb ratios of calc-alkaline rocks. Rather than being immobile, these elements actually provide a good monitor of progressive alteration in a single flow.

Conclusions

Intense rock–water interaction in the Garon Lake sub-seafloor geothermal system accompanied spilitization of volcanic rocks and contemporaneous high-level gabbro sills. Massive chemical exchange occurred in and adjacent to zones of dynamic flow of seawater-derived brine; essentially isochemical hydration occurred where flow was sluggish or stagnant. Hydrothermal alteration preserved volcanic features (pillow selvages, amygdules, hyaloclastite-filled interstices) and pseudomorphed igneous fabric as it converted bimodal basalt–rhyolite tholeiites to rocks that are petrographically indistinguishable from metamorphosed andesites and dacites. The major and trace element geochemistry of the altered rocks are 'intermediate' in character and show calc-alkaline affinity on most discrimination diagrams.

The predominance of these 'intermediate' rocks at Matagami and in other mineralized volcanic centres in the Archaean of Canada, led to the original assumption that exhalative massive sulphide ores of the Noranda type were associated with 'calc-alkaline' volcanic rocks, and, by inference, with active volcanism along consuming plate boundaries[1,4,25]. It is now evident that these conclusions may be in error. Rather than denoting a tectonic setting, these 'intermediate' 'calc-alkaline' volcanic rocks may in fact reflect the geochemical imprint of sub-seafloor geothermal activity that generated important ore deposits.

Antigenic drift between the haemagglutinin of the Hong Kong influenza strains A/Aichi/2/68 and A/Victoria/3/75

Martine Verhoeyen, Rongxiang Fang, Willy Min Jou, René Devos,
Danny Huylebroeck, Eric Saman & Walter Fiers

Laboratory of Molecular Biology, State University of Ghent, Ledeganckstraat 35, B-9000 Ghent, Belgium

A DNA copy of the gene coding for the influenza A/Aichi/2/68 haemagglutinin protein was cloned in the plasmid pBR322 and the complete nucleotide sequence determined. Comparison of this primary structure and the deduced amino acid sequence with the haemagglutinin gene and protein of strains belonging to the same (H3) subtype and to different subtypes, of both human (H2) and avian (Hav1) origin, documents further at the molecular level the two independent modes of antigenic variation of the virus—drift and shift.

THE ability of type A influenza strains to change their antigenic properties is a major obstacle to controlling the viral disease by vaccination, and the virus continues to be an important cause of illness in the human population. Two types of change have been recognized: antigenic 'drift' seems to be the result of a certain number of local alterations in the viral surface proteins (thought

0028-0836/80/340771—06$01.00

to be selected under the pressure of the immune system), whereas antigenic 'shift' is a radical change of the antigenic properties of the surface protein, leading to the emergence of new pandemic strains. The origin of these pandemic strains is unknown, but it has been speculated that they result from a recombination event between a human virus and an influenza strain from an animal reservoir[1].

Type A influenza viruses have a negative-stranded RNA genome consisting of eight distinct RNA segments[2–4]. The two surface antigens, haemagglutinin and neuraminidase, are glycoproteins and have been assigned to viral RNAs 4 and 5 or 6 (depending on the strain), respectively[2,3]. We have recently determined the primary structure of the haemagglutinin gene from the relatively recent human influenza strain A/Victoria/3/75 (H3N2), starting from cloned DNA[5] and using fast DNA sequencing techniques. Compared with RNA and protein sequencing methods, this approach has the advantage of much greater speed and accuracy and avoids special problems, such as those encountered during the sequencing of hydrophobic regions of polypeptides.

We describe here the cloning and elucidation of the structure of the haemagglutinin gene of A/Aichi/2/68, which formed the beginning of the so-called Hong Kong (H3N2) period. The gene sequence and deduced amino acid sequence are compared with those of our previously reported Victoria strain[5], with an intermediate H3N2 isolate, A/Memphis/102/72 (this haemagglutinin was sequenced as cloned DNA[6] and except for a small hydrophobic region also as protein[7,8]), with amino acid data from monoclonal variants[9] and field strains[10], with the gene sequence of A/Japan/305/57 (H2N2)[11], which occurred at the start of the 1957–67 influenza wave, and with the fowl plague haemagglutinin gene (Hav1)[12].

Cloning the A/Aichi/2/68 haemagglutinin gene

The high yielder, recombinant strain X31, which carries the haemagglutinin and neuraminidase genes of A/Aichi/2/68, was used as the RNA source in our study. Double-stranded (ds) DNA copies of the haemagglutinin genetic information were synthesized and cloned essentially as described previously for the haemagglutinin gene of the A/Victoria/3/75 strain[5]. The major steps of the procedure are briefly summarized as follows: the mixture of eight negative-stranded X31 virion RNA segments was polyadenylated at the 3′ end[13], converted into dsDNA copies, sized on a 1.5% agarose gel and the material corresponding to full-length haemagglutinin dsDNA recovered form *Escherichia coli* K12 HB101 (refs 5, 14). Thirty-nine dTTP and annealed to oligo(dA)-tailed plasmid pBR322 in the *Pst*I restriction site, and the resulting hybrid was used to transform *Escherichia coli* K12 HB101 (refs 5, 14). Thirty-nine tetracycline-resistant colonies were obtained. When hybridized[15] to a ^{32}P-labelled gene 4 RNA probe, four of the clones showed positive hybridization. One plasmid (pXHA14) containing an insert of approximately 1,860 base pairs (including the A · T tails used for cloning) was chosen for further characterization.

Nucleotide sequence of pXHA14

The insert in plasmid pXHA14 was characterized by restriction mapping according to Smith and Birnstiel[16]. Subsequently, fragments were prepared by digestion with the appropriate restriction enzymes, 5′-terminally labelled, and sequenced according to the method of Maxam and Gilbert[17]. The nucleotide sequence is shown in Fig. 1 as the coding information or complement of the viral RNA. As the structure is highly homologous to the previously determined Victoria haemagglutinin gene (Fig. 1), we did not systematically attempt to read both strands. Nevertheless, more than half of the sequence was confirmed by analysis of both strands.

As expected from the cloning strategy used[5,14,18] (initiating second DNA strand synthesis starting from a terminal hairpin of the first DNA strand, followed by S_1 nuclease treatment), a small portion of the haemagglutinin genetic information corresponding to the 3′ end of the cDNA is missing from the clone. As we started from negative-stranded influenza RNA, this region corresponds to the 3′ end of the coding information (beyond the arrow in Fig. 1). Because two other strains belonging to the same subtype have been shown to share exactly the same 3′-noncoding sequence[5,6], we did not attempt to complete this sequence for the Aichi strain. Assuming identity in this region, 27 nucleotides would be missing from the pXHA14 plasmid, compared with 24 nucleotides missing from plasmid pVHA14, which contains the Victoria haemagglutinin information[5]. Taking into account an additional 27 base pairs at the 3′ end of the influenza-specific information in pXHA14, the total length of the Aichi haemagglutinin RNA is 1,765 nucleotides: 29 nucleotides precede the signal for the AUG translation initiation codon, the translated region extends over 1,698 nucleotides (specifying 566 amino acids), and the (presumed) 3′-terminal noncoding stretch comprises 38 nucleotides (including the signal for the UGA terminator).

The detailed organization of the haemagglutinin RNAs belonging to the Hong Kong (H3) subtype (Victoria[5], Memphis[6–8], Aichi) seems to be identical except for the insertion of three nucleotides (specifying an asparagine residue at position 8′ of the HA1) in the relatively recent Victoria/3/75 strain (Figs 1, 2). The haemagglutinin RNA from another human subtype (H2)[11] and from an avian subtype (fowl plague)[12] are of comparable length.

The protein sequence

The haemagglutinin is synthesized as a single polypeptide chain which is subsequently modified by glycosylation and post-translational processing. The latter involves removal of an NH_2-terminal signal peptide[19] and proteolytic cleavage into HA1 and HA2 to yield mature haemagglutinin and infective virus[20,21]. Assuming that the Aichi sequence also starts with the NH_2-terminal blocking group pyroglutamic acid, as found in the Memphis H3 strain[22] (a blocked amino terminus of the HA1 is a general characteristic of H3 human strains and of two putative progenitor animal strains[23–25]), the signal sequence would be 16 amino acids long, as in Victoria[5] and Memphis[6,22]. Within the H3 subtype, the length and hydrophobic character of the signal peptide seem to be maintained, but the exact sequence is not (Figs 1, 2). There is no variation between the positions of cysteine residues in H3 strains. Also, the sequence of the Japan and fowl plague strain can easily be aligned according to the cysteines, allowing for a minimum number of insertions/deletions between strains[5,26]. It is therefore to be expected that the disulphide bonding pattern is the same between these three subtypes and probably in all influenza A haemagglutinins, thus giving the haemagglutinin molecules a very similar three-dimensional conformation. The disulphide bonds have recently been determined for the A/Memphis/102/72 strain[27].

As in the other H3 strains Victoria and Memphis and also in the H2 Japan strain, the region excised from between HA1 and HA2 consists of a single arginine residue; this situation contrasts with fowl plague haemagglutinin, where six residues are removed[12,28]. A second hydrophobic sequence, at the NH_2 terminus of the HA2, which may have a role in interaction with and penetration of the cell membrane during infection, is highly conserved in all influenza A strains examined so far, even in a single B-type strain, and also in the NH_2 terminus of the F1 subunit of Sendai virus[25]. Near the C terminus of HA2 there is a third hydrophobic region (amino acids 185–210 of HA2 in Fig. 1), which is involved in anchoring the haemagglutinin in the lipid viral envelope. The precise functioning of the signal interrupting the translocation of membrane proteins ('stop-transfer' sequence[29]) remains to be established. However, in contrast to the signal sequence, this stop-transfer sequence seems to be constant within the H3 subtype in at least three different field strains.

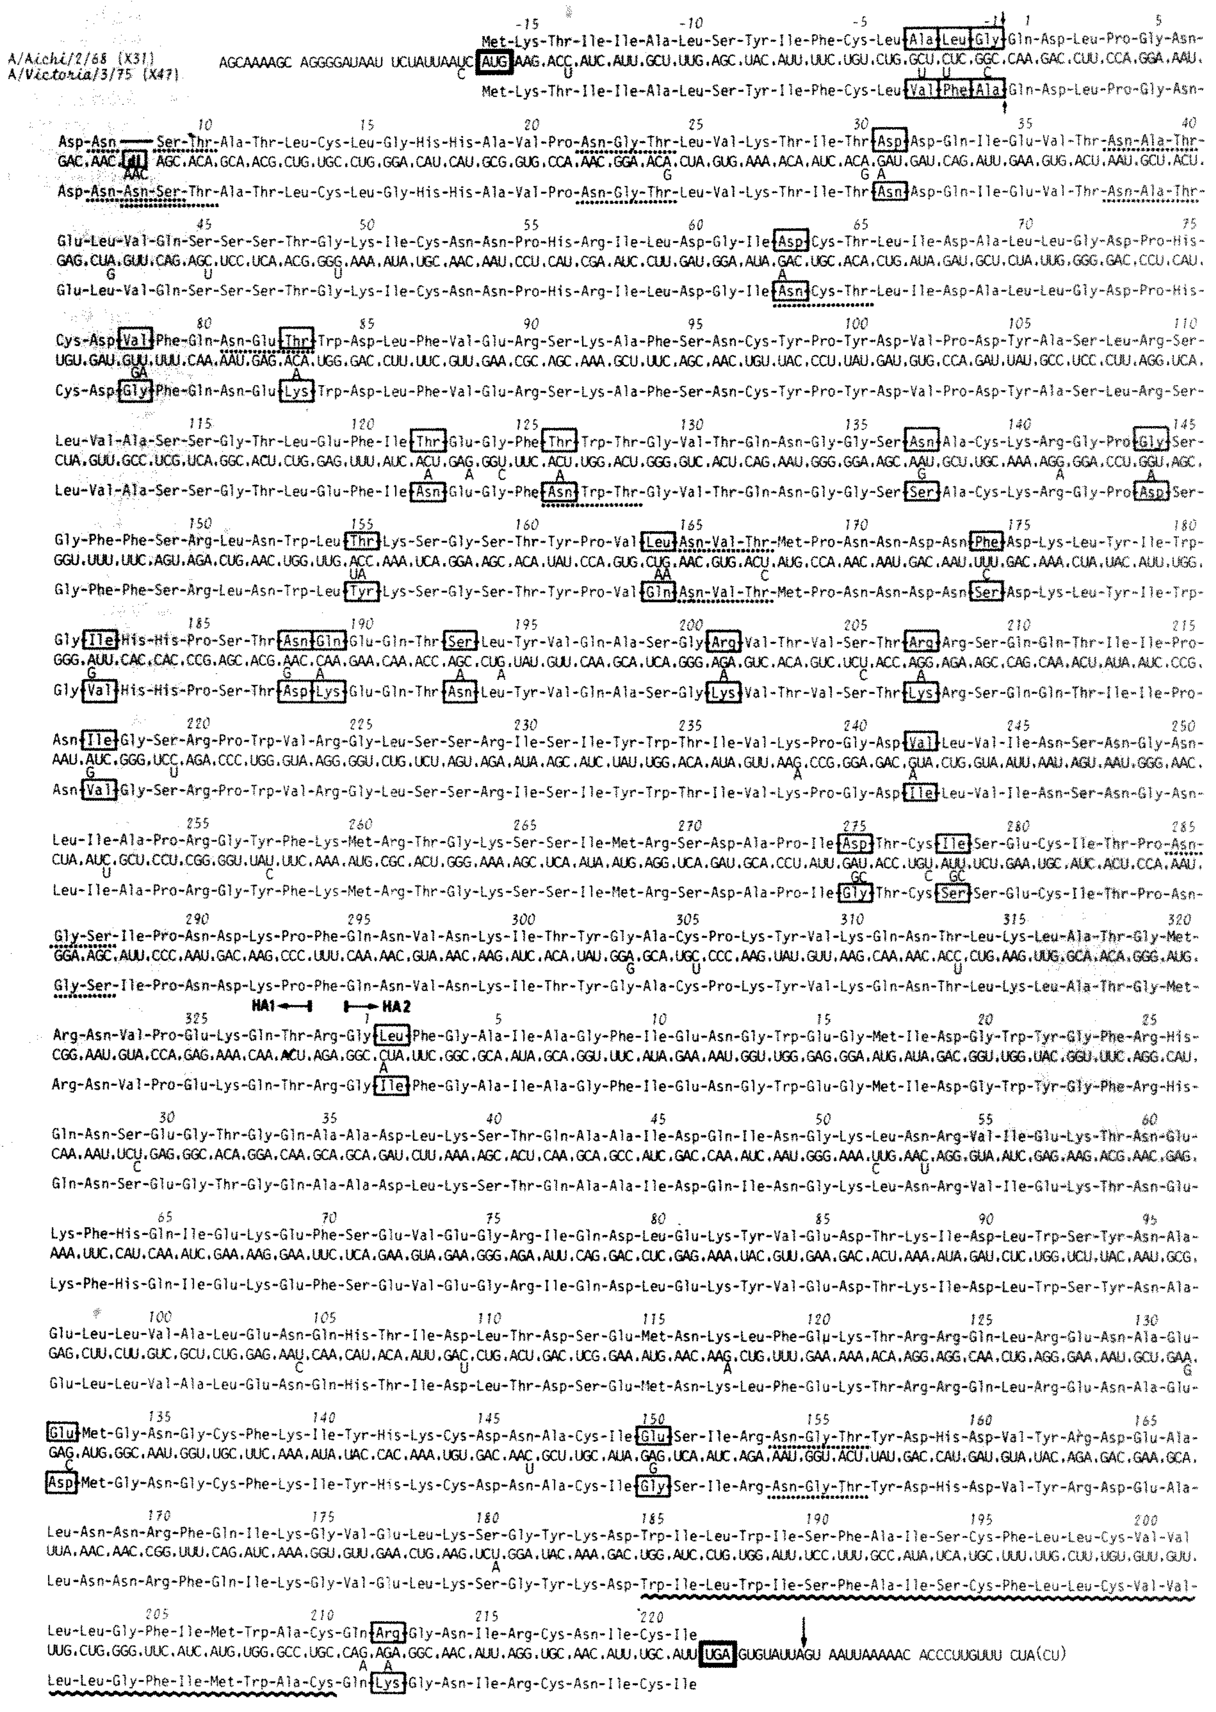

Fig. 1 Comparison of the haemagglutinin genes and deduced amino acid sequence of influenza strains A/Aichi/2/68 and A/Victoria/3/75. The nucleotide sequence of the Aichi gene is shown as the complementary viral RNA (coding strand); only the substitutions in the Victoria gene[5] are given. The Aichi nucleotide sequence is derived from cloned DNA; however, the sequence shown from the 3′ end up to the vertical arrow was missing from the cloned DNA and is assumed to be identical to the same region in Victoria (see text). The initiation and termination codons are shown in heavy boxes. Differences between amino acid sequences are shown in light boxes. Potential glycosylation sites are indicated by dotted lines. The wavy line indicates the hydrophobic region of HA2 that is embedded in the lipid membrane of the virion.

The percentage of homology in the HA1 portion is modest but usually in the same range between each two strains belonging to a different subtype (between 34 and 37%), whereas the homology is higher in HA2 (H3:H2, 50%; H3:Hav1, 66%; H2:Hav1, 52%). The fact that the HA2 is much more similar between H3 and Hav1 than between two human strains (H3 and H2) whereas the HA1 varies to approximately the same extent demonstrates how difficult it is to define the evolutionary relationship between different pandemic strains. The fraction conserved in all three subtypes (taking Aichi as the H3 prototype) is only 21% in HA1, but 42% in HA2. These values illustrate the importance of the HA1 portion to the antigenic variability of the influenza haemagglutinin.

Comparison of H3 strains: genetic drift

The nucleotide sequence of the haemagglutinin gene and the deduced amino acid sequence of the protein of the Aichi/68 and Victoria/75 strains are compared in Fig. 1. There are 67 nucleotide differences (3.8%): an insertion in the Victoria gene of three nucleotides close to the NH_2 terminus of the HA1 (coding for an extra asparagine residue) and 64 nucleotide substitutions. Of these latter changes, 63 occur in the coding region: 34 are silent nucleotide substitutions and the other 29 changes cause 28 amino acid differences (there is one case, at position 155 of the HA1, of two nucleotide changes resulting in a single amino acid change). Thus, in total there are 29 amino acid differences (including one insertion) or a 5.1% amino acid divergence accumulated over a 7-yr period (1968–75). By comparing maps of soluble tryptic peptides and amino acid composition data from nine strains isolated between 1968 and 1977 with the amino acid sequence of the A/Memphis/102/72 strain, Laver and collaborators[10] found a minimum (only soluble peptides were examined) of 20 amino acid changes occurring during that period. Another conclusion was that once a residue had changed, it did not change again in the later variants, except for a few apparent reversions to the original amino acid (apparent because there is a no reason to believe that prototypes of successive epidemics as isolated from nature form a direct genealogical lineage). The same observations are made when the complete amino acid sequence of the three H3 haemagglutinin molecules, Victoria/75 (ref. 5), Memphis/72 (refs 6–8) and Aichi/68, are compared (Fig. 2). Again, a likely explanation for the apparent reversions is that, for example, the Memphis strain is not the parent of the Victoria strain. Also, at the level of silent mutation, the same phenomenon of an occasional apparent reversion is observed (not shown).

As expected, most amino acid changes were found in the HA1 part of the protein (Fig. 2, Table 1); indeed, the antigenic character is thought to reside largely, if not entirely, in this section[30–32]. Over the 1968–75 period of antigenic drift, 22 (6.7%) of the amino acids have changed in HA1 whereas only 4 (1.8%) have been replaced in HA2. Comparing all three H3 subtypes (Fig. 2), 27 variable residues are observed in HA1 and 5 in HA2. Note that there is some clustering of the amino acid changes in the middle third (amino acids 110–226) of the HA1 in the three strains examined. A similar differential variability between both subchains of the haemagglutinin molecule has been observed by Laver and colleagues[10]. Variants have been isolated which are resistant to monoclonal antiserum, and the haemagglutinins of these have probably changed at only a single amino acid position[9]. As these variants are still neutralized by total antiserum against the parent virus, it seems very likely that a more profound change (of at least two amino acids) would be required to generate a new field strain capable of overcoming the immunity of the population.

Taking into account the number of different natural variants that have been isolated and the number of epidemics reported during the period considered[33,34], it is reasonable to assume that a not unimportant fraction of the 22 differences in HA1 observed between Aichi/68 and Victoria/75 (probably at least one-third and possibly up to two-thirds or even more, that is, 7–15 amino acids or more) have played a part in the antigenic variability. Also, if one considers the relative abundance of differences between HA1 and HA2 to reflect the antigenic variability within HA1 above the background of tolerable mutation rates, a value of 16 residues is obtained. However, these changes may be clustered in several 'antigenic sites' (each comprising a limited number of amino acids involved in the reaction with the antibody[9,35]) or they may influence the way the antigenic site is presented to the antibody by conformational changes. Thus, the analysis of amino acid sequences in a limited number of natural strains is not in itself sufficient for a delineation of antigenic sites.

Another approach is the analysis of variants selected with monoclonal antibodies. The Hong Kong variants studied by Laver and colleagues[19] have amino acid changes at positions 54, 143, 205 and a fourth one in the region 217–224 of the HA1 (the latter two changes were observed in the variants selected with the same monoclonal antibody). There are no amino acid changes around residue 54 in the three strains compared in Fig. 2, but a change of both the adjacent residue 53 and amino acid 54 (but to a different amino acid from that in the monoclonal variant) have been described[10]. Again, the amino acids next to residue 143, residues 144 (Fig. 2) and 145 (ref. 10), have been found to change in field strains. Natural changes around the third variant (205) are at positions 207 (Fig. 2 and ref. 10) and 208 (ref. 10). Thus, from all cases where a direct comparison is possible, in only one instance was an amino acid change found in the same position in a monoclonal antibody-selected variant and in a field strain (residue 54), and even then the residue by which it was replaced was completely different (to a lysine and a serine, respectively), suggesting that the immunological selection in nature works differently from that in the laboratory model experiments. The reason for this (systematic) discrepancy is unknown, although it is quite clear that the immunological pressure in an infected immune individual is very different from the selection pressure working in a murine monoclonal hybridoma to select laboratory variants.

Most of the amino acid changes in these H3 haemagglutinins have been acquired by single base substitutions and are rela-

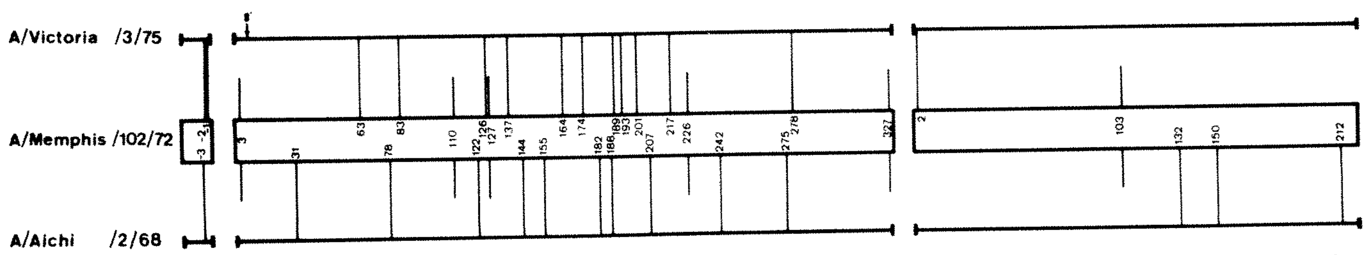

Fig. 2 Differences between the amino acid sequence of three H3 haemagglutinins derived from the virus strains A/Aichi/2/68 (the present paper), A/Memphis/102/72 (ref. 6) and A/Victoria/3/75 (ref. 5). The Memphis sequence used here is the complete one obtained by Sleigh *et al.*[6], rather than the one obtained by Ward and Dopheide[7,8], which lacks the hydrophobic region close to the C-terminus of the HA2. Apart from this, both sequences are essentially the same. Each difference is indicated by its number in the signal sequence (S), HA1 and HA2 portions of the molecule, respectively, and by a line connecting the strains involved. Two small lines at the same position in the Memphis strain indicate non-identity with either Aichi or Victoria (apparent reversions; see text).

Table 1 Variation observed among three H3 haemagglutinins

	Nucleotide changes leading to an amino acid change			Silent nucleotide changes		Total of nucleotide changes	
Comparison	No. of changes	% Nucleotide changes	% Amino acid changes	No. of changes	% Nucleotide changes	No. of changes	% Nucleotide changes
Aichi-Memphis	16 (4)	1.6 (0.6)	4.6 (1.8)	14 (9)	1.4 (1.4)	30 (13)	3.0 (2.0)
Memphis-Victoria	16 (2)	1.6 (0.3)	5.2 (0.9)	13 (3)	1.3 (0.4)	32 (5)	3.2 (0.8)
Aichi-Victoria	22 (4)	2.2 (0.6)	6.7 (1.8)	23 (10)	2.3 (1.5)	48 (14)	4.9 (2.1)
Total variable sites	27 (5)	2.7 (0.8)	8.2 (2.3)	24 (11)	2.4 (1.7)	54 (16)	5.5 (2.4)

The HA1 and HA2 regions are considered separately; the values for HA2 are given in parentheses. For the HA1 region the total number of nucleotides and amino acids is 984 and 328, respectively. The AAC insertion (asparagine residue 8') in the Victoria strain has been taken into account only in columns 3 (% amino acid changes) and 6 and 7 (total of nucleotide changes). The HA2 region comprises 663 nucleotides and 221 amino acids in all strains.

tively frequently observed interchanges between proteins in general[36]. Apart from this relationship directly determined by the genetic code, chemically, the substitutions are often of a conservative nature: Gly↔Ala; Ile↔Val; Leu↔Phe; Leu↔Ile; Glu↔Asp; Arg↔Lys. There is one amino acid change (Thr→Tyr) which is both infrequently observed and of a chemically drastic nature. Whether this latter change (at position 155 of HA1) is antigenically important is not known. Not surprisingly, it is the only change caused by two nucleotide substitutions.

Glycosylation sites

All potential glycosylation sites (known to be at Asn-X-Ser or Asn-X-Thr sequences) of the Aichi haemagglutinin are identical to the sites in A/Memphis/102/72, and these glycosylation sites have recently been directly confirmed[7,8]. Thus, it is probable that the glycosylation pattern has remained constant during the period 1968–72. However, one site (position 81 in HA1) disappears and two potential new sites (at positions 63 and 126) are created in Victoria relative to the 1968 prototype (and Memphis/72). Thus, the pattern of glycosylation in the HA1 is not invariable within the H3 subtype. The effect (if any) of this variation on the antigenic properties remains to be established. Note that the positions of the glycosylation sites are rather variable between different subtypes, except at position 154 of the HA2 chain, which has been conserved in all influenza A strains examined so far[5–8,11,12].

Further considerations

Not only nucleotide substitutions leading to an amino acid change but also silent mutations occur somewhat more frequently in the sequence coding for HA1 (2.3%) than in that coding for HA2 (1.5%) (Table 1). This enhanced value is statistically significant at the 5% level as tested by χ^2 analysis. If this trend is consolidated by more data, the question arises as to the meaning of this higher variability in HA1 independent of selection pressure at the protein level. It could perhaps be interpreted as base changes selected as a function of the preservation of a defined secondary structure in the viral RNA that has been more disturbed by nucleotide changes causing amino acid replacements in HA1 than HA2. A well defined secondary (and tertiary) structure may be important in the formation of the nucleoprotein complex or for packaging the eight RNAs in a molar ratio in the particle. Another case where the importance of secondary structure in the genome of RNA viruses has been well documented involves the RNA phages, where it has been shown that the number of base changes between RNA phages is 2.5 times lower in double-stranded regions than in single-stranded regions[37].

If one considers the actual number of silent and non-silent single base changes in the 61 codons for the 20 amino acids in the HA1 and the HA2 coding sequence and compares these values with those that would be expected assuming that single base replacements are acquired on a random basis, the differences are quite striking. According to this assumption, 25.5% of the substitutions would be expected to be neutral and 74.5% would cause an amino acid change[38]. In reality, one finds in the HA1: silent changes, 23; non-silent changes, 20; non-silent changes expected taking the silent ones as the 25.5% value, 67. In the HA2 region these values are: silent changes, 10; non-silent changes, 4; non-silent changes expected, 29. This means that in HA1, 70% of the potentially non-silent mutations would be selected against; this percentage is even higher (86%) in HA2. A similar comparison between RNA phages leads to a value of 93% (ref. 37). All these deviations from randomness are statistically meaningful at the 0.1% level (χ^2 test). Although these estimates are not very accurate (it is not valid to assume an equal probability for a nucleotide to change in any direction), they are, nevertheless, a relative measure of the selection pressure to maintain the amino acid sequence in a molecule or its subregions.

Considering the nature of the nucleotide substitutions, transitions are much more frequent than transversions: of the 64 single-base substitutions between Aichi and Victoria, 49 are transitions and only 15 are transversions. Similarly, comparison of nucleotide sequences from two RNA bacteriophages, MS2 and R17, reveals 29 transitions and 5 transversions[37]. Even in the (at least at first approximation) neutral third-letter position of fourfold degenerate codons, 12 out of 15 changes are transitions between the influenza strains, and all 11 changes are transitions in the comparison between the two phages. It is quite possible that these transitions arise during replication by the formation of G · U instead of the normal G · C or A · U interactions[37].

Finally, it is too early to understand the basis of drift from the sequence information available for the haemagglutinins of natural H3N2 strains and of variants selected by monoclonal antibodies. The three-dimensional structure of the X31 haemagglutinin will probably soon be solved[39], especially as the primary amino acid sequence is now available for reference. This may then, in combination with the available and forthcoming sequence information, provide a solid framework for understanding the variability of the virus within a subtype, the mechanism of antigenic drift and the number and distribution of antigenic sites on the haemagglutinin molecule.

We thank Dr J. Skehel for a gift of X31 RNA and W. Kuziel for help with the manuscript. This research was supported by grants from the Fonds voor Kollektief Fundamenteel Onderzoek and the Gekoncerteerde Akties of the Belgian Ministry of Science. D. H. thanks the IWONL and M.V. thanks the NFWO for fellowships.

RNA splicing generates a variant light chain from an aberrantly rearranged κ gene

Edmund Choi*, Michael Kuehl† & Randolph Wall*

Both C_κ regions in MPC 11 cells are rearranged into active transcription units, one producing a normal κ chain and the other an internally deleted κ fragment lacking a V region. The gene coding for the κ fragment mRNA is aberrantly rearranged and lacks a site for $V \rightarrow C_\kappa$ splicing. An alternative splicing event which deletes the V region from the nuclear RNA precursor generates the κ fragment mRNA.

IMMUNOGLOBULIN light-chain variable (V) and constant (C) regions are rearranged in the formation of active genes (that is, transcription units)[1-4]. These somatic rearrangements join a specific germ-line V region with a J region while retaining the intervening sequence (intron) separating the J and C regions in germ-line DNA[1-4]. Some myeloma cells also contain C regions arranged differently from either the germ-line pattern or the pattern in the active transcription unit producing immunoglobulin light chains[5,6]. The detailed structure of such rearranged C regions has not been determined. These presumably aberrant DNA arrangements have been proposed to be the mechanism for allelic exclusion in immunoglobulin-producing cells. However, it has not been shown whether or not such aberrantly rearranged C regions are transcribed. Indeed, the relationship of DNA rearrangements to the activation of immunoglobulin genes for transcription remains to be resolved.

Immunoglobulin messenger RNAs, like virtually every eukaryotic mRNA now studied, are processed from larger nuclear RNA precursors by RNA splicing[7-10]. It seems that RNA splicing may be an obligatory step for the generation of stable mRNA[11-13]. One clue to the signals possibly used in RNA splicing has emerged from the nucleotide sequencing of cloned eukaryotic genes containing introns. All eukaryotic genes now studied (including several immunoglobulin light- and heavy-chain genes, with one notable exception) have the characteristic nucleotides 5′-/*GT*-intron-*AG*/-3′ at the junctures between introns and exons (summarized in ref. 14). Compilation of subsequent sequences has shown that the 5′ (upstream) and 3′ (downstream) ends of introns approximate to the following consensus or 'optimal' splice sites[14-16]

5′-exon-AG/$\underline{\mathit{GT}}$AAGTA——intron——
——TTTTYTTTTTTCTTNC$\underline{\mathit{AG}}$/G-exon-3′

These upstream and downstream splice sites flanking an intron presumably must be brought together for RNA splicing to occur. One of the abundant, small nuclear RNA (snRNA) species called U-1 (ref. 17) is exactly complementary to these 'optimal' sequences at RNA splicing sites. A mechanism for RNA splicing has been proposed in which U-1 snRNA is the recognition component of the nuclear RNA splicing enzyme complex and hybridizes with both ends of an intron so as to align them in exact register for RNA splicing[15,16]. However, the significance of these presumptive signals and the molecular mechanisms of RNA splicing remain to be elucidated.

We have approached these questions by investigating how cloned MPC 11 myeloma cells simultaneously produce both a normal κ light-chain containing precursor, P, V, J and C_κ regions, and a variant κ light-chain fragment containing *P* and C_κ regions but lacking V and J regions[18,19]. Combining nuclear RNA and DNA mapping approaches, we find that the two κ mRNAs in MPC 11 cells are independently transcribed from two separate transcription units with rearranged C_κ regions. Aberrant rearrangement of one C_κ region in MPC 11 cells generates the transcription unit for the κ fragment light chain. The nuclear RNA transcript of this aberrantly rearranged C_κ region undergoes an unusual RNA splicing step which generates the κ fragment mRNA. The detailed structure of this variant MPC 11 C_κ gene is presented in the accompanying article[20].

MPC 11 cells contain two rearranged C_κ regions

The expression of two different κ light chains in MPC 11 cells suggests that there must be two differently rearranged C_κ regions. This prediction was confirmed by Southern mapping[21] of the C_κ regions in *Bam*HI-cleaved DNA from MPC 11 (clone 45.6) and spleen cells. Hybridization with a cloned cDNA probe (pL21-5, 22) which contains the C_κ region reveals that 45.6 cells contain strongly hybridizing fragments of 3.0 and 7.7 kilobases (Fig. 1). Spleen DNA which has non-rearranged C_κ regions contains a single C_κ band at 14 kilobases. Weakly hybridizing fragments of 5.1, 5.5 and 5.7 kilobases, present in all the cell lines and spleen DNA, are probably due to a small amount ($\simeq$50 nucleotides) of MOPC 21 V-region sequences in the pL21-5 probe[22] which react with MOPC 21 and related V regions in the DNA. The MOPC 21 V-region does not cross-hybridize with either the MPC 11 or MOPC 321 V regions (E.C., unpublished results).

0028-0836/80/340776—04$01.00

To determine which C_κ restriction fragments correspond to the normal and fragment MPC 11 light chains, we examined a variant (clone NP.2) which expresses only the κ fragment but not the normal light chain. In contrast to those of 45.6 cells, the *Bam*HI digests of NP.2 cells reveal only a single strongly hybridizing fragment of 3.0 kilobases. As this is the only C_κ fragment in NP.2 cells, it must represent the rearranged C_κ region which encodes the κ fragment chain. Apparently, the 7.7 *Bam*HI fragment represents the C_κ region which encodes the normal κ light chain in MPC 11 cells, because the loss of normal light-chain expression in NP.2 cells is correlated with the loss of this fragment. Thus, the loss of normal light-chain expression in the NP.2 variant clone, which was isolated from MPC 11 cells by nitrosoguanidine mutagenesis, seems to be due to the deletion of the rearranged C_κ region coding for this chain.

Nuclear RNA species derived from the normal and fragment genes

Previous results from our laboratory[23] and from Schibler *et al.*[9] revealed multiple κ light-chain nuclear RNA species in MPC 11 cells. To distinguish between the nuclear RNA processing pathways for normal κ and the κ fragment mRNAs, we compared the κ nuclear RNA species in wild-type MPC 11 45.6 cells making both κ chains with those in the NP.2 variant line which synthesized only the C_κ fragment chains.

Polyadenylated nuclear RNA was fractionated on methyl mercury hydroxide gels, transferred onto diazophenylthioether (DPT) paper ('RNA blots', ref. 24) and hybridized with nick-translated C_κ-gene probe (Fig. 2, panel *a*). The 45.6 cells contain five distinct C_κ nuclear RNA species: 6.5, 5.6, 3.6, 1.2 and 0.8 kilobases. The 1.2- and 0.8-kilobase species represent the normal κ light-chain and κ fragment mRNAs, respectively[9,23]. These κ nuclear RNA species are in approximate agreement with those previously reported[9,23] except that the largest band is here resolved into 6.5- and 5.6-kilobase species. When the C_κ-gene probe was hybridized to nuclear RNA from NP.2 cells, only the 3.6- and 0.8-kilobase species were seen (Fig. 2, panel *a*).

These findings outline the two different κ light-chain RNA processing pathways in MPC 11 cells. No larger κ nuclear RNA species are detected either by RNA blots or in brief pulse-labelling experiments (E. C., M. K. and R. W., unpublished results). Although it is not formally proven here, we presume that the polyadenylated 6.5- and 3.6-kilobase species represent the primary transcripts for the κ light-chain and κ fragment mRNAs, respectively. The definition of the sequences in these presumptive primary transcripts provides a means of further defining the structures of the two active κ transcription units in MPC 11 cells.

To characterize these κ transcripts further, we isolated two specific restriction fragments of the C_κ-gene clone[2,3] (see Fig. 2, inset). One contains a portion of the intron between the J regions and C_κ region (designated IS), the other fragment encompasses the entire J-region cluster (designated J; see Fig. 2, inset). The intron probe hybridized to the 6.5- and 5.6-kilobase precursors in 45.6 cells (Fig. 2, panel *b*). It also hybridized to the 3.6-kilobase species in both 45.6 and NP.2 cells, indicating that this nuclear RNA species contains sequences from the $J \rightarrow C_\kappa$ intron in normal κ light-chain transcription units. As expected, this probe did not hybridize with either the 1.2- or the 0.8-kilobase mRNA species.

We next determined which nuclear RNA species contained J-region sequences. As expected, the restriction fragment containing all five known κ J regions hybridized with the 6.5-, 5.6- and 1.2-kilobase κ RNAs in 45.6 cells (Fig. 2, panel *c*). In contrast, the 3.6- and 0.8-kilobase κ species in 45.6 or NP.2 cells did not hybridize with the J probe (Fig. 2, panel *c*), suggesting that the transcription unit for the κ fragment does not contain J regions.

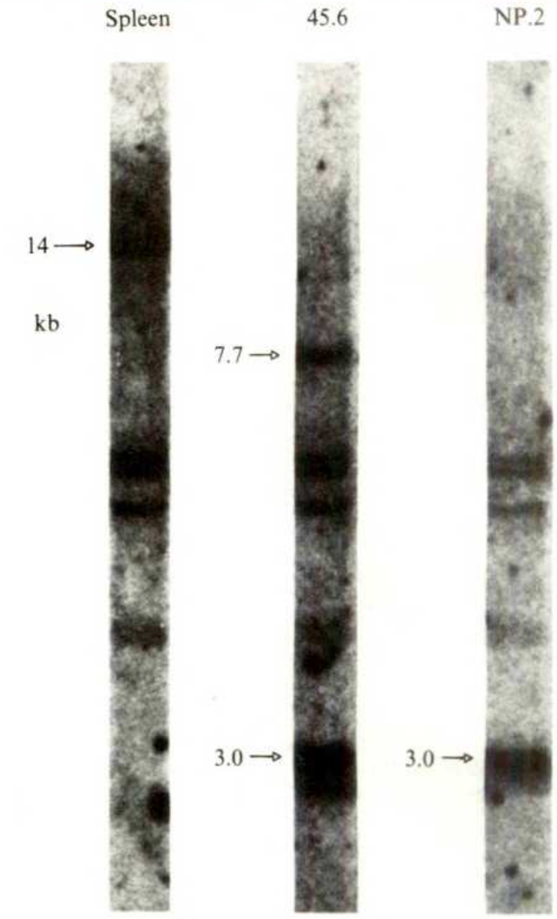

Fig. 1 Southern hybridization analysis of the κ constant region specific *Bam*HI DNA fragments of spleen and MPC 11 wild-type and variant plasmacytomas. Fragments generated by *Bam*HI digestion of BALB/c spleen, MPC 11 clone 456, and MPC 11 clone NP.2 DNAs were fractionated by electrophoresis in 0.75% gels, alkali denatured, neutralized and transferred to nitrocellulose filters[21]. The filters were hybridized to 0.2 μg of nick-translated ^{32}P-labelled pL21-5 plasmid DNA (1.5×10^8 c.p.m. per μg) and subjected to autoradiography. The pL21-5 cDNA plasmid probe contains approximately 550 nucleotides of MOPC 21 κ mRNA sequence, including all the 3'-untranslated, constant region and J-region sequences as well as 50 nucleotides of MOPC 21 V-region sequences[22]. Fragment lengths were determined by comparison with ethidium bromide-stained *Eco*RI and *Hin*dIII fragments of phage λ phage DNA. Lane *a*, spleen DNA; lane *b*, MPC 11 clone 45.6; lane *c*, MPC 11 clone NP.2 DNA.

It has previously been shown that the MPC 11 κ fragment mRNA contains a MOPC 321-like hydrophobic precursor (P) region linked to the C_κ region[19]. To determine if the nuclear RNA precursor to the C_κ fragment mRNA also contains the MOPC 321 V region, we hybridized a nick-translated restriction fragment containing the V region of MOPC 321 to nuclear RNA from 45.6 and NP.2 cells. Only the 3.6-kilobase species in both cell lines contains a V region which hybridizes with the MOPC 321 variable region (Fig. 2, panel *d*). This probe did not hybridize to the 6.5- or 5.6-kilobase RNA precursors in 45.6 cells, establishing that there are no MOPC 321 V-region sequences on the precursors to the normal κ light chain of MPC 11 cells.

The two independent κ nuclear RNA processing pathways are clearly defined by these results. Those RNA precursors in the normal κ light-chain processing pathway are identified by the presence of J-region sequences, and those in the κ fragment pathway are distinguished by the presence of MOPC 321 V-region sequences.

The processing pathway for the full-length κ mRNA is

$$6.5 \text{ kilobases} \rightarrow 5.6 \text{ kilobases} \xrightarrow[\text{splice}]{V\rightarrow C_\kappa} \rightarrow 1.2\text{-kilobase mRNA}$$

In the transcription unit for the normal MPC 11 κ light chain, the V region is joined to J_4 and contains a 3.5-kilobase intron separating the joined V+J from the C_κ region[3,4]. This intron is removed in the processing step from the 5.6-kilobase nuclear RNA to the 1.2-kilobase mRNA, apparently with another

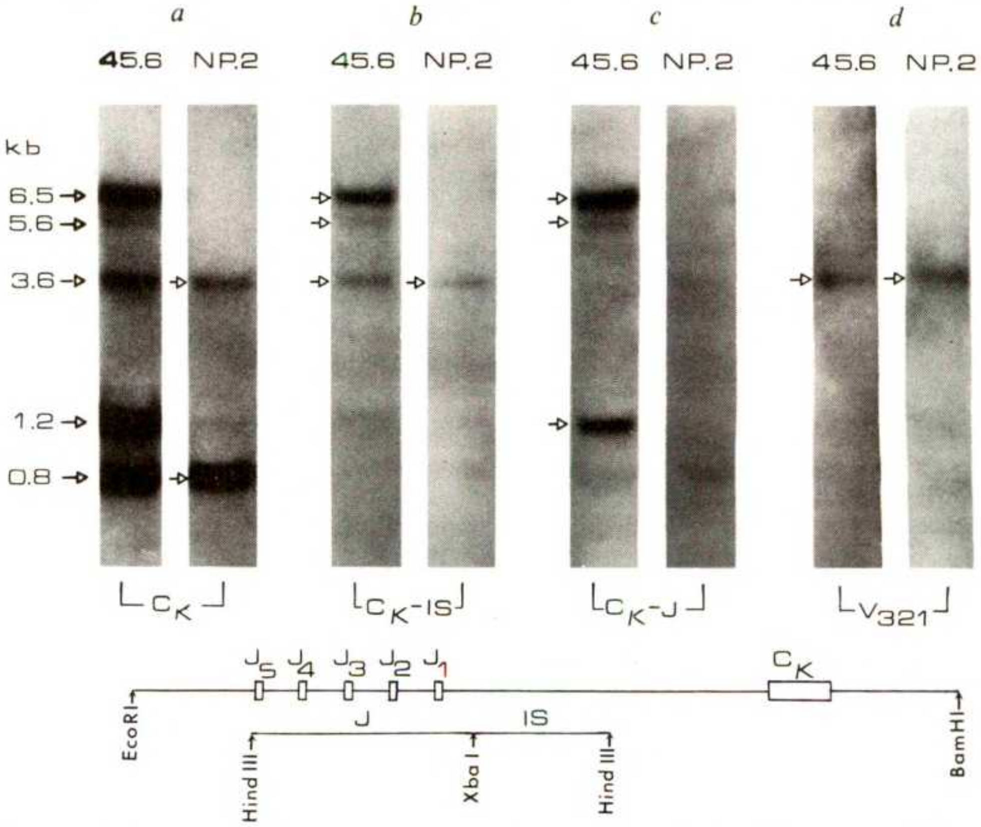

Fig. 2 Analysis of nuclear RNA species in 45.6 and NP.2 cells. Nuclear RNA was prepared from detergent-washed nuclei[31]. Poly(A)$^+$ nuclear RNA was fractionated on 1% agarose gels containing 5.0 mM methyl mercury hydroxide[32]. Nuclear RNA was loaded at 20 μg per lane. All operations involving methyl mercury hydroxide were carried out using appropriate safety measures. The RNA transfer was carried out as described by Wahl *et al.*[33] except that DPT paper was used instead of diazobenzyloxymethyl paper. Following transfer, the DPT paper was hybridized with nick-translated probes and washed in conditions described by Wahl *et al.*[33]. The restriction fragments used for nick translation were isolated from agarose gels[23]. The specific activities of the ^{32}P-labelled probes ranged from 7×10^7 to 2×10^8 c.p.m. per μg; $2-3\times10^6$ c.p.m. were hybridized to each lane. The following probes were each hybridized to a pair of lanes containing the nuclear RNA from 45.6 and NP.2 cells. Panel *a*, C_κ embryo genome clone. The 6.5-kilobase *XbaI–Hin*dIII restriction fragment[3] from the C_κ clone is outlined in the inset below the RNA lanes. Panel *b*, intervening sequence probe. A 1.1-kilobase *XbaI–Hind*III restriction fragment designated IS in the C_κ embryo gene was used. Panel *c*, J-region probe. A 1.7-kilobase *Hin*dIII/*Xba*I restriction fragment designated J in the diagram was used. panel *d*, 321 variable region probe. An *Ava*I restriction fragment containing the 321 variable region was isolated from a recombinant cDNA clone. Filters in panels *b*, *c* and *d* rehybridized with the C_κ embryonic probe used in lane *a* showed that all the κ nuclear species were present on these filters (data not shown). The following mouse rRNAs were used to calculate the sizes of hybridized nuclear RNA bands 45s(14.1 kilobases), 32s (6.6 kilobases), 28s (5.2 kilobases) and 18s (2.1 kilobases)[34].

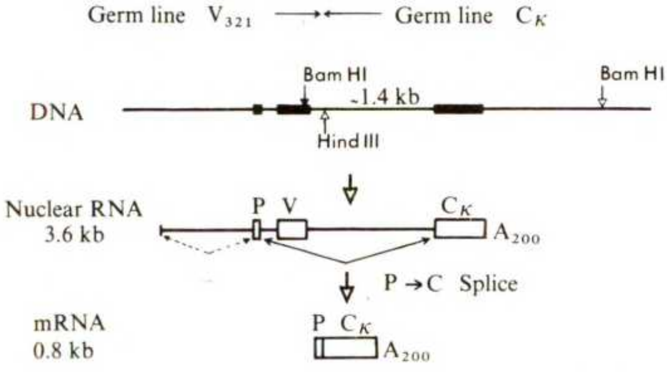

Fig. 3 The transcription unit and nuclear RNA processing pathway for the MPC 11 C_κ fragment mRNA. Polyadenylation of the 3.6-kilobase nuclear RNA precedes RNA splicing. Other details of the model are discussed in the text.

undefined intron amounting to approximately 1 kilobase. This V→C_κ splicing event may proceed throught a rapidly labelled intermediate of approximately 2.1 kilobases which is readily detected in pulse-labelling experiments[23] but not in RNA blots, as the latter technique primarily detects stable species of nuclear RNA.

The processing pathway for the κ fragment mRNA seems to be

$$3.6\ \text{kilobases} \xrightarrow{\text{P}\rightarrow\text{C}_\kappa\ \text{splice}} \rightarrow 0.8\text{-kilobase mRNA}$$

Because the 3.6-kilobase nuclear RNA precursor lacks a J region and the germ-line MOPC 321 V region lacks an upstream splice site, this V region cannot be spliced to the C_κ region. The κ fragment chain lacks the last three carboxy-terminal amino acids of the MOPC 321 P region[18,19]. This suggests that the normal splicing site at the 3′ end of the P region is spliced to the site at the 5′ side of the C_κ region, thereby generating the fragment light-chain mRNA (Fig. 3). It is not known if the P region is alternatively spliced to the 5′ end of the 321 V-region gene. The RNA product of such a splice, removing only approximately 0.2 kilobases, would probably not be distinguished in RNA blots. Moreover, the product RNA might be rapidly degraded in the nucleus. The efficiency of P→C_κ splicing is not known. However, it is likely that this unusual splice occurs at a comparatively high frequency, because the 3.6-kilobase RNA species and the κ-fragment mRNA comprise, respectively, some 20% of the κ RNA in the nucleus and cytoplasm of 45.6 cells. The P→C_κ splice removes approximately 2 kilobases. An additional splice removing approximately 0.8 kilobases also apparently occurs in the generation of the κ fragment mRNA. This splice presumably involves 5′-untranslated leader sequences (Fig. 3).

Structure of the κ fragment transcription unit

The fragment transcription unit apparently contains P, V and C regions, but lacks J regions. Moreover, it contains the intervening sequence up to 1.1 kilobases from the 5′ side of the C_κ region (that is, sequences homologous to the *Xba*I*Hin*dIII fragment; Fig. 2, inset). A model consistent with these results would predict that the embryonic MOPC 321 V region is joined to a point in the intervening sequence preceding the embryonic C_κ gene (including the *Hin*dIII site 1.1 kilobases from the C_κ region), such that the J regions are deleted. The presence of the fragment κ gene on a 3.0-kilobase *Bam*HI restriction fragment allows us to localize the rearrangement further. A *Bam*HI restriction site is located 1.2 kilobases 3′ to the embryonic C_κ gene[2,3]. The sequences flanking the 3′ end of the C_κ gene are conserved during the somatic rearrangement of the DNA to form the active immunoglobulin gene[2,3,6]. Assuming that the C_κ gene amounts to 0.5 kilobases (including the contiguous 3′-untranslated region), the *Bam*HI site 5′ to the C_κ gene is approximately 1.4 kilobases away. No *Bam*HI site exists in this region in the embryonic C_κ gene[2,3]. Therefore, this *Bam*HI site must have originated on the 3′ end of the rearranged MOPC 321 V region[2]. A likely *Bam*HI site is found at amino acid 96 in the germ-line MOPC 321 variable region[2]. This would place the rearranged 321 V region approximately 1.4 kilobases away from the C_κ region (Fig. 3). This predicted arrangement of the MPC 11 κ fragment transcription unit has been confirmed by direct nucleotide sequence by Seidman and Leder[20].

Discussion

These results clearly show that both C_κ alleles can be rearranged into concomitantly active transcription units. However, with regard to allelic exclusion, it should be noted that these MPC 11 cells produce only a single functional secreted κ chain. Because the aberrant rearrangement which generates the κ fragment occurs by recombination between homologous germ-line DNA sequences[20], it is likely that other immunoglobulin-producing cells will also express V regions joined at this intervening sequence site. Certainly, the demonstration that such rearranged C_κ genes are transcribed suggests that the activation of immunoglobulin C_κ genes for transcription does not necessarily result from the normal V→J joining event. Recent findings indicate that in certain myeloma cell lines, an unrearranged C_κ gene is apparently transcribed concomitantly with the rearranged C_κ gene which generates mRNA[25]. This suggests that DNA rearrangement may not initiate the transcription of an immunoglobulin gene but may rather generate a complete transcription unit bounded by an initiation site for transcription (contributed by the V-region segment) and a poly(A) addition site (contributed by the C-region segment). These two elements may be sufficient to delineate a transcription unit capable of producing a stable, polyadenylated primary transcript which can be processed to immunoglobulin mRNA.

The MPC 11 κ fragment mRNA contains two exons (P, C_κ) which are not normally spliced together in immunoglobulin mRNA. Such shuffling of exons presumably does not occur very frequently in normal mRNA splicing. However, RNA splicing can apparently bypass a mutant splicing site provided that the RNA precursor contains other introns with functional splicing sites. In such precursors, as in the MPC 11 κ fragment, such an event could result in the deletion of a complete exon.

This seems to be the most likely explanation for the large number of immunoglobulin heavy-chain deletion variants which have lost internal domains or the hinge region[26,27]. A particularly striking example of such a heavy chain deletion variant is the IF2, γ_1 chain, which lacks the C_H1 domain and has the V_H region joined directly to the hinge[28]. A γ_1 heavy-chain gene which may resemble the IF2 variant gene has been cloned from MOPC 21 myeloma tumour DNA[29]. This MOPC 21 γ_1 clone is identical in nucleotide sequence to another γ_1 gene clone from embryo DNA[30] except that the trinucleotide, GTG, which directly follows the C_H1 domain, is deleted[29,30]. Presumably, RNA transcripts of this MOPC 21 γ_1 gene lack a functional splice site at the C_H1/intron juncture and would be expected to splice the V_H region to the hinge, producing an internally deleted variant chain like IF2. Future studies on immunoglobulin deletion variants should serve to define further the signals and steps in RNA splicing.

These studies were supported by NIH research grants AI13410, CA12900 and AI12525. E. C. was supported by NIH Training Grant CA 09056. DPT paper was developed by Brian Seed, C_κ embryo clone was made available to us by P. Leder, and the MOPC 321 cDNA clone was from S. Tonegawa.

A mutant immunoglobulin light chain is formed by aberrant DNA- and RNA-splicing events

J. G. Seidman & Philip Leder

Laboratory of Molecular Genetics, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland 20205

A mutant immunoglobulin gene has been formed by an abnormal (non V/J) recombination event such that abnormal RNA splicing is required to form a mutant light chain. The structure of the gene suggests that the small palindrome thought to be involved in V/J joining also provides the basis for this abnormal DNA recombination and that the absence of a J segment and RNA splice signal allows an abnormal RNA splicing reaction to occur.

THE generation of antibody diversity depends on a specialized form of genetic recombination that operates in somatic cells during lymphocyte differentiation[1–4]. The combinational power of joining one of several hundred variable region genes to one of the four J-region segments encoded close to the constant-region gene creates literally thousands of unique genetic possibilities[5–9]. Recent DNA cloning and nucleotide sequences analyses have revealed many of the molecular details of this

0028–0836/80/340779—05$01.00

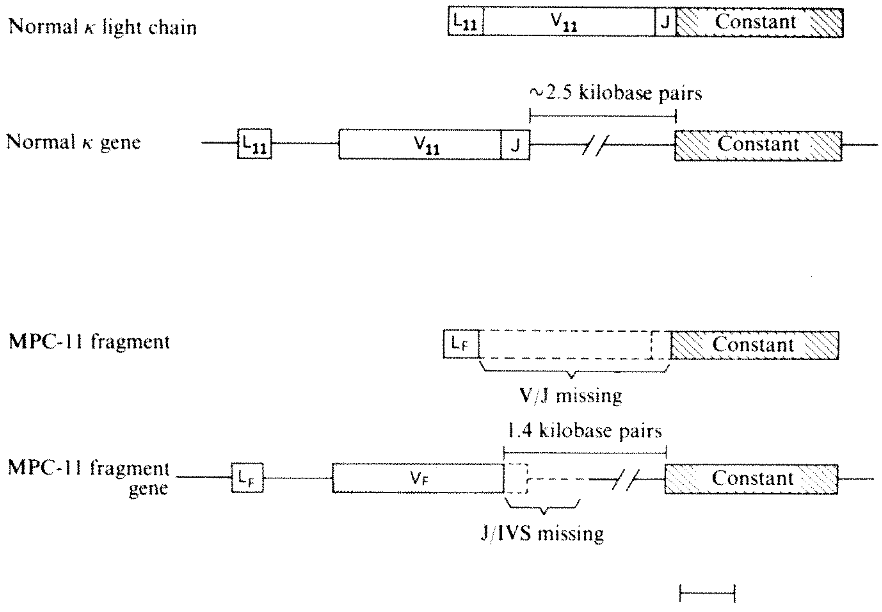

Fig. 1 The structure of the MPC-11 light chains and their genes. The MPC-11 cell synthesizes two κ light chains—a normal κ light chain and the MPC-11 fragment. We presume that the normal κ light chain is encoded by a normal κ gene, while the MPC-11 fragment is encoded by the MPC-11 fragment gene. The leader of the MPC-11 normal κ light chain (L_{11}) and the leader of the MPC-11 fragment (L_F) do not have the same amino acid sequence[12,13]. The amino acid sequence of L_F is identical to the leader of the MOPC-321 light chain[12,13]. Scale bar, 0.1 kilobase pairs.

process, including a plausible molecular basis for the special recombination event[8,9]. They also provide an accurate picture of an active κ immunoglobulin gene[7]. In its final form, the κ light-chain gene consists of three separate coding elements separated by two intervening sequences of DNA. Obviously, the formation of a light chain requires both DNA- and RNA-splicing reactions.

Kuehl and Scharff[10] have described an immunoglobulin-producing cell that is relevant to both these processes. They showed that the cell line MPC-11 produced two light chains, one apparently normal and the other, a lower molecular-weight fragment, at first thought to contain only constant region sequences. Further studies showed that a derivative of this cell line had lost its ability to produce normal light chains, but that it continued to produce the fragment. In addition, the fragment was encoded in a shorter-than-normal mRNA species[11]. These studies led to the conclusion that there must be two independently active κ genes in MPC-11 cells and that (at least in this instance) the process of allelic exclusion that affects most antibody-producing cells had been circumvented[10]. Subsequent amino acid sequence determinations[12,13] on an *in vitro* synthesized fragment precursor showed that it consisted of a hydrophobic leader sequence joined directly to the κ constant region and that the sequence corresponding to the variable region (the joined V and J segments) was completely lacking (Fig. 1). Moreover, the hydrophobic leader sequence of the fragment was different from that of the intact light chain produced by MPC-11. Instead, it corresponded to a sequence associated with the VK21 subgroup of κ light chains[12,14], an observation that strengthened the notion that each MPC-11 light chain corresponded to a separately expressed allele.

While the simplest explanation for these observations might have been that both chromosomal genes underwent V/J recombination in MPC-11 and that one, the fragment gene, suffered a subsequent deletion of the separately encoded V/J segment, this is not the case. While it might also seem possible that the rearranged gene arose from the normally rearranged gene by a subsequent deletion, this is ruled out by our finding that the normally rearranged chromosome has lost (by deletion associated with V/J recombination) the V-region genes corresponding to those used to form the fragment gene (J.S. and P.L., unpublished data). Since we also found that the fragment gene lacks all J regions, neither gene could serve as precursor for the other and both, therefore, appear to have been derived from independent, allelic germ-line chromosomes. Using DNA cloning, direct sequence analysis and *in situ* hybridization, we show that both alleles have indeed undergone rearrangement in the MPC-11 cell line, but that the fragment gene has undergone a recombination event that has joined its V region to a site close to the κ constant region, but not associated with any J segment. This joining has apparently been guided by the same palindromic sequence (CACAGTG) that occurs adjacent to all V and J segments thus far sequenced, for the recombination has occurred at the only instance of this palindrome between the J regions and the κ constant-region gene (E. Max, unpublished). Since the J region normally provides the RNA splice site at the 5′ end of the intervening sequence between the variable and constant regions, its absence in the fragment gene must prevent the normal RNA splice from occurring. Thus the fragment mRNA must be formed by an aberrant RNA splice involving the hydrophobic leader segment skipping its normal splicing partner, the V segment, and being joined directly to the C region. The nucleotide sequence suggests a mechanism for the aberrant DNA splicing event that involves homologous rather than normal V/J recombination.

In an accompanying study, Choi, Kuehl and Wall[15] show how this mutant gene generates mRNA precursors that follow the required aberrant RNA splicing pathway and that their structure can be reconciled with the structure of the mutant gene described here.

Restriction fragments containing the constant region gene in MPC-11 DNA

Confirmation of the prediction[10] that MPC-11 cells encode two separate and active κ constant-region genes was obtained from *in situ* hybridization experiments in which all the restriction fragments that encode κ constant regions could be identified (Fig. 2). If two constant region genes are present in MPC-11 DNA and have undergone somatic rearrangement, one would expect to find two new restriction fragments each containing a constant region, neither of which should be identical to the fragments observed in embryonic DNA. Cleavage of MPC-11 DNA with the restriction enzyme *Bam*HI produces two such fragments, one 7.7 and the other 3.0 kilobase pairs in length (Fig. 2). The presence of two non-germ-line genes in MPC-11 DNA does not, however, prove that both of these genes are involved in the synthesis of the two light chains expressed in MPC-11 cells. Nor does it allow us to identify the fragment responsible for mutant light-chain production. Other plasmacytoma cells have been shown to contain several non-germ-line genes other than the one which is expressed as a light-chain polypeptide (ref. 7 and E. Max, S. P. Kwan, J. G. S. and P. L., unpublished results). The assignment of the two *Bam*HI restriction fragments to the normal and fragment light-chain genes can be made by taking advantage of several cell lines derived by Scharff and co-workers from MPC-11 that continue to produce the fragment peptide but no longer produce the normal MPC-11 light chain.

One of these cell lines, NP2, yields DNA containing only the 3-kilobase pair *Bam*HI constant-region containing fragment (Fig. 2). Presumably the 7.7-kilobase pair fragment missing in NP2 but present in the parental line encodes the normal MPC-11 light chain, while the 3.0-kilobase pair *Bam*HI fragment must encode the fragment polypeptide. Apparently the NP2 cells have suffered a deletion of the normal MPC-11 light-chain gene and this deletion accounts for their inability to synthesize this light chain. Interestingly, another cell line, B47L3NP, has also lost the ability to produce the normal MPC-11 light chain, but has retained the 7.7-kilobase pair *Bam*HI fragment (Fig. 2). Obviously the mechanism by which this gene is inactivated is not accounted for by a major deletion, making it a fruitful subject for further investigation.

The MPC-11 fragment gene consists of a variable region and constant region without a J segment

To determine the genetic mechanism that led to the formation of the fragment peptide, we isolated the MPC-11 *Eco*RI DNA fragment that encodes the rearranged fragment gene using preparative agarose gel electrophoresis[17]. The proper fragment, about 20 kilobase pairs long, could be identified because it yielded the expected 3.0-kilobase pair *Bam*HI fragment (Fig. 2). The fragment was cloned in λ vector CH4A, identified and further purified using standard recombinant DNA techniques[18].

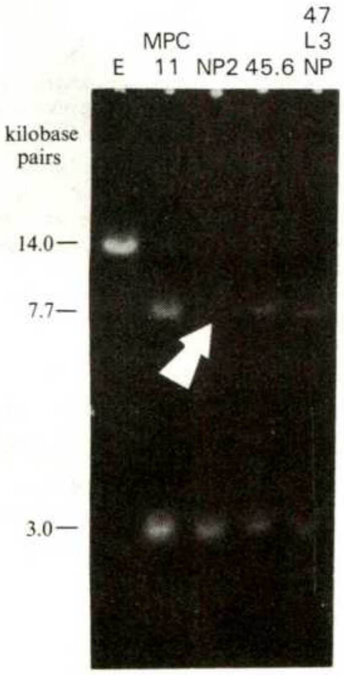

Fig. 2 The constant region containing fragments in DNA derived from embryonic light chain producing and non-producing cells. The DNA from 14-day-old BALB/c embryos (E), MPC-11 and NP2 myeloma tumours, and the 45.6 and B47L3NP (47L3NP) cell lines was restricted with *Bam*HI nuclease, and fractionated on an agarose gel, blotted onto nitrocellulose filters and hybridized to ^{32}P-labelled constant region probes as described previously[6,16]. The B47L3NP cell line was derived from 45.6 and no longer secretes a normal κ light chain. NP2 was originally derived from MPC-11 cells as a cell that does not secrete normal MPC-11 light chain, and has since been carried as a myeloma. The constant region probe hybridizes to one fragment of embryonic DNA (14.0 kilobase pairs) but two fragments of MPC-11 DNA (7.7 and 3.0 kilobase pairs). The arrow indicates the absence of the 7.7-kilobase pair fragment in NP2 DNA; we presume that this fragment encodes the MPC-11 normal κ light chain. The 3.0-kilobase pair *Bam*HI fragment derives from the MPC-11 fragment gene.

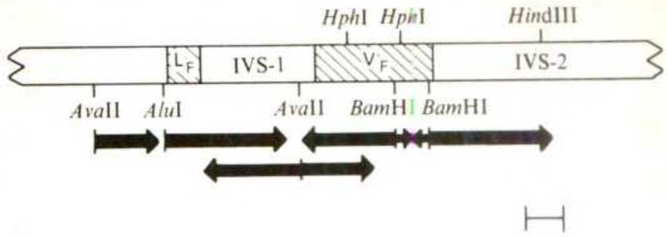

Fig. 3 The restriction fragments used to determine the nucleotide sequence of the MPC-11 fragment gene. A 20-kilobase pair constant region containing *Eco*RI fragment was cloned from MPC-11 DNA into Charon 4A (CH4A MPC-11 fragments) using the procedures described previously[6]. This phage contained a 5-kilobase pair *Hin*dIII fragment that hybridized to the 2.8-kilobase pair *Hin*dIII fragment derived from embryonic DNA that contained all of the κ J-region segments and 1.0 kilobase pairs of intervening sequence[8]. The 5-kilobase pair *Hin*dIII fragment was subcloned into pBR322 (pBR322–MPC-11 fragment) as previously described[8]. Three *Bam*HI fragments (1.8, 0.6 and 0.1 kilobase pairs) were excised from this plasmid and subjected to the nucleotide sequencing procedures described by Maxam and Gilbert[19]. The arrows indicate the orientation of the sequences determined and the approximate length of the sequence obtained from each restriction fragment. Scale bar: 0.1 kilobase pairs.

Preliminary restriction mapping and hybridization experiments indicated that the fragment gene did not contain any of the κ J-region segments (data not shown). That is, the cloned MPC-11 fragment gene did not hybridize to restriction fragments containing several κ J regions, and it did not contain the *Xba*I, *Sac*I or *Bgl*II restriction sites that are about 1,000 base pairs to the 3′ side of the κ J regions (refs 8, 9, and our unpublished results). Thus, it seemed that the MPC-11 fragment gene was formed by a recombination event that occurred about 1,400 base pairs from the κ constant region at a position that contained no J-region genes.

These conclusions could be confirmed and further details revealed by direct sequence determination. Accordingly, an appropriate *Hin*dIII fragment was sub-cloned from the hybrid phage into pBR322 and the sequence of the relevant region determined using the chemical degradation procedure of Maxam and Gilbert[19] according to the strategy outlined in Fig. 3. The complete sequence of the segment, translated in accordance with the genetic code is shown in Fig. 4.

The fact that the hydrophobic leader segment identified by our sequence was in agreement with the amino acid sequence determined on the fragment peptide[12,13], confirmed that we had cloned the correct gene. But the sequence also revealed that the aberrant recombination event that formed the fragment gene had brought in an unexpected, cryptic V-region coding sequence that was not expressed in the fragment polypeptide. In contrast to the situation in normal light-chain genes, the V-region sequence was not adjacent to a J segment.

The MPC-11 fragment gene was formed by an unusual recombination event

Normally a κ light-chain gene is formed by a recombination event that joins one of many κ variable-region genes to one of four J regions to create a gene with the structure indicated in Fig. 1 (normal κ gene). The structure of the MPC-11 fragment gene (Figs 1, 4) is unusual. As noted above, this gene has no J region and lacks part of its intervening sequence. It is, therefore, unlikely that this gene was formed by the site-specific recombination events that normally join V and J segments. Clearly

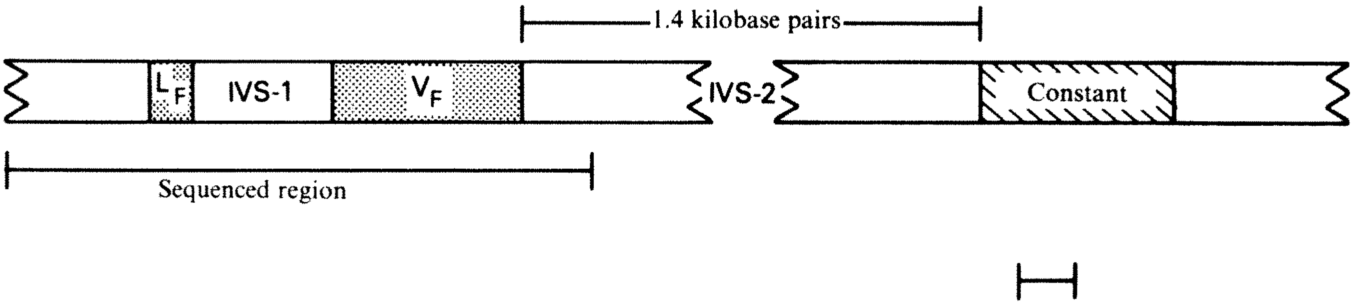

Fig. 4 The nucleotide sequence of the MPC-11 fragment gene. The nucleotide sequence was determined as described in Fig. 3. The portion of the gene that has been sequenced is indicated in the diagram. The leader corresponds to the first amino acid coding block and the variable region to the second coding block. The line over the sequence at the 3′ end of the variable region corresponds to the homologous segment found in several κ variable regions and the κ intervening sequence. Scale bar, 0.1 kilobase pairs.

one of the germ-line precursors of this gene must have been the germ-line κ constant-region gene. The fragment containing this gene has been cloned and much of its nucleotide sequence has been determined (refs 8, 9 and E. Max, unpublished data). The 3′ end of the MPC-11 fragment gene is identical in sequence to a region about 1.4 kilobase pairs 5′ from the K constant-region coding sequence. The other germ-line precursor of MPC-11 fragment gene must be the κ variable-region gene we see here in rearranged form (Fig. 4). From the amino acid translation of its nucleotide sequence, it is clear that this variable region gene is a member of the BALB/c $V_\kappa 21$ subgroup[20]. In fact, one of the proteins that falls into this subgroup but is derived from NZB mice ($V_\kappa 21$ C) has an amino acid sequence identical to the variable-region gene found in the MPC-11 fragment gene[21]. It seems that the MPC-11 fragment gene derived its variable region from one member of the BALB/c $V_\kappa 21$ subgroup.

How was this $V_\kappa 21$ variable region gene brought to within 1.4 kilobase pairs of the κ constant-region gene into a region that lacks J segments? We and others[8,9] have suggested that normal V/J gene recombination involves the recognition of a palindromic sequence ($\mathrm{CAC}^{\mathrm{A}}/_{\mathrm{T}}\mathrm{GTG}$) that is found immediately to the 5′ side of all J regions and to the 3′ side of all V regions thus far sequenced[7-9,22,23]. This V/J joining event does not take place by homologous recombination because these palindromic sequences are removed from both the variable and the J region during recombination. Homologous recombination would have preserved one copy of the homologous sequence. The sequence CACAGTG occurs only once between the J- and C-region genes and this is exactly at the site of the recombination event that formed the fragment gene (see below); the palindrome has been preserved in the MPC-11 fragment gene (Fig. 5).

Homology between the germ-line V- and C-region segments, in fact, extends beyond the V/J palindrome. As noted above, the 2.5-kilobase pair intervening sequence that separates the germ-line κ constant-region gene from the J-region segments contains the palindromic CACAGTG only once at a position about 1.4 kilobase pairs from the C-region gene. By aligning the recombined fragment gene sequence and the germline J/C segment, the point of divergence between the two sequences identifies the point of recombination. When the two sequences were aligned we realized that the recombination event must have taken place within 15 base pairs of the 3′ end of the $V_\kappa 21$C variable region gene at a point 1.4 kilobase pairs from the C-region gene. The sequence 5′-CACAGTGATA-3′ (or a sequence that differs by only a single nucleotide) has been found at the 3′ side of the three κ variable-region genes that have thus far been characterized[7,22]. This sequence is also found at the 3′ side of the variable-region gene found in the MPC-11 fragment gene and has also been located at the recombination site in the germ-line J/C fragment. Thus it seems that this fragment gene was formed by homologous recombination taking advantage of

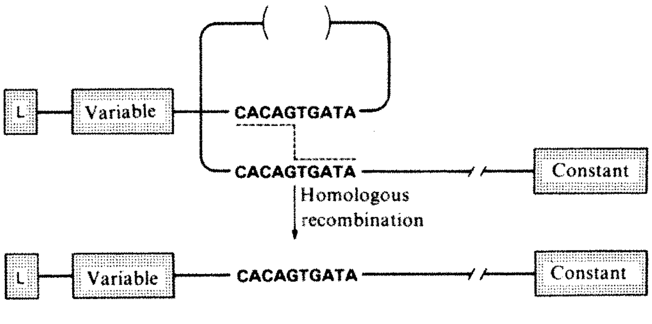

Fig. 5 A model for the homologous recombination event that formed the MPC-11 fragment gene. The data that suggest that this recombination is intrachromosomal and occurs on the non-rearranged chromosome will be presented elsewhere[25].

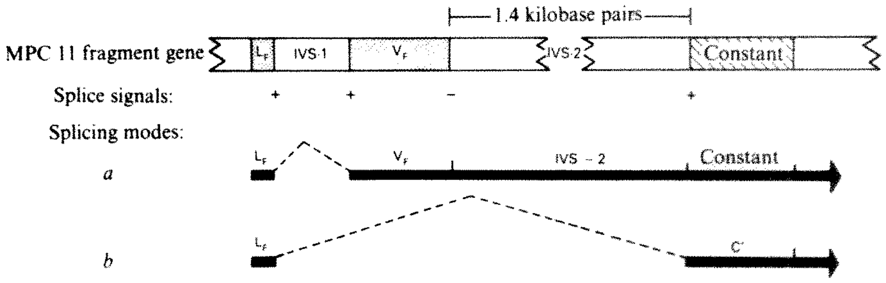
Fig. 6 The two possible splicing modes for RNA transcripts of the MPC-11 fragment gene. By analogy to a normal light-chain gene, the MPC-11 fragment gene must have three of the four normal splice signals (+); the missing splice signal (−) is due to the lack of a J-region gene. These three splice signals could be used in two different modes, to generate two different mRNAs.



sequences that are found on both the germ-line variable-region and κ constant-region/J-region intervening sequences. The event is shown diagrammatically in Fig. 5. This finding further suggests that this position might behave as a hot spot for aberrant light-chain gene formation. Indeed, similar genes may account for short mRNA species seen in a number of plasmacytoma cell lines[24].

Forbidden splicing of the precursor RNA is required to form the fragment peptide

A comparison of the structures of the fragment peptide and its corresponding gene presents something of a paradox in that the V-region sequence is present in the gene, but absent in the fragment polypeptide (Fig. 1). Normally, the V-region coding sequence is joined to a J segment that must contribute, in addition to a 13-codon long segment of DNA, a signal for RNA splicing so that the V/J segment can be joined to the constant-region sequence in the mature mRNA. In the case of the fragment gene, there is no J segment and therefore apparently no signal for joining V and C regions into a continuous mRNA. The theoretical splicing alternatives for the fragment gene transcript are shown diagrammatically in Fig. 6. A normal splice pair exists between the leader and V-region segments (Fig. 6*a*), but this splice would lead to the formation of leader-variable region peptides coupled to the translation product derived from the intervening sequence. No such peptides have been sought or found. The only way the mRNA corresponding to the fragment peptide could be formed is by joining the leader sequence directly to the constant-region sequence (Fig. 6*b*), skipping the normal leader/V splice. Formation of the fragment peptide must, therefore, involve not only an abnormal DNA recombination event but also an abnormal RNA splice.

Ordinarily an RNA splice that produces a mutant protein would be expected to be quite rare. Errors in splicing occurring in even a small proportion of splice segments would seem disadvantageous in a large gene containing many splice junctions since they would seriously reduce the yield of normal mRNA. Evidently some feature of the transcript must specify the splicing order, assuring that proper donors and acceptors are matched and joined. The fragment light chain gene evidently lacks this control. The simple notion that processing can only occur by splicing next to adjacent donors and acceptors is ruled out by this mutant gene, because the existence of the MPC-11 fragment proves that the constant region competes successfully with the variable region for joining to the leader sequence (fragment mRNAs constitute roughly 20% of normal mRNA levels[11]). On the other hand, it is possible to imagine that forbidden splices occur only when there is an imbalance between donors and acceptors. That is, perhaps a preference for adjacent donor/acceptor joining normally reduces the availability of unmatched partners and provides sufficient specificity to guide normal splicing. The difficulty with this notion, while accounting quite well for the events that occur in this mutant light-chain gene, is that it does not satisfactorily account for the variation in splicing observed in several viral mRNA precursors in which alternative splice pathways are frequently used[26–28].

Violation of allelic exclusion: activation of light-chain promoters

Kuehl and Scharff and their co-workers[10] concluded that, in contrast to the usual situation in antibody-producing cells, two genes must be active in the MPC-11 cell. The basis by which allelic exclusion is avoided in MPC-11 can be discerned by taking into account the structure of these genes and the recent observation by Perry *et al.*[24] that both constant-region genes, germ line and rearranged, are actively transcribed in many plasmacytomas. Most antibody-producing cells contain only one gene that has undergone V/J recombination so as to produce a normal light chain. Notwithstanding the fact that both genes are transcribed, only the properly rearranged one will produce a light-chain product. In the case of MPC-11, one normal light-chain gene has presumably been formed (Fig. 2), but the fragment gene, though abnormally formed, is actively transcribed and has sufficient elements of structure so as to produce a mutant light chain. This observation, taken together with those of Perry *et al.*[24], suggest to us that a higher order of control activates regions of a chromosome and that promoters that happen to fall within this region will be actively transcribed. For example, all V-region sequences might carry their own promoters which remain inactive until moved into an open region of a B-cell chromosome. Such a region obviously surrounds the C-region locus. The availability of many cloned V-region segments suggests that the existence of multiple, independent V-region promoters can be tested experimentally.

We thank Drs Michael Kuehl and Matthew Scharff for their gifts of cells used in these studies and for their helpful advice, Barbara Norman and Marion Nau for their participation in these studies and Terri Broderick for her assistance in the preparation of the manuscript.

Since the discovery of the intense bursts of γ rays by Klebesadel *et al.*[1] in 1973, little progress has been made in the identification of the sources of the bursts. The initial observations provided directions to several sources with sufficient accuracy to establish the approximate isotropic distribution of the sources[2], but not to provide a basis for association with any known objects. γ-ray burst astronomy entered a new phase in 1976 with the launch of Helios 2 and Solrad 11 containing the first experiments designed expressly for that purpose[3,4]. It then became possible to derive several error boxes that were very narrow in one dimension[3,5]. Using these data it was determined that the bursts are not associated with any type of object that has previously been recognized as a high energy astrophysical source—for example, X-ray sources. In 1978 a true interplanetary network of burst detectors was established with the launch of instruments on Pioneer Venus Orbiter[6], ISEE 3[7-9] and Venera 11 and 12[10,11]. With baseline separations that can exceed 1 AU, this network provides a basis for the location of the γ burst sources with an accuracy sufficient for optical identifications. We briefly describe here one of these instruments, a joint Berkeley/Los Alamos experiment on the ISEE 3 spacecraft, and present some initial results from that experiment. These results are currently being combined with those from the other experiments to obtain accurate burst locations to be reported elsewhere.

The University of California X-Ray Spectrometer[7] was originally designed to monitor solar emission continuously over the energy range 4.8–14 keV (1.2 cm^2 Xe/CO$_2$ proportional counter) and 12–1,264 keV (22 cm^2 NaI(Tl) scintillation detector). Additional electronic instrumentation, provided by the Los Alamos Scientific Laboratory (LASL), was later incorporated into the experiment to record the data from the intense, short lived γ-bursts at a very high rate and with good timing accuracy. This addition consisted of a data handling system that accepts photon counts from the higher energy PHA channels of the scintillation detector and monitors the counting rate for rapid increases that indicate either a γ burst or a solar flare. When a transient event of either origin occurs, high time resolution data are accumulated in a 36 kbit solid state memory for later transmission at a much reduced rate. During a γ burst the summed counting rate from six PHA channels covering the energy range 136–1,264 keV is recorded at the highest time resolution. For counting rates below 1,365 s^{-1} the accumulations are made over fixed intervals of 11.72 ms. At higher rates the operation automatically changes to a 'time-to-spill' mode wherein the resolution improves linearly with counting rate to an ultimate 0.24 ms, while the statistical significance of each accumulation remains constant. Six-channel energy spectra covering the same 136–1,264 keV range are accumulated simultaneously at a factor of 12 coarser time resolution. None of the bursts observed to date have challenged the counting rate capacity or ultimate time resolution of the instrument. (The extremely intense 5 March 1979 event was largely blocked by the spacecraft.)

The ISEE 3 spacecraft was launched in August 1978 and was placed into a heliocentric orbit so that it remains approximately on the Earth–Sun line (at the inner Lagrangian point) at a geocentric distance of 0.01 AU (5 light s). Between launch and 19 April 1979, 12 γ bursts, each confirmed by other instruments, have been detected and recorded by the UCB/LASL experiment. Bursts known to have occurred on 24 November 1978 and 13 January 1979 were missed due to incomplete (~90%) satellite tracking coverage. Virtually all spurious events that we have seen here were caused by statistical fluctuations in the background counting rate, as opposed to cosmic ray-induced noise or other non-statistical sources. These spurious events can occur as frequently as ~1 per day, depending on the trigger criteria in effect. As the criteria are selectable by command, we have sacrificed some sensitivity to eliminate the spurious events during most of the mission. Table 1 lists the dates and times of the confirmed γ burst events and their approximate peak intensities (defined as the highest 0.14 s wide time-history bin) and total integrated fluxes. The latter two quantities have not been corrected for detector efficiency or spacecraft shielding and scattering. Thus, the intensity entries in Table 1 are useful only as a very rough guide and as an indication of the sensitivity and dynamic range of the instrument. For example, it can be inferred that the sensitivity limit of the instrument is ~2 photons cm^{-2} ($\leq 10^{-6}$ erg cm^{-2}). Of course, more intense bursts might be missed because of their spectra, directions, or time histories.

Figure 1 shows samples of the temporal and spectral data obtained so far. We do not discuss the singular event of 5 March 1979 as it has been treated extensively elsewhere (see, for example, refs 12–14). The 4 November 1978 event (Fig. 1), though unusually intense, exhibits most of the classical γ-burst characteristics such as fast rise and fall times, multiple peaked structure, and near background rates between peaks. As can be seen qualitatively in Fig. 1*Ab*, a χ^2 analysis of the spectral information showed no evidence for spectral variability, to within the statistical uncertainties. In view of the complex time history, this spectral constancy above 130 keV seems surprising, and must bear critically on the emission mechanism for this burst. The Apollo 16 γ burst[15-17] and others[4] also featured complex structures combined with no detectable spectral variability. Finally, an intriguing pattern can be seen in the time history of this event. Namely, the bulk of the emission is concentrated in three double peaks, with ~9 s between doublets and with the components of the doublets separated in time by amounts proportional to their intensities. While we make no claims regarding the significance of this possible pattern, we point it out as the type of information that can be extracted from continuous, high time resolution γ-burst data records. Clearly, the short-lived nature of the bursts means that a collection of

Table 1 γ bursts observed by the UCB/LASL experiment on ISEE 3

Date	Time (UT)	Intensity (photons cm^{-2} s^{-1})	Flux (photons cm^{-2})

* Data were lost during the intense part of the burst.

0028-0836/80/340784—03$01.00

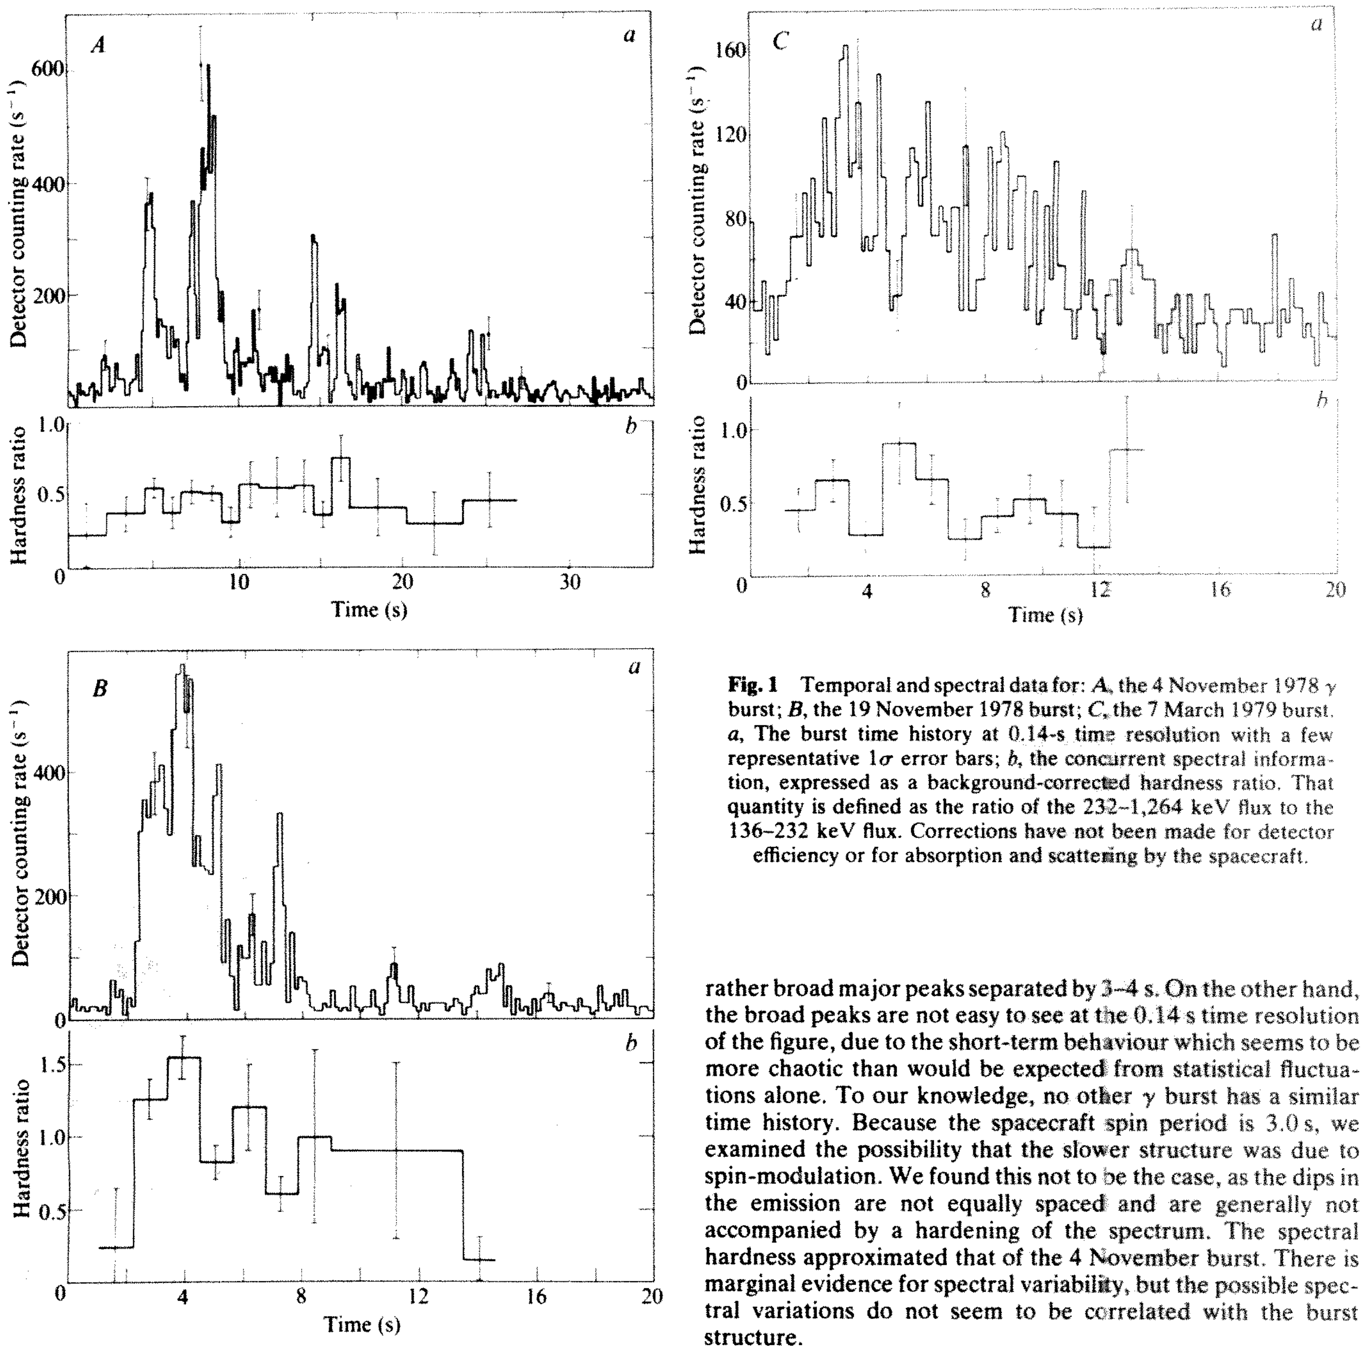

Fig. 1 Temporal and spectral data for: *A*, the 4 November 1978 γ burst; *B*, the 19 November 1978 burst; *C*, the 7 March 1979 burst. *a*, The burst time history at 0.14-s time resolution with a few representative 1σ error bars; *b*, the concurrent spectral information, expressed as a background-corrected hardness ratio. That quantity is defined as the ratio of the 232–1,264 keV flux to the 136–232 keV flux. Corrections have not been made for detector efficiency or for absorption and scattering by the spacecraft.

such information is needed before the significance of this or other possible patterns can be assessed.

The 19 November 1978 burst (Fig. 1*B*) was also one of the most intense ever recorded. As pointed out by Evans *et al.*[6], its time history is atypical in that after the initial sharp rise the counting rate remained at a very high level for an unusually long time. Alternatively, the initial 3 s of the burst might appear to consist of a blend of several sharp peaks that are atypically close together. Also, the average spectrum of the burst is unusually hard, as can be seen by comparing Fig. 1*B* with Fig. 1*A* and *C*. Finally, there is clear evidence for spectral variability correlated with the burst structure. Although the counting statistics do not allow a precise correlation, there is no doubt that the sharp spikes seen in Fig. 1*Aa* at ~5 and at ~7 s have softer spectra than the early part of the burst, and this is probably true also for the spikes at 11 and 14 s. Of course, the spectral hardness may simply be decreasing monotonically.

The 7 March 1979 burst (Fig. 1*C*), though not particularly intense at any given instant, had a fairly large total flux and an unusual time history. It is possible to discern in Fig. 1*Ca* several rather broad major peaks separated by 3–4 s. On the other hand, the broad peaks are not easy to see at the 0.14 s time resolution of the figure, due to the short-term behaviour which seems to be more chaotic than would be expected from statistical fluctuations alone. To our knowledge, no other γ burst has a similar time history. Because the spacecraft spin period is 3.0 s, we examined the possibility that the slower structure was due to spin-modulation. We found this not to be the case, as the dips in the emission are not equally spaced and are generally not accompanied by a hardening of the spectrum. The spectral hardness approximated that of the 4 November burst. There is marginal evidence for spectral variability, but the possible spectral variations do not seem to be correlated with the burst structure.

To obtain a more quantitative comparison of the burst time histories, a Fourier analysis program was carried out. The methods used were not entirely the standard techniques, but have been used or discussed previously[14,18,19]. Each time series consisted of 35.86 s of data in 3,060 time bins each 11.72 ms wide. The data were subjected only to linear detrending; no grouping or smoothing was used. The spectra were examined up to the Nyquist frequency of 42.67 Hz, but only te region below 8 Hz is shown in Fig. 2, since there is little significant higher frequency information. The results generally confirm our previous qualitative statements on the burst time histories, and also point out some less obvious features. The power spectra of the two November 1978 events both show significant peaks in the 0.1–1 Hz region, indicating a degree of regularity in their time histories. One curious pattern that was pointed out above in the 4 November 1978 burst, probably produced the spectral peak at 0.1 Hz. The 0.3 Hz spectral peak is most likely due to the ~3 s separation of the spikes seen in Fig. 1*A* at 2, 5, 8, 11, and 14 s. Also, further examination of the 19 November time history shows that the several count rate peaks are separated by ~1.1 s or a multiple thereof, giving rise to the 0.9 Hz spectral peak. The very broad peak below 0.3 Hz reflects the duration of the main part of the γ burst, but may also be due in part to the widely separated counting spikes near the end of the burst. On the other hand, the power spectrum of the 7 March 1979 event approximates that of white noise due to counting fluctuations, except for the low-frequency power below ~0.5 Hz. Thus, the chaotic appearance of the 7 March time history (Fig. 1*Ca*) is either not statistically significant, or contributes only a small amount of power spread approximately uniformly over a broad frequency band. The spiky appearance of this spectrum is due mainly to the greatly magnified vertical scale relative to the other power spectra shown. Of the three bursts, only the 19 November event clearly shows excess power at higher frequencies, even beyond 8 Hz. This high frequency power undoubtedly results from the sharp counting rate transitions evident, though not optimally displayed, in Fig. 1*B*.

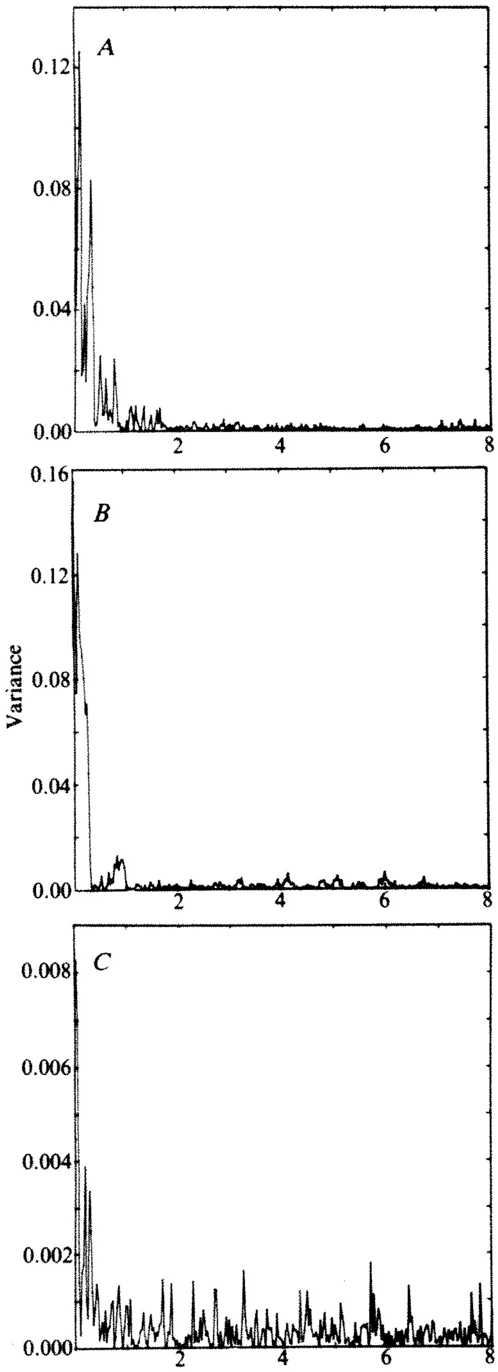

Fig. 2 Power spectra for the three γ-ray bursts shown in Fig. 1. *A*, 4 November 1978; *B*, 19 November 1978; *C*, 7 March 1979. The ordinate is variance per Fourier harmonic. Each time series consisted of 3,060 accumulations at time intervals of 11.72 ms for a total time of 35.86 s. The data have been detrended before analysis in each case. No grouping or smoothing has been used. Only the lower portion of the frequency spectrum, up to 8 Hz, is shown (the Nyquist frequency is 42.67 Hz).

This temporal and spectral information from the UCB/LASL γ burst experiment on ISEE 3 indicates that the three bursts studied had comparable integrated fluxes, but showed significant differences in their power spectra as well as in the qualitative appearances of their time histories. There are also important differences in their average energy spectra, and in their degree of spectral variability. Thus, the present examples show that the γ-burst phenomenon is diverse, and that the sources of the bursts constitute either a very loose class or possibly more than one class of objects. This fact must be taken into account in analyses, for example, the interpretation of log N/log S curves, which assume a 'standard' γ burst object.

We thank Earl Tech and other members of the data analysis section of the LASL high altitude physics group for assistance, and Bill Aiello and Henry Primbsch for their work on the experiment hardware. This research was supported by NASA under contract NAS5-22307 and by the US Department of Energy.

The results of hard X-ray observations of Sco X-1 by HEAO 1 and OSO 7 are reported here. We have found that the X-ray spectrum between 20 and 70 keV is consistent with thermal bremsstrahlung from a hot plasma[1] at a temperature of 5.15 ± 0.05 keV. Observations with the instruments of HEAO 1 on 6–7 September 1978, and with those of OSO 7 during 1972, have not confirmed reports[2] that the bremsstrahlung spectrum is accompanied by an extra component at energies greater than 40 keV—indeed, our observations yield a two-standard deviation upper limit to the flux in this region of 6.4×10^{-6} photons cm^{-2} s^{-1} keV^{-1}.

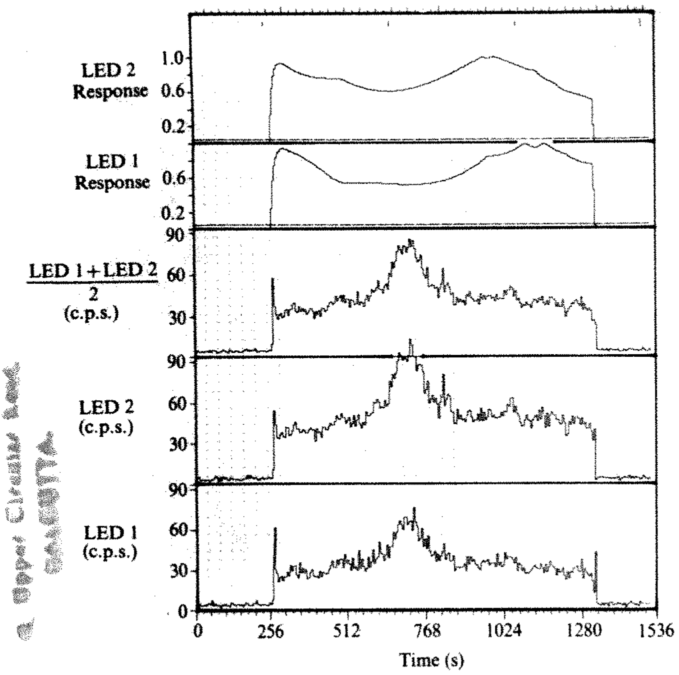

Fig. 1 The aspect-corrected counting rates for the two low energy detectors (LED) aboard HEAO 1 during one 17-min exposure to Sco X-1 on 7 September 1978 covering the energy range 20–220 keV. Also shown is the mean of the two sets of rates and the collimator response to Sco X-1 for each detector. Time 0.000 corresponds to 1 h 8 min 22 s UT. c.p.s., counts per second.

The UCSD/MIT high energy X-ray and low energy γ-ray instrument[3] aboard HEAO 1 consisted of seven NaI(Tl)/CsI(Na) phoswich scintillation detectors covering various energy ranges from 10 keV to 10 MeV that were actively shielded by 4–10 cm of CsI. Two of these detectors, of $\approx 100\ \mathrm{cm}^2$ each, sensitive over the range 20–220 keV, were collimated by Sn/Cu slats to 1.5° × 20° FWHM. An observation of Sco X-1 was conducted on 6–7 September 1978 by alternating between source and background regions separated by 2° with 17-min segments for each. This length of time was chosen to sample uniformly, on the average, regions of different particle-induced background due to varying cosmic-ray cutoff throughout the orbit. In this way an important systematic uncertainty in background subtraction could be minimized.

The HEAO 1 observation provided 17 separate exposures to Sco X-1; of these, one displayed pronounced variability, that is an X-ray flare which is shown in Fig. 1. In addition to the 2-min flaring by a factor of ≈ 2, this exposure differs from the others by having about twice the average intensity off the flare of the others. As spectral shape may vary with intensity[1], the exposure containing the flare was not included in the accumulation of the mean spectrum. It was, instead, studied in detail for spectral changes during this period of both enhanced intensity and activity.

The net counts spectrum was fitted by folding various analytical models through the instrumental response, which included photopeak efficiency, non-linear pulse height to energy conversion, resolution, and K-escape effects, to form a model counts spectrum. This was then compared with the net counts spectrum, and best-fit parameters were determined by minimizing χ^2. Spectrum dependent efficiencies were calculated and divided into the net counts spectrum to form the inferred mean incident photon spectrum, which is shown in Fig. 2.

The mean spectrum was fit by both a thermal bremsstrahlung model, including a Gaunt factor, and the same model modified to account for Compton interactions in a hot, fully ionized cloud surrounding the X-ray source[4]. The resultant best-fit temperatures were 5.15 ± 0.05 keV and 3.24 ± 0.05 keV, respectively, and the latter fit was insensitive to optical depth to electron scattering in the range $\tau = 5$–20. The best-fit temperatures are in agreement with earlier results at lower energies[1,4]. The inferred mean incident flux and the best-fit ($kT = 5.15$ keV) thermal bremsstrahlung model are shown in Fig. 2 together with the inferred flux from the flare alone. An attempt was then made to test for the presence of a high energy excess in the mean spectrum with respect to either thermal model. Assuming a power law form for the excess ($\mathrm{d}N/\mathrm{d}E \propto E^{-1}$), none was detected at 95% confidence and the 2σ upper limit to any excess is 6.4×10^{-6} photons $\mathrm{cm}^{-2}\ \mathrm{s}^{-1}\ \mathrm{keV}^{-1}$, or 0.56 μJy, in the range 72–222 keV.

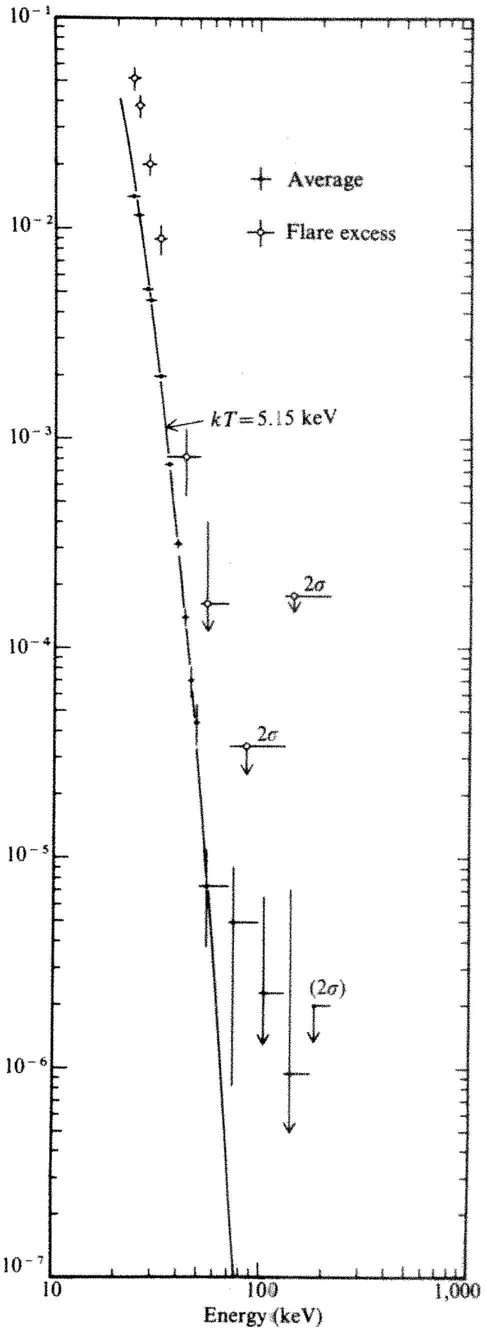

Fig. 2 The inferred incident spectrum of Sco X-1 from 20 to 220 keV from the observations by the HEAO 1 satellite beginning on 6 September 1978. ●, The flux averaged over the entire 12-h observation with the exception of one 17-min interval that contained a flare of 2-min duration (see Fig. 1). ○, The flux from the flare alone with the remainder of the 17-min exposure used as background. All error bars are 1σ unless otherwise noted.

The study of the flare exposure was divided into the flare alone (from 655 to 778 s in Fig. 1) and the remainder of the exposure (from 256 to 655 s and 778 to 1,331 s in Fig. 1). The spectrum of the flare alone, which is also shown in Fig. 2, is the net flux above the remainder of this exposure, and can be compared to the mean spectrum of the other exposures to determine if the same process could have caused both spectra. Acceptable fits to the flare alone are possible with best-fit values for kT of 6.1 ± 0.5 keV and 3.5 ± 0.5 keV for the two thermal models, respectively, or with a power law index of 6.6 ± 0.2. The narrow energy range over which the flare was observed, however, precludes the selection of one model over another, but the data are consistent with a thermal origin for the flare. No evidence for a high energy excess above the thermal model was seen in the flare, with the 2σ upper limit being 1.4×10^{-4} photons cm^{-2} s^{-1} keV^{-1}, or 11 μJy, from 52 to 222 keV.

For the remainder of the flare exposure, the best-fit values for kT of this enhanced activity were 4.9 ± 0.2 and 3.1 ± 0.1 keV, respectively, for the two thermal models mentioned above and the 2σ upper limit to any excess flux was 3.4×10^{-5} photons cm^{-2} s^{-1} keV^{-1}, or 3.1 μJy, from 72 to 222 keV.

The UCSD OSO 7 SKYMAP[5] contains 280 s of live time to Sco X-1 from scanning in mid (May–June) and late (November–December) 1972. These data come from a 64 cm^2 NaI(Tl) detector sensitive from 5 to 500 keV, that was actively shielded by CsI(Na) and had a field of view of 6.5° FWHM. This observation differs from that of HEAO 1 in that data were accumulated over two 18-day periods separated by six months, and thus represents more of a long-term average compared with the brief observation by HEAO 1.

The OSO 7 observation of Sco X-1 was fitted in a similar manner. The fitting process yielded a best-fit temperature of 6.5 ± 0.5 keV for the thermal bremsstrahlung model and 3.2 ± 0.2 keV for the Compton modified thermal model. The ≈ 1.5 keV higher temperature as compared to the HEAO 1 result is consistent with the range of temperatures reported over the past several years for Sco X-1 (ref. 1). As in the HEAO 1 measurements, no excess above the thermal spectrum was observed, and the 2σ upper limit to the flux from 60 to 208 keV was 6.2×10^{-5} photons cm^{-2} s^{-1} keV^{-1}, or 5.4 μJy.

Over the past decade and a half, only four observations claim 3σ or greater excesses above a thermal model with fluxes of a few 10^{-4} photons cm^{-2} s^{-1} keV^{-1} in the 50–100 keV range[6-9]. All four of these have systematic uncertainties, such as possible source confusion, varying background counting rates, and broad instrumental resolution, that reduce the significance of their results. If, indeed, this excess is time variable, however, the magnitude of the change must be more than an order of magnitude at 100 keV.

Models of the Sco X-1 binary system generally include mass flow onto a compact object surrounded by an accretion disk. Both thermal bremsstrahlung[10] and power law[11] spectral shapes have been predicted for the X-ray data. The observed temperature for thermal models will not be a true measure of the plasma temperature as various proposed processes might alter the spectral shape. A high-temperature plasma ($kT \approx 75$ keV) could be degraded by Compton interactions to form a spectrum with a lower measured temperature[12]. On the other hand, an intense soft X-ray flux ($kT \approx 3$ keV) impinging on the plasma material could undergo Compton scattering to higher energies with either a resultant higher measured temperature[4] or possibly the appearance of a high energy excess[10] or both. The absence of an observed high energy excess indicates that the mean free path for inverse Compton scattering must be either so low that the scattered flux is below instrument sensitivity, or so high that the reprocessed spectrum resembles an exponential of higher measured temperature. A third possibility is that kT is not high enough to scatter photons to greater than 40 keV.

The nature of the collapsed object powering the X-ray emission in Sco X-1 is uncertain. The minimum mean luminosity of this observation is 1.3×10^{36} erg s^{-1}, using 270 pc as a minimum distance[13]. This places it near the limiting luminosity for spherical accretion onto a white dwarf[14]. Add to this the factor of 5 overall increase in the flare, and it seems quite unlikely that spherical accretion onto a white dwarf could be responsible. On the other hand, accretion onto a neutron star could easily generate such luminosity. Non-spherical accretion onto white dwarfs, however, can also generate luminosities in the 10^{37} erg s^{-1} range that may be observable[1] (N. D. Kylafis, personal communication), and, therefore, allow the white dwarf hypothesis.

Solar-flare produced ^{3}He in lunar samples

M. N. Rao & T. R. Venkatesan

Physical Research Laboratory, Ahmedabad 380 009, India

Lunar rocks and soils undergo long-term irradiation by solar and galactic cosmic rays (SCR and GCR) leading to compositionally-distinct spallation spectra for noble gases[1,2] and leaving behind fossil records characteristic of different irradiation features. Because the SCR effects are restricted to the first few millimetres of rocks and soils in contrast to GCR, various studies based on solar flare tracks[3,4], thermoluminescence[5], and radionuclides[3,6] over the past decade have aimed to decipher these fossil records bearing the imprints of the low (SCR) and high (GCR) energy irradiation phenomena. These studies have greatly helped our understanding of the energy spectra and fluxes of charged particles streaming out of the Sun. We have already reported quantitative studies, aimed at isolating the SCR and GCR produced Ne and Ar isotopes in several lunar soils and rocks[1,2] and have calculated their solar flare exposure ages which agree with the 'surface' exposure ages based on ^{26}Al and particle track studies[3]. We describe here, for the first time, using ^{3}He in samples from three different depths of lunar rocks, a method for deducing the absolute SCR (flare) proton fluxes in the past few million years which compare favourably with those derived from ^{26}Al and ^{53}Mn studies[3,6] of other lunar samples.

When a large crater is formed on the surface of the Moon, deeply buried rocks are excavated to the surface. During such shock events, rocks could be either completely or partially degassed of their noble gas. The helium in a heavily shocked rock is considered to have completely degassed. As the earlier ^{3}He history in this rock was completely erased out at the time it was brought to the lunar surface by the shock event, its subsequent irradiation on the lunar surface results in equal exposure times to SCR and GCR. If $m(^{3}\mathrm{He})$ is the measured spallogenic ^{3}He content per g of the rock with a simple history, we have

$$m(^3\text{He}) = (P_g + P_s)T$$

where P_g and P_s are the GCR and SCR ^{3}He production rates respectively. Choosing a deep interior sample (R3) from a rock, such that $P_s = 0$, means that $m(^3\text{He}) = P_g T$. As P_g is known, T for R3 can be calculated. Samples close to the top surface (R1) will contain a mixture of SCR, GCR, SW (solar wind) components of ^{3}He and intermediate samples (R2) deeper than 3–4 mm from the top surface will contain only GCR and SCR produced ^{3}He. The ^{3}He in R1 sample is corrected for solar wind contribution using the measured ^{4}He content and a ^{3}He/^{4}He ratio of 3.6×10^{-4} as found in several bulk lunar soils[7]. The corrected ^{3}He in R1 represents the SCR + GCR production.

In the case of rocks with a simple history, the SCR proton flux is deduced as follows. Assuming (1) T (GCR) = T (SCR) and (2) the diffusion losses, if any, are same for both GCR and SCR produced ^{3}He, we can calculate T (GCR) from R3 which is equal to $m(^3\text{He})/P_g$ as shown above. T will decrease if there is any gas loss and irrespective of such losses, $m(^3\text{He})/T$ will give the true production rate. Using the calculated T, we compute the total SCR + GCR production rates, $(P_s + P_g = m(^3\text{He})/T)$ for other samples (R1 and R2) and plot these values against depth as shown in Fig. 1. Then, using assumed SCR fluxes and the known GCR flux, we calculate the combined production profiles for various depths in the rock and match the production profiles with the data points. The SCR parameters that fit best to the data points describe quantitatively the SCR flux to which this rock was exposed.

We measured He, Ne, Ar contents in six samples from known depths of two well documented rocks 61016 and 64435. Using the analytical methods described elsewhere[2] we could resolve quantitatively the SW, SCR and GCR components for the ^{21}Ne and ^{38}Ar in these samples. Using the production rates of Hohenberg *et al.*[8], we calculated their SCR and GCR ages (Table 1) and the results obtained by both ^{21}Ne and ^{38}Ar methods show agreement within experimental errors. The measured ^{40}Ar contents are much less compared with the expected ^{40}Ar from ^{40}K decay during 3,100–3,400 Myr after solidification[9]. We attribute the loss of ^{40}Ar (about 90%) to the shock event at the time of South Ray crater formation that excavated the rocks from lunar interior. During the same event more than 99% of the radiogenic ^{4}He was also lost. Thus the assumption that T (GCR = T (SCR) can be applied to the rock samples from 61016 and 64435.

Table 1 GCR and SCR ages of lunar rocks

Rock	^{21}Ne age (Myr) SCR	^{21}Ne age (Myr) GCR	^{38}Ar age (Myr) SCR	^{38}Ar age (Myr) GCR
61016*	1.3 ± 0.2	4.0 ± 0.3	1.7 ± 0.2	3.7 ± 0.3
64435	0.6 ± 0.1	1.2 ± 0.2	0.8 ± 0.2	1.4 ± 0.2

R1, R2 and R3 samples of 61016 are taken from 0.3–2 mm; 4–7 mm and 16–18 mm depths whereas another set of R1, R2 and R3 samples of 64435 are taken from 0.2–1.5 mm; 4.5–7.5 mm and 7.5–9.0 mm depths, respectively.

* See ref. 2.

As pointed out earlier, the T (GCR) obtained from $m(^3\text{He})/P_g$ represents the apparent age of the rock and it will be lower than the true value if there are ^{3}He losses. Helium may sometimes be lost by diffusion and this source of gas loss is discussed below. To study the depth dependence of ^{3}He diffusion, we consider the R2 and R3 results of rock 64435. The observed ^{3}He contents are $(0.44 \pm 0.02) \times 10^{-8}$ and $(0.43 \pm 0.03) \times 10^{-8}$ cm^3 STP g^{-1} respectively and they do not show much variation as a function of depth. Further, a study of ^{3}He/^{21}Ne and ^{3}He/^{38}Ar ratios in these samples may throw light on the diffusion pattern of ^{3}He relative to other cosmogenic isotopes of Ne and Ar. The ratio of the ^{3}He (SCR + GCR)/^{21}Ne (SCR + GCR) in different samples of rocks 61016 and 64435 range from 3.5 to 4.0. The near-constancy of the observed ^{3}He/^{21}Ne ratios suggest that the depth-dependent diffusion effects are not significant in these samples. Similar observations are made by studying ^{3}He/^{38}Ar ratios in these samples from rocks 61016 and 64435. In this context, note that ^{3}He losses were observed in some feldspar-bearing lunar[10] rocks and meteorites[11]. It is not clear whether these losses are due to diffusion or to shock effects. For example, Heymann *et al.*[11] showed that in meteorites such as Shergotty and Zagami, even though feldspar-rich, the ^{3}He was almost quantitatively retained. In Sera de Mage also, no loss of ^{3}He in big feldspar grains was observed. This suggests that shock effects have an important role in affecting ^{3}He losses in some of these samples. However, even if there are minor diffusion losses, this method holds good as long as the losses are not depth-dependent.

As we do not have the deepest samples where P_s is almost zero, we adopt the following procedure to deduce the SCR proton fluxes from our studies. We calculate the theoretical ^{3}He production profile as a function of depth for combined SCR + GCR production per Myr, using the Reedy–Arnold model[12] and a SCR proton flux of J ($E > 10$ MeV) = 70 p cm^{-2} s^{-1} and $R_0 =$ 100 MV (ref. 6) and a GCR flux of 1.7 p cm^{-2} s^{-1}. The production cross-sections are taken from ref. 13. Figure 1*a* represents this theoretical profile. Using the SCR + GCR combined production rate for the 61016–R3 sample at a depth of 5.1 g cm^{-2}, we calculate T (GCR) for 61016 to be (1.6 ± 0.1) Myr. This agrees with the SCR ages based on ^{21}Ne and ^{38}Ar (see Table 1) and the surface age of 1.5 Myr based on particle track studies[3]. Then we use this T (GCR) to find the $m(^3\text{He})/T$ for the R1 sample of 61016. The observed R3 value is normalized so as to fall on curves *a* or *b* in Fig. 1 and the other data points are scaled accordingly. These values are plotted in Fig. 1. Similarly in case of 64435–R3 sample, using the (SCR + GCR) ^{3}He production rate at the corresponding depth, we calculate the T (GCR) for rock 64435 which turns out to be (0.55 ± 0.10) Myr. This agrees with the SCR ages based on ^{21}Ne and ^{38}Ar within the error limits (see Table 1). We plot the $m(^3\text{He})/T$ values for the R2 and R1 samples in Fig. 1 as a function of depth as described above. Within the error limits, all the points of rocks 61016 and 64435 seem to fit curve Fig. 1*a*.

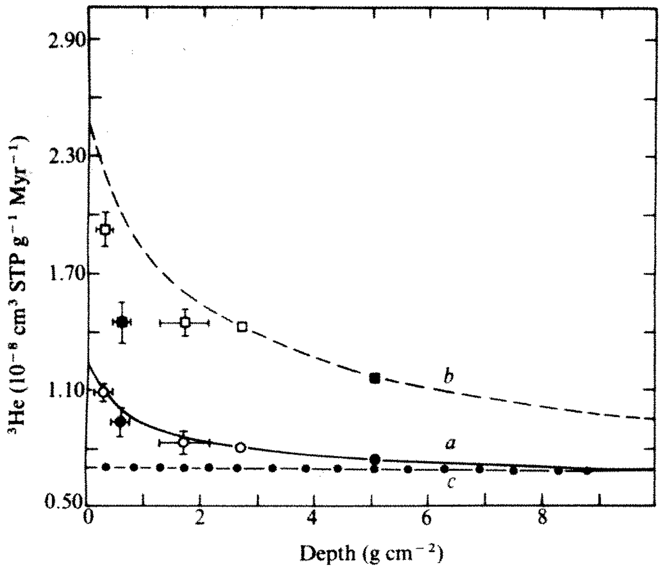

Fig. 1 Production profiles of (SCR + GCR) ^{3}He as a function of depth in lunar rocks 64435 (□, ○) and 61016 (■, ●). The deepest points (R3) of 64435 (at 2.7 g cm^{-2}) and of 61016 (at 5.1 g cm^{-2}) are normalized to fall on curves *a* or *b*. The other R1 and R2 points are scaled accordingly. The normalizing points are shown without error bars. The solid curve *a* is generated from the SCR proton flux given by Kohl *et al.*[6] and the dashed curve *b* is generated from the SCR flux given by Bhandari *et al.*[3]. Curve *c* represents the depth profile[12] for GCR production of ^{3}He using the particle flux mentioned for proton energies above 1 GeV. ^{3}He in R2 sample of 61016 could not be measured due to power failure.

We can then check how these data points, using the same procedure, fit to a different SCR proton flux of J ($E > 10$ MeV) = 125 p cm^{-2} s^{-1} and $R_0 = 150$ MV, deduced by Bhandari *et al.*[3] for the same rocks based on ^{26}Al studies. The combined (SCR + GCR) ^{3}He production profile calculated for this SCR flux is shown by Fig. 1*b*. The T (SCR) calculated for this flux for 61016 turns out to be 1.0 Myr and for 64435, 0.3 Myr which are smaller than the surface exposure ages of 1.5 Myr and 0.5 Myr respectively, deduced by track studies[3]. Using the normalization procedure, for R3 points of rocks 61016 and 64435, we calculate the other R1 and R2 points with the new (SCR + GCR) ^{3}He production rates and plot the points as a function of depth in Fig. 1.

The fit of the data points to curve *b* is clearly less satisfactory than to curve *a*. This shows that the ^{3}He production profile generated using a SCR proton flux of J ($E > 10$ MeV) = 70 p cm^{-2} s^{-1} and $R_0 = 100$ MV (ref. 6) seems to fit the data points better. The erosion, solid angle and so on, corrections for these samples are expected to be minor. Further experiments are in progress using well-documented samples to understand this discrepancy in the fluxes as well as to find the suitability of this method to determine the solar flare exposure ages of lunar samples in time scales >10 Myr where the radioactivity methods using ^{26}Al and ^{53}Mn are inapplicable because of saturation effects.

We thank Professors D. Lal and N. Bhandari for valuable discussions during this work which is carried out under Lunar Science Proposal Nos. SL-9191 and SL-9095, and J. T. Padia for assistance.

Excitation of the Na D-doublet of the nightglow

D. R. Bates & P. C. Ojha

Department of Applied Mathematics and Theoretical Physics,
Queen's University Belfast, Belfast BT7 1NN, UK

We infer from the absolute intensity of the nocturnal D-doublet emission, the abundance of free Na and other relevant information that there is very little possibility of an alternative to Chapman's theory[1] that the excited Na atoms involved are released by NaO–O collisions. The nature of the collision process is discussed here. We point out that a remarkably high branching ratio for the reaction path leading to excited (rather than normal) sodium is necessary. A high branching ratio is explained by considering the symmetry properties of the correlated electronic states.

In 1939 Chapman[1] proposed the oxidation–reduction cycle:

$$\mathrm{Na + O_3} \xrightarrow{k_1} \mathrm{NaO + O_2} \qquad (1)$$

$$\mathrm{NaO + O}\begin{cases} \xrightarrow{fk_2} \mathrm{Na(^2P) + O_2} & (2a)\\ \xrightarrow[(1-f)k_2]{} \mathrm{Na(^2S) + O_2} & (2b)\end{cases}$$

Thermochemical studies[2] have removed doubts over whether process (2a) is exothermic.

The case against the possibility of invoking another chemiluminescent cycle may be seen to be virtually conclusive: thus rocket measurements[3] show that the emission comes from near the 90-km level and lidar measurements[4] show that the number density n(Na) in this region is around 4×10^3 cm^{-3}, so that even with a rate coefficient as fast as 2.5×10^{-10} cm^3 s^{-1} and a 10-km thick layer, the typical nightglow intensity[5] of 100 R would necessitate the number density of the reactant being some 1×10^8 cm^{-3}; ozone is almost certainly the only atmospheric constituent which readily reacts with or excites atomic sodium and which may have such a high nocturnal abundance near 90 km; and, if it is accepted that process (1) must be involved, then so almost certainly must process (2) because of the lack of another reducing process which meets the double requirement of being at least as effective in the atmospheric region concerned and of being sufficiently exothermic. Furthermore, interferometric measurements on D-line profiles[6] reveal that the Na(^{2}P) atoms have a kinetic energy of 0.046 eV which suggests that they arise from a chemical process like process (2a) rather than from dissociative recombination involving NaO$^+$ or NaO$_2^+$ produced from incoming Na$^+$ ions as has been conjectured[7].

An understanding of the nature of processes (1) and (2) came when Kolb and Elgin[8] suggested that both are of the electron-jump type. From the ionization potentials of Na and NaO and the electron affinities of O$_3$ and O they calculated the crossing distances r_X for the {Na–O$_3$} : {Na$^+$–O$_3^-$} and {NaO–O} : {NaO$^+$–O$^-$} covalent–ionic potential pairs. Assuming the cross-sections to be πr_X^2, they deduced the rate coefficients. The values of r_X are 4.5 Å and 2.3 Å respectively (the latter being smaller than originally[8] obtained due to the use of what should be a better[9] estimate of the ionization potential of NaO); the corresponding rate coefficients at 200 K are

$$k_1 = 3.4 \times 10^{-10}\ \mathrm{cm^3\ s^{-1}}, \qquad k_2 = 1.0 \times 10^{-10}\ \mathrm{cm^3\ s^{-1}} \qquad (3)$$

Note, however, that processes (1) and (2) are not of the class typified by

$$\mathrm{K + I_2 \rightarrow KI + I} \qquad (4)$$

to which the electron-jump model is commonly applied[10,11]. A key feature of process (4) is that the I$_2^-$ formed in a vertical transition at the crossing is so highly excited vibrationally that it dissociates readily leaving the I$^-$ and K$^+$ ions bound together by their Coulomb attraction and leaving the I atom free. In the case of processes (1) and (2), there is little vibrational excitation in a vertical transition and, moreover, the product molecules are not produced directly from oppositely charged fragments. The mechanism is that, while the reactants are on the ionic potential surface, they make a hard collision which excites internal energy and thereby makes an exothermic channel more likely to be followed than reversal through the entrance channel. For process (1), the fission of the collision complex occurs along {NaO$^+$–O$_2^-$} : {NaO–O$_2$} and for process (2), along {Na$^+$–O$_2^-$} : {Na–O$_2$}, where the {NaO$^+$–O$_2^-$} and {Na$^+$–O$_2^-$} potential surfaces are for the same electronic states as the {Na$^+$–O$_3^-$} and {NaO$^+$–O$^-$} potential surfaces, respectively.

Oxidation and reduction proceeds rapidly enough to maintain chemical equilibrium between Na and NaO and it is convenient to express the D-doublet photon emission rate as

$$E(5{,}893) = fk_1 n(\mathrm{Na}) n(\mathrm{O_3}) \qquad (5)$$

0028–0836/80/340790—02$01.00

Table 1 Symmetry properties of the Na–O correlated molecular states

Row	Fragments	Correlated molecular states*
(*a*)	$NaO(X^2\Pi)+O(^3P)$	$^2A'(3), ^4A'(3), ^2A''(3), ^4A''(3)$
(*b*)	$NaO^+(X^3\Sigma^-)+O^-(^2P)$	$^2A'(1), ^4A'(1), ^2A''(2), ^4A''(2)$
(*c*)	$Na^+(^1S)+O_2^-(X^2\Pi_g)$	$^2A'(1), ^2A''(1)$
(*d*)†	$Na^+(^1S)+O_2^-(^4\Sigma_g^+, ^4\Delta_g)$	$^4A'(2), ^4A''(1)$
(*e*)	$Na(^2S)+O_2(X^3\Sigma_g^-)$	$^2A''(1), ^4A''(1)$
(*f*)	$Na(^2S)+O_2(a^1\Delta_g)$	$^2A'(1), ^2A''(1)$
(*g*)	$Na(^2S)+O_2(b^1\Sigma_g^+)$	$^2A'(1)$
(*h*)	$Na(^2P)+O_2(X^3\Sigma_g^-)$	$^2A'(1), ^4A'(1), ^2A''(2), ^4A''(2)$

* Following the standard notation[18], A′ indicates a state whose eigenfunction is symmetrical with respect to the plane and A″ one whose eigenfunction is anti-symmetrical while the numeral in brackets is the number of such states.

† Only the two lowest[18] suitable states of O_2^- are displayed.

the number densities on the right being better determined than the other number densities concerned. Kolb and Elgin[8] did not discuss the factors which control the branching ratio *f* but commented that a value between 10^{-1} and 10^{-2} would apparently be required to account for the nightglow. Recent data requires that *f* be not greatly below unity.

Stellar occultation measurements by Reigler and others[12,13] show that near the Equator $n(O_3)$ is some 1×10^8 cm^{-3} or less between 85 and 90 km rising to $\sim2\times10^8$ cm^{-3} at 95 km. Real variations occur and considerable uncertainty remains. Measurements[14] (31 °N, February) on the 110.8 GHz O_3 rotational line give 5×10^8 cm^{-3} at 80 km falling to about 1×10^8 cm^{-3} at 85 km; indirect deduction[15] from satellite data (20 °N, June) on the intensity of the (9, 3) hydroxyl band give 6×10^8 cm^{-3} between 80 and 85 km and 3×10^8 cm^{-3} at 90 km. Atmospheric model calculations[13] give a nocturnal distribution with a broad maximum of around 2×10^8 cm^{-3} in the 85–95 km region. Simultaneous lidar measurements on n(Na) and photometer measurements on the intensity I(5,893) of the D-doublet have been carried out at São José dos Campos (23 °S)[16]. The inference was drawn that the peak photon emission rate was at 88 km, where n(Na) was 3×10^3 cm^{-3}, and had the value 1×10^2 cm^{-3} s^{-1}. To reproduce this, it may be seen from process (5) that, with k_1 as in process (3), *f* would have to be about 0.3 even if $n(O_3)$ were as great as 3×10^8 cm^{-3}. Later lidar and photometer measurements[17] lead to compatible values. We need to examine whether *f* for process (2) can indeed be as high as required for the nightglow.

Parting along $\{Na^+–O_2^-\}:\{Na–O_2\}$ may yield either

$$Na(^2P)+O_2(X^3\Sigma_g^-) \tag{6}$$

or

$$Na(^2S)+O_2^*(X^3\Sigma_g^-, b^1\Sigma_g^+ \text{ or } a^1\Delta_g) \tag{7}$$

the asterisk indicating possible vibrational excitation. The crossings giving rise to reaction products (6) are at a greater separation than the numerous crossings giving rise to reaction products (7) and these latter are not readily traversed as is evident from the large[18] cross-section (34–38 Å^2) for the quenching process

$$Na(^2P)+O_2 \rightarrow Na(^2S)+O_2^*(X^3\Sigma_g^-, b^1\Sigma_g^+ \text{ or } a^1\Delta_g) \tag{8}$$

Furthermore, compared with the channels yielding products (6), the many relatively exothermic channels yielding products (7) are very strongly favoured statistically. Thus, it might seem that *f* must be minute.

However, consider the symmetry properties of the correlated molecular states concerned. Referring to Table 1, species $^4A'$ appears in reactant row (*a*), the product row (*h*) and the intermediate ionic rows (*b*) and (*d*) the last of which involves excited O_2^-, but does not appear in the product rows (*e*) to (*g*). Because the species does not change during an encounter, it follows that the simple electron-jump model gives the statistical weight ratio of 1/3 for *f* the branching ratio. Although the closeness of the fragments at the crossings may affect the quantitative predictions of the model regarding k_2 (which is not of critical importance) and *f*, there is certainly no reason to doubt that the branching ratio is as high as Chapman's theory demands.

D.R.B. thanks Professors T. M. Donahue and M. Nicolet for correspondence on the nocturnal ozone abundance.

Physicochemical speciation of lead in drinking water

Roy M. Harrison & Duncan P. H. Laxen

Department of Environmental Sciences, University of Lancaster,
Lancaster LA1 4YQ

Recent studies have highlighted the importance of drinking water as a route of human exposure to lead[1,2]. Whilst there are ample data on lead concentrations in drinking water[3], little is known of its physical and chemical forms (physicochemical speciation)[4]. Such information is important as the speciation of ingested lead influences the efficiency of absorption from the gastrointestinal tract[5]. Knowledge of speciation should also provide a fuller understanding of the factors controlling the solubility of lead in potable waters[6] and hence assist in devising the most cost-effective means of plumbosolvency control. We have determined experimentally the speciation of lead in three different tapwaters and report here diverse forms of dissolved and particle-associated lead, dependent primarily on the chemical matrix of the raw water.

Based on calculations of equilibrium solubilities, the Water Research Centre has predicted that basic lead carbonate, $2PbCO_3.Pb(OH)_2$ is the most stable insoluble lead compound to be formed in the conditions pertaining to most potable waters in Britain[6]. We have analysed the off-white surface deposit from inside a lead water pipe using X-ray powder diffraction and confirm this to be basic lead carbonate. However, as the Water Research Centre indicated[6], higher concentrations of lead can occur in potable waters than would be predicted by equilibrium of free lead ions with basic lead carbonate. The formation of ion pairs, or organic complexes of lead, or the presence of lead in insoluble particulate form in the water were all suggested as possible means by which these enhanced concentrations might occur, although no experimental measurements were made.

A range of techniques suitable for metal speciation exist, all of which essentially classify the species according to some operationally defined association[7]. We have recently developed a

Table 1 Analysis of tapwater samples

Sample	Alkalinity (μg ml^{-1} as $CaCO_3$)	pH	Organic carbon (μg ml^{-1})	Specific conductance (μS)
Lancaster University	21	7.5	9.4	130
Bentham	20	6.8	1.6	92
Glasgow	4	6.7	8.0	42

speciation scheme for freshwaters, which combines several established techniques[8]. It is based principally on a size fractionation of the metal species. Briefly, samples were collected in polythene bottles and filtered as soon as possible (in parallel, not in series) through Nuclepore filters under pressure in Amicon stirred cells. In two cases filtration was started within 2 h of collection, whilst with the Glasgow sample filtration was unavoidably delayed for 24 h. Nuclepore filters were selected as they have inherently better size discrimination properties than membrane filters and suffer lesser contamination and adsorption problems. Both filter and filtration apparatus were pretreated with a $Ca(NO_3)_2$ solution to minimize adsorption losses[9]. They were rinsed with deionized double-distilled water to remove excess $Ca(NO_3)_2$ and then with a portion of sample before filtration. Recovery tests with pre-filtered samples of tapwater and riverwater, as well as with a synthetic river water, using filters of 0.015–12 μm pore size showed recovery to be independent of filter pore size. Mean recoveries were as follows: Pb, 86%; Cu, 94%; Fe, 101%; Mn, 100%. A fuller discussion of the significance of these adsorption tests is given elsewhere[8]. Note, however, that if, as is likely, adsorption is independent of filter pore size then adsorption losses will only affect the quantification of the smallest size fraction, as the others are calculated by difference and are hence independent of adsorption losses. Contamination during filtration was very low: Pb, <0.1 ng ml^{-1}; Cu, <0.1 ng ml^{-1}; Fe, <0.5 ng ml^{-1}; Mn, <0.05 ng ml^{-1}.

The total metal concentrations in each filtrate were determined by flameless atomic absorption for Fe and Mn, and by anodic stripping voltammetry (ASV) for Pb and Cu following UV-ray acid digestion. A standard additions calibration was applied in all cases. As a measure of the ASV-labile concentration at the natural pH of the sample, ASV analyses were performed on the 1-μm filtrate at a hanging mercury drop electrode, using CO_2 in nitrogen as a buffer. A titration procedure was used to indicate the extent and strength of any complexation and the slope of the titration curve after saturation of the complexation capacity was used to quantify the labile response.

Labile metals were also defined by their uptake on Chelex 100 exchange resin. A 48-h batch technique was employed, using 2 ml of resin in the calcium form per 60 ml of sample in a polythene bottle. This provided a measure of metal complexes with slower dissociation kinetics. Finally, UV-ray irradiation (1 kW Hanovia lamp) was used to destroy organic matter and so release metals previously associated with the organics in a non-ASV-labile form. The increase in labile metal following UV-ray irradiation is a measure of the metals strongly bound with organic matter[7]. This procedure has, however, proved to be inapplicable for most freshwaters, there being a loss rather than gain of ASV-labile metal, due probably to uptake onto hydrous ferric oxide precipitated during the irradiation[8]. It still, nevertheless, provides qualitative information on the nature of the ASV-labile metal.

Particular care has been exercised in the evaluation of the ASV-labile results, due to recently recognized limitations of the method[10,11]. However, interpretation of the data is strengthened by a consistency between the results derived from each of the techniques. Finally, note that in common with all speciation studies, the results might to some unknown extent reflect artefacts of the various handling operations, starting with the sampling itself.

Three tapwater samples were analysed. These included two morning first draw waters, from Glasgow (Scotland) and Bentham (North Yorkshire). The former came from a house with lead-lined tank and lead piping, the latter from a house with copper piping internally, but a lead service pipe. Both waters were of rather low alkalinity and pH (Table 1) and could be described as aggressive in respect of plumbosolvency. The other sample was from the University of Lancaster (copper piping with high-lead soldered capillary joints) and was taken after a thorough flushing of the pipes.

The results are presented in Table 2. Copper has been included, as its speciation behaviour usually differs from that of lead, the latter forming predominantly inorganic species, the former organic[12]. As a substantial proportion of the lead appeared in the colloidal size fractions, the elements iron and manganese were also analysed, as these elements can exist in waters as colloidal hydrous oxide particles or coatings, as well as in association with organic macromolecules[13]. The colloidal hydrous oxides are effective at adsorbing metals from waters and show a particularly strong affinity for lead[14]. The University tapwater sample had a total lead concentration of only 3.3 ng ml^{-1}, the major proportion of which, 76%, was filterable (<0.015 μm). This filterable lead was however not ASV-labile, and hence cannot exist as Pb^{2+}. The water supply is a mixture of moorland surface water and River Lune water and has a substantial organic content (Table 1). Titration of the tapwater sample with lead showed further ability to complex lead as indicated by the ASV signal until the complexation capacity had been exceeded. This complexation capacity was lost following UV-ray irradiation of the sample, which destroys organic matter. The major portion of the lead is, therefore, probably present as non-labile low molecular weight organic complexes, although some may also exist as non-labile inorganic species.

In the Bentham tapwater, which is derived from spring waters and is of low organic content, 53% of the lead and 33% of the copper were associated with colloidal particles of 0.015–1.0 μm. A significant fraction of the lead (19%) was in the particulate size range 1–12 μm. This may have been due to basic lead carbonate which precipitates as rather large particles (unpublished results). The size distribution of the lead in the colloidal size range parallels that of iron rather closely. The mole ratio Pb/Fe is $\sim$0.2 in all three fractions between 0.015 and 1.0 μm. This is consistent with the lead occurring in association with hydrous oxides of iron, either by ion-exchange, by specific adsorption or by co-precipitation. The Chelex-labile copper corresponds closely to the ASV-labile metal, whilst for lead more metal is Chelex-labile. This additional labile metal must, furthermore, be due in some way to release from the colloidal metal fraction. It is either a result of weak lead complexation with organic macromolecules or a slow release from the hydrous oxides due to the disturbed equilibrium in the presence of the Chelex resin. There was no apparent complexation capacity for additional lead during titration of the sample, and UV-ray irradiation did not cause a change in the peak potential of the ASV lead signal, adding weight to the suggestion that inorganic species of lead predominate in this water.

The Glasgow sample, abstracted originally from Loch Katrine, contained the highest concentration of total lead, 372 ng ml^{-1}, and the highest percentage of ASV-labile lead, 63%. Again a high proportion (71%) of lead was associated with the colloidal size fractions, although in contrast to the Bentham water most of this colloidal lead (75%) was in the small size range 0.015–0.08 μm. Note that a significant proportion of this colloidal lead must contribute to the ASV and Chelex-labile lead. During titration of the sample with additional lead a separate lead signal at a more anodic potential developed after $\sim$800 ng ml^{-1} of lead had been added. This is indicative of complexation of the ASV-labile metal in the original sample[15]. After UV-ray irradiation of the sample the original ASV signal disappeared to be replaced by a more anodic peak. It seems that a large proportion of the lead in this sample (63%) existed as ASV-labile organic complexes, a major portion being of high molecular weight (0.015 μm is equivalent to a molecular weight of ~300,000). In the case of copper in the raw sample, ASV-labile metal could not be distinguished. Copper forms stronger complexes with organics than lead and its complexation is often non-ASV-labile[12], as seems to be the case with this sample.

In the three waters examined there is apparently little or no free ionic lead. A significant portion of the lead exists in the colloidal size fractions, associated with hydrous iron oxides or organic macromolecules depending on the composition of the water. There is some particulate lead in the 1–12 μm size range, which may be metal precipitate, or may be associated with clay minerals, but little or no lead in larger particles, >12 μm. This would suggest that the lead in the samples examined is not a result of particles flaking off the basic lead carbonate lining of the lead water pipes.

Plumbosolvency is clearly not a simple equilibrium between solid basic lead carbonate and dissolved Pb^{2+} ions and ion pairs. It depends rather on the adsorption and complexation capacity of the hydrous oxides and organic complexing agents such as humic acids. Techniques of plumbosolvency control depend on an increase in the sample *p*H and hardness/alkalinity[6,16]. The lead concentration is, however, not always reduced to the extent predicted by theoretical calculations of equilibrium solubility[6,16] and the complex lead speciation in real tapwaters, as indicated by our results, may account for this result. The reduction in plumbosolvency achieved by *p*H and hardness/alkalinity control may be a function of a decrease in the rate of lead dissolution and/or the effect of competing cations such as Ca^{2+} for adsorption, ion-exchange and complexation sites, in addition to the anticipated decrease in equilibrium solubility.

One option that has been considered for reduction of lead levels in drinking water is the use of chelating resin at the consumer's tap[6]. Our results demonstrate that this measure is likely to have a limited effectiveness, as a substantial fraction of the lead will probably be in a non-ion-exchangeable form.

The health implications of our findings are uncertain. However, at *p*H 1–2 in the acidified samples, all lead is ASV-labile (Table 2) and is probably present as free metal ions. Hence at the *p*H of the stomach, tapwater lead will also take this form and hence may well be more available for absorption than the lead bound in foodstuffs. This may explain the high effectiveness of removal of lead piping in reducing blood lead levels in the study previously cited[2].

Measurements of $CHFCl_2$ in background tropospheric air

S. A. Penkett*, N. J. D. Prosser*, R. A. Rasmussen† & M. A. K. Khalil†

The likely impact of fluorocarbons on the Earth's ozone layer has recently been reviewed in two major reports[1,2] which, although showing difference of emphasis, both concluded that uncontrolled emissions of F11 ($CFCl_3$) and F12 (CF_2Cl_2) would lead to a substantial reduction in the level of ozone in the Earth's ozone shield (13–16%). The effect of F11 and F12 on ozone would be considerably reduced if they were removed on a large scale by some mechanism which operated in the troposphere. Such a mechanism has been proposed for F11, which involves conversion to F21 ($CHFCl_2$) on the surface of aerosols suspended in the atmosphere[3]. Crescentini and Bruner[4] have recently reported measurements of the F21 concentration that were of sufficient magnitude to suggest that tropospheric removal of F11 was occurring on a scale greater than stratospheric removal. We report here data which refute this suggestion by showing that the level of F21 in the clean background troposphere is virtually unmeasurable.

Several attempts have been made to measure the concentration of F21 in the atmosphere. It was first detected by Rasmussen[5] using a gas chromatograph/mass spectrometer (GC/MS) combination, and he quoted a value of ~10 p.p.t.v. (1 p.p.t.v. = 1 part in 10^{12} by volume). Singh *et al.*[6] reported F21

0028–0836/80/340793—03$01.00

background concentrations of 14.9 ± 4.9 p.p.t.v. as preliminary data for a clean site in Yosemite National Park, California. Subsequently, their more extensive global measurements[7] in the Northern and Southern Hemispheres concluded a tropospheric average of 5 ± 3 p.p.t.v. However, they felt that the lack of a significant interhemispheric gradient for an anthropogenic compound with such a short atmospheric lifetime implied that it was probably an artefact of analysis, although they were unable to determine its source. Measurements in their studies were made using a gas chromatograph equipped with an electron capture detector (GC/ECD). F21 is a difficult species to measure and measurements made with the electron capture detector are not the most reliable as the detector is nonspecific. Glasgow *et al.*[8] reviewed the artefact problems associated with these early F21 measurements. Crescentini and Bruner[4] have shown that a species is present in air which has a mass spectrum identical to that of F21, and they estimate its concentration to be as high as 20 p.p.t.v. in air collected in central Italy. If this were the case for the well-mixed troposphere, then decomposition of F11 to F21 could represent a very substantial sink for F11. The present measurements using a GC/MS combination suggest that the level of F21 in the background troposphere is probably well below 1 p.p.t.

A Hewlett-Packard 5710 gas chromatograph and a VG micromass 16F mass spectrometer combination were used to make the measurements on concentrated air samples. Two concentration techniques were used, both based on collection of liquid air and subsequent removal of the major permanent gases at liquid nitrogen temperature. In one method the oxygen and nitrogen were removed by a stream of pure helium and carbonyl sulphide was used as an internal standard to estimate the effective volume injected (see ref. 9 where xenon was used for a similar purpose). The other method relied on carefully trapping a known volume of liquid air (~3 ml), then pumping away the oxygen/nitrogen excess. Alternatively, a small volume of gaseous air was injected into the cryotrap. Tests with a standard showed that a 95% recovery of material could be achieved by this method. The concentrated samples were then injected into a 3-m OV101 column held at 30 °C, using helium as a carrier gas. COS was measured using mass 60 and F21 was measured using masses 67, 69 and 102. Because of the extremely low concentrations of F21 that were present, this was generally done using the single ion mode. Attempts to measure all three ions simultaneously resulted in rather poor signal-to-noise ratios. A typical chromatogram that resulted for mass 67 in the single ion mode is shown in Fig. 1. Chromatograms for masses 69 and 102 showed similar peak separation and signal-to-noise ratios. The peak ascribed to F21 in Fig. 1 had an identical retention time as an F21 standard, also a linear response to F21 concentrations between 100 p.p.t.v.and 10 p.p.b.v. (1 p.p.b.v. = 1 part in 10^9 by volume) was shown by the instrument. These latter standards were injected in 10-ml syringes so that the mass of F21 entering the detector at the 100 p.p.t. level was actually lower than that injected in the concentrated air samples, which typically contained the equivalent of 2 litres of air.

All of the data collected in this programme of F21 measurements are shown in Table 1. The first 14 results are values of the F21 concentration in the ambient air at Harwell, five of which used one technique for quantitative estimation and nine used another. The average value of the 14 estimations is 1.6 p.p.t.v. with $\sigma = 0.7$ p.p.t.v. There is no significant difference in the two groups of data obtained by the two techniques (1.8 ± 0.5 p.p.t.v. and 1.5 ± 0.7 p.p.t.v.), and this gives us confidence that our average of 1.6 p.p.t.v. is correct. The possibility that some compound other than F21 is being measured is not very high, as the results obtained using masses 69 and 102 are almost identical to those obtained using mass 67. Chloroethane, which contains a peak at *m/e* 67 in its mass spectrum, was observed to co-elute with F21 in this study; however, chloroethane does not have *m/e* peaks at 69 and 102.

Estimates of the F21 concentration in air samples from other locations are also shown in Table 1. Samples 16–19 represent particularly clean air samples, and there the average falls to 0.08 p.p.t. Whether this number is significantly different from the noise level (~0.05 p.p.t.v.) is not possible to tell with the present experimental system. The numbers can be taken to indicate that the F21 concentration in the background troposphere is well below 1 p.p.t.v.

Tests have been made for contamination and decay in the containers used to bring the air to Harwell. Samples 15–18 were contained in aluminium cans with metal-bellows valves. There was no evidence for any decay in a similar can filled with Harwell air on 21 March 1979 and analysed on 21 May 1979 and 13 June 1979. Sample 19 was contained in a stainless steel can, but there is no reason to suspect decay in this system. Previous tests by one of us (R.A.R.) also showed that no growth of F21 occurred over a two-week period.

Our value for F21 in rural air in Southern England (1.6 p.p.t.v.) is substantially lower than previously reported estimates at other locations[4–7]. Rasmussen[10] has since revised his estimate of F21 concentrations originally reported (~10 p.p.t.v.) and now considers a value of 1.5 p.p.t.v. to be more likely. The data of Singh *et al.*[6,7] were all obtained by GC/ECD and the chances of overestimation are quite large. A major problem in the analysis of F21 is to devise a column that will give complete separation of F21 from other neighbouring compounds. Rasmussen in his early work observed that chloroethane (C_2H_5Cl, boiling point, 12.7°C) had a retention time similar to F21 (boiling point, 8.9 °C) in the conditions of analysis used with an SP 2100 column and temperature programming. Singh *et al.*'s[11] elution of F21 (boiling point, 8.9 °C) before CH_3Br (boiling point, 3.5 °C) on a DC 200 column substrate is inconsistent with the elution sequence of materials with increasing boiling points on that type of column. Additionally, the separation of F21 from CH_3I (boiling point, 43 °C) on 0.5% SP 1000 Carbopack B column has presented difficulties[12]. This leaves only Crescentini and Bruner's[4] high value to be accounted for. Assuming that they may have been sampling polluted air, we collected air samples in the area between Liverpool and

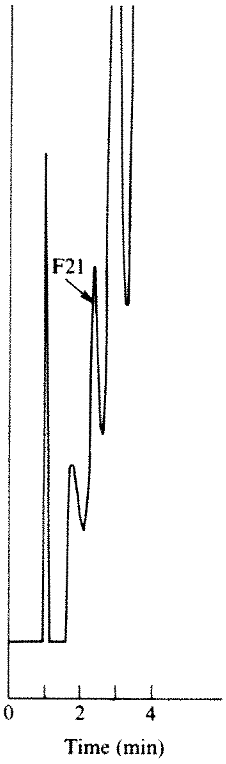

Fig. 1 F21 ambient air stored between 21 March and 21 May 1979; 2.6 p.p.t.v. at *m/e* 67. The sample size was 730 ml.

Manchester. When measured using mass 67, samples 23–26 showed elevated levels of F21 with values between 4 and 37 p.p.t.v. Unfortunately these values were not confirmed by measuring masses 69 and 102, and samples collected more recently in this area show only very low F21 levels (~1.5 p.p.t.v.). Whilst it is thus quite feasible that Crescentini and Bruner were sampling F21 in polluted air, there still remains some doubt that concentrations as high as 20 p.p.t.v. occur.

If the only sink for F11 in the troposphere involved F21 production, then a lifetime for F11 could be derived from a knowledge of the relative F11/F21 concentrations and the rate of decay of F21. In the troposphere, the most likely sink for F21 is reaction with OH radicals, so:

$$\mathrm{CCl_3F\ (F11)} \rightarrow \mathrm{CHCl_2F\ (F21)} \xrightarrow{[\mathrm{OH}]} \text{products}$$

and

$$\tau(\mathrm{F11}) \sim \frac{[\mathrm{F11}]}{[\mathrm{F21}]}\,\tau(\mathrm{F21})$$

This simplified equation yields a τ(F11) of 200–300 yr. The concentrations of F11 and F21 were taken to be 165 p.p.t.v. and 1.6 p.p.t.v., respectively. $\tau(\mathrm{F21}) \sim \{\bar{K}[\overline{\mathrm{OH}}]\}^{-1}$ is between 2 and 3 yr based on the reaction rate constant of F21 with OH of $1.5 \times 10^{-12} \exp(-1{,}184/T)$ cm^3 molecule^{-1} s^{-1} (ref. 13) at the average temperature of 260 K with mean OH densities in the range $0.6\text{–}1 \times 10^6$ molecules cm^{-3} (ref. 14). This equation for τ(F11) is approximately valid when F11 and F21 are in a steady state. We calculated the lifetime of F11 using more complex expressions without the steady-state assumption, but the results were not significantly different. Furthermore, we used the average of the highest observed concentrations of F21 (1.6 p.p.t.v.). Our other measurements imply that, in fact, the global concentration of F21 is probably well below this value (~0.1 p.p.t.v.), which would in turn imply that such a conversion of F11→F21 is much less significant than calculated above. Therefore, our measurements show that the lifetime of F11 due to its possible conversion to F21 is much longer than that derived from stratospheric photolysis[15], which is ~50 yr. For this tropospheric removal process of F11 to be equivalent to stratospheric photolysis, a background F21 concentration of 6 p.p.t.v. would be required; a dominant tropospheric removal process would need a level exceeding 10 p.p.t.v.

In the discussion above, we have considered the extreme case where all the observed atmospheric burden of F21 results from destruction of F11. In fact, all or part of the atmospheric burden may be due to other sources which include direct industrial emissions[8] and volcanic emissions[16,17].

Definite statements can be made only if more data are collected on the atmospheric concentrations of F21 in the background atmosphere, which would also justify more detailed theoretical treatments than discussed in this study. Our present experimental results show that non-urban F21 concentrations range from ~0.1 to 2.5 p.p.t.v., indicating that even if there are environmental processes which destroy F11, converting it to F21, they would not be a significant global, tropospheric sink for F11.

We thank Dr R. G. Derwent for helpful discussions and Steve Crawford and Bob Dalluge for laboratory assistance. This work was funded by the Chemical Manufacturers Association and the UK Department of the Environment. The samples 23–26 were obtained with help from ICI Ltd. Support from the NSF, grants ATM 7806628 and DPP 77-23468, is gratefully acknowledged.

A climatically responsive tree-ring record from *Widdringtonia cedarbergensis*, Cape Province, South Africa

Peter W. Dunwiddie

Quaternary Research Center, University of Washington, Seattle, Washington 98195

Valmore C. LaMarche Jr

Laboratory of Tree-Ring Research, University of Arizona, Tucson, Arizona 85721

The use of dated tree-ring series to reconstruct past climate has received much attention in recent years[1,2]. The development of long and climatically responsive chronologies in many areas of the Southern Hemisphere is an important step towards better understanding past environments in these areas[3,4], but little dendrochronologically related work of any sort has been done on the African continent[5–11], and most of this has consisted primarily of ring counts to estimate ages. We report here on the development and climatic interpretation of the first dated annual ring-width index chronology from Africa south of the Sahara.

Tree-ring samples were collected from a large number of sites in South Africa[12] as part of a broader-scale effort to reconstruct climatic variability in the Southern Hemisphere. The results of reconnaissance sampling, combined with previous experience elsewhere, led us to concentrate on conifers in the genera *Podocarpus* (Podocarpaceae) and *Widdringtonia* (Cupressaceae) in western and southern Cape Province. One species, *W. cedarbergensis*, seemed to offer particular promise by virtue of its apparent great age, its tree-ring properties, and its occurrence in marginal habitats of the Cedarberg Mountains.

The Die Bos site, which provided the tree-ring samples on which this analysis is based, is located in the rocky Cedarberg Mountains about 200 km north of Cape Town. It is one of the largest remaining stands of *W. cedarbergensis*, whose numbers have been greatly reduced by woodcutting and wild fires. Scattered *Protea* (sp.) trees and shrubs are the main associates on this sparsely vegetated site. The climate in the Cedarberg is moderately warm in summer and cold in winter, and the area receives between 300 and 900 mm of precipitation per year, mainly in winter.

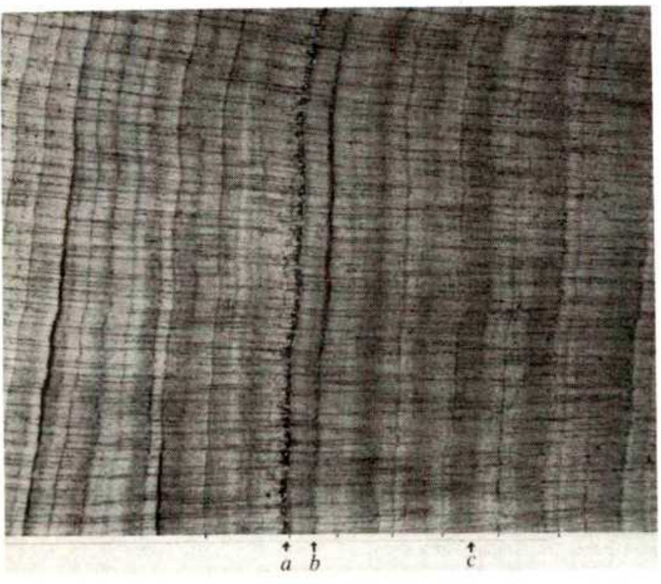

Fig. 1 Detail of growth rings in *W. cedarbergensis*. *a*, Frost ring in earlywood of 1787; •*b*, resin band in centre of 1786 ring; *c*, intra-annual band in latewood of 1783 ring. Rings following 1787 have clearer latewood terminations than do earlier ones.

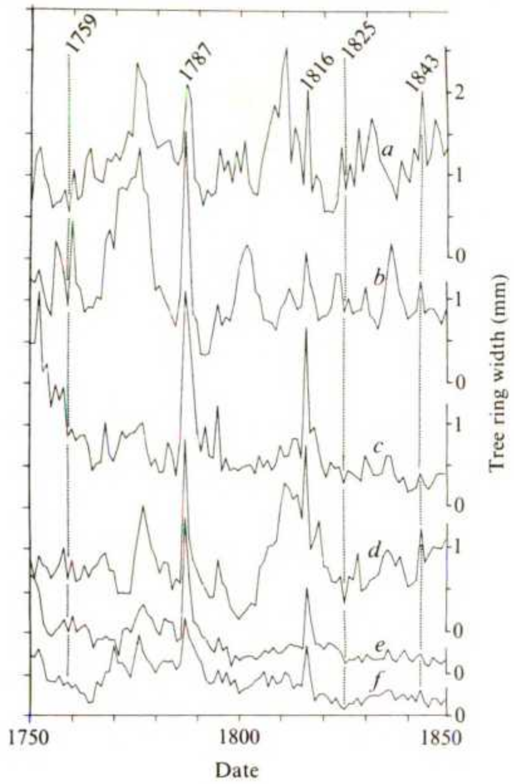

Fig. 2 Portions of ring-width plots for six trees from the Die Bos site illustrating crossdating in the period 1750–1850.

Our sample includes 58 increment cores from 28 living trees up to 12 m tall and 150 cm in diameter. These are supplemented by cross-sectional disks from 19 dead trees and stumps. Lobate growth is uncommon in this material, as is the wedging out of individual rings. Circuit uniformity is generally good, with ring-width patterns being similar on various radii of the same tree. However, several growth features make cross-dating unlike that in most other species (Fig. 1). Many rings lack an abrupt termination of latewood growth, and may have several false bands within the latewood, making determination of the precise ring boundary difficult. Resin-filled bands of cells occur in some rings that may appear as sharper, more distinct lines than the true boundary. The 'signature' rings commonly used by dendrochronologists to crossdate specimens (rings that are relatively narrow on many trees in a site) are not common. Rather, unusually wide rings (Fig. 2), which in some cases (1787, 1816) exhibit characteristic frost damage in the earlywood are more reliable dating checks. These frost rings (Fig. 1) are unusual because trees of most species are not susceptible to such damage after they reach several centimetres in diameter. At Die Bos, mature trees are found with frost rings that date consistently between trees. It is not known why these rings are often relatively wide as well. Figure 2 also illustrates the wide variation in growth rates and sensitivities found in trees at this site. Some, like trees *c* and *e*, are relatively slow-growing, but have several extremely wide rings. Others, such as *a* and *b*, have many relatively wide rings, some of which crossdate with other trees. There is little doubt that the rings dated in this chronology are annual, for several reasons. First, the extreme seasonality of the

0028-0836/80/340796—02$01.00

Mediterranean-type climate is likely to limit growth to a single growing season each year. Second, locally absent ('missing') rings are infrequent, and relatively few rings in any specimen are ambiguous; false bands can usually be clearly differentiated from the annual rings by careful inspection and crossdating.

The site chronology beginning in AD 1564 (Fig. 3) was developed by standard methods[1] after all suitable samples were dated. It represents the average of ring-width index series from 52 radii on a total of 32 trees, an unusually large sample size. An analysis of variance[1] based on data for the 1892–1976 subperiod showed that 29% of the total sample variance is retained by the site chronology, indicating a fairly high degree of ring-width variation in common between different radii and different trees. Presumably, this reflects a fair degree of common response to year-to-year variations in the local environment, including climate.

A climatic response function[1] was computed to evaluate the nature of the climatic 'signal' contained in the site chronology (Fig. 4). It is based on comparison, using multivariate analytical methods, of monthly climatological data from a nearby station with the annual ring-width index during the period 1931–60. The climatic variables used are the monthly average daily maximum temperature and the total monthly precipitation during each month in an 18-month climatic interval beginning in spring (October) of the year preceding initiation of ring growth, and ending in autumn (March) of the calendar year following the year in which growth begins. That is, this interval includes the past and present growing seasons. The growing season for this species probably includes the period October through March. Previous ring-width index was not used in generating the response function shown here, but incorporating previous growth in the analysis produces very similar results.

The response function results show a high degree of correlation of tree growth with climatic factors; 73% of the year-to-year variability in ring-width index can be explained by departures from normal temperature and precipitation during the 18-month interval preceding and concurrent with the growing season. However, the response is complex, with opposite responses to the same variables occurring in different seasons of the year. A dominant feature is the positive response to precipitation of the previous and current spring and early summer (September or October to December). Coupled with a negative response to higher than normal temperatures in the previous and current early summer (November–December), this suggests that one component of the relationship is a negative response of tree growth to spring and early summer drought. However, in some months, a negative response to precipitation and positive response to temperature also occur. We can tentatively interpret the long tree-ring chronology (Fig. 3) as a record of spring and early summer moisture availability, but other chronologies from a greater diversity of habitats and a broader geographic area must be developed, studied, and compared to understand better the climatic history of southwestern South Africa over the past several hundred years. For example, the occurrence of frost rings in most trees following the extremely large volcanic eruption of Tambora at 8 °S in 1815 may suggest a dust veil effect on temperatures of interest to climatologists.

Dendrochronological study of *W. cedarbergensis* can also provide a fire frequency record. Several charred disks from the Die Bos site have an outer ring dated 1872, and some living trees exhibit a marked growth surge beginning the next year, suggesting a release effect following fire. A marked resin band in the ring for 1771, along which many specimens split, may be the result of an earlier fire. Fire-scarred living trees are unusual in this resinous, flammable species; trees are generally either killed or left unscarred by fire.

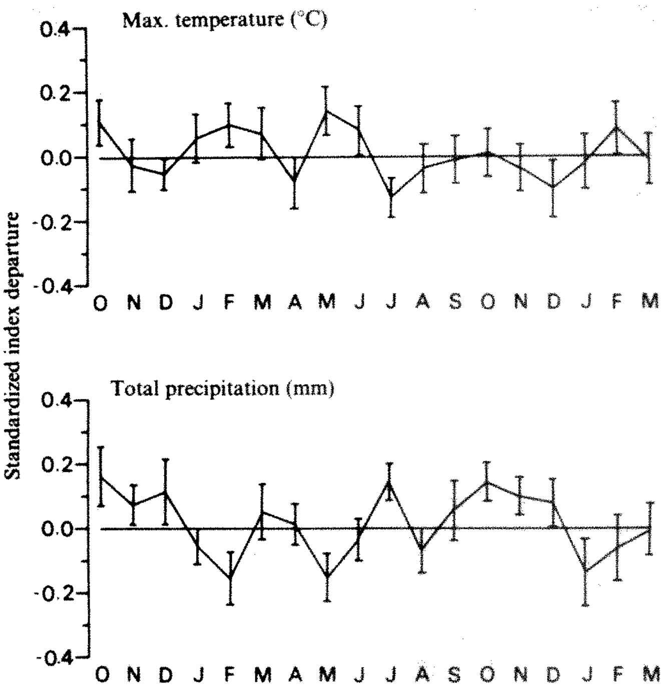

Fig. 4 Climatic response function for the Die Bos *Widdringtonia cedarbergensis* chronology. Based on combined climatological data from Clanwilliam, Calvinia, and Langgevens, Cape Province, 1931–60.

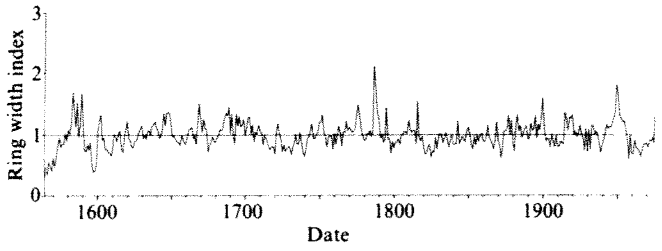

Fig. 3 Site chronology of average ring-width indices, Die Bos, Cape Province.

There is potential for development of much longer tree-ring chronologies than that presented here. Dead wood decays slowly in this semi-arid environment, especially in rock crevices or overhanging rock shelters, and wood from stumps, logs, and remnants can be cross-dated with living material. Ring-width plots for trees *a* and *d* (Fig. 2) illustrate the matching of such 'floating' series with growth records of living trees at the site.

This analysis illustrates the potential for development and climatic interpretation of long tree-ring records from southern Africa. In addition to study of ring-width variability, other approaches such as analysis of stable isotopic composition may yield further information. Some of this material has already been supplied for isotopic analysis.

We thank F. Kruger, A. Lamb, and F. Hanekome for support and field assistance, E. Ashton for selected climatological data from copies of the South African Weather Bureau's magnetic tapes. This research was supported by the Climate Dynamics Program, Division of Atmospheric Sciences, NSF.

Organic matter fluxes from sediment traps in the equatorial Atlantic Ocean

Stuart G. Wakeham, John W. Farrington, Robert B. Gagosian, Cindy Lee, Hein DeBaar, Gale E. Nigrelli, Bruce W. Tripp, Steven O. Smith & Nelson M. Frew

Department of Chemistry, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543

The vertical flux of particulate organic matter to the ocean floor is controlled by complex remineralization and transport processes. Rapidly sinking, large (>32 μm) particles may account for most of the vertical mass flux[1-3]. Experiments involving collection of sedimenting particles in traps deployed at varying depths in the water column provide a way of assessing these processes directly[2-12]. Measurement of organic carbon content of trap material may lead to a general understanding of the flux of particulate organic matter to the sea floor[3,8-10]. However, details of the transport and transformation phenomena involving sinking particulate organic material can be elucidated only by determining distributions of specific organic compounds associated with the particles[11,12]. We report here direct flux measurements and composition of lipids obtained by organic geochemical studies of particulate material collected in a deep-sea moored sediment trap experiment in the equatorial Atlantic Ocean.

The PARFLUX E station was located on the Demerara abyssal plain (5,288 m) ~750 km from the Guyana coast at 13°30.2′ N, 54°00.1′ W. Four sediment traps were placed along a fixed mooring at depths of 389, 988, 3,755 and 5,068 m, and recovered after 98 days (November 1977–February 1978). The water column had a weak oxygen minimum between 200 and 400 m, and the main thermocline was located at 300 m. No significant nepheloid layer was reported[7]. Sodium azide was added to each trap before emplacement and diffused into the collection cup[13] during the experiment to retard bacterial spoilage of the trapped material.

Particulate samples were wet sieved and split with a rotary splitter[3]. Aliquots were taken for geological[3], elemental and isotopic[7], and organic geochemical (present) studies. About one-sixteenth of each sample (0.03–0.4 g sediment depending on availability) was extracted with toluene/methanol (1:1). Amino acids present in this extract were partitioned into saturated salt solution, while the remaining lipids were partitioned into hexane. The hydrolysed amino acids were analysed by a modification of the fluorescence technique of Hill *et al.*[14]. An aliquot of the hexane-soluble lipids (0.5–5 mg of lipid) was hydrolysed for total fatty acid analysis. A second aliquot (0.4–4 mg) was separated into constituent organic compound classes by adsorption chromatography (Merck silica gel 60, 5% deactivated with water) by elution with a series of solvents of increasing polarity (ranging from hexane, toluene in hexane, increasing proportions of ethyl acetate in hexane, ethyl acetate, to methanol).

The molecular composition of compound classes collected (given in Table 1) was determined by glass capillary gas chromatography (GC) (Carlo Erba 2150 and 4160, and Hewlett Packard 5710 and 5840 chromatographs; 15–25 m × 0.3 mm i.d. columns, deactivated by persilylation and coated with SE-52[15]) and capillary gas chromatography/mass spectrometry (GC/MS) (Finnigan 3200 and 1015 SL). Electron impact and isobutane- or methane-chemical ionization spectra were obtained, depending on the compound class. Fatty acids were analysed as methyl esters[16], and fatty alcohols and sterols as acetate derivatives[17]. Wax esters, steryl esters, and triacylglycerols were analysed intact by capillary GC and GC/MS. Compounds were identified where possible by comparison with GC retention times and mass spectra of authentic standards. Concentrations of hexane-soluble lipids were estimated by weighing an aliquot on an electrobalance; concentrations for compound classes are sums of individual compounds determined by gas chromatography. Laboratory blanks were carried through the entire workup and were generally significantly lower than samples. We cannot estimate sampling variability as single samples were collected, but analytical precision for each compound class is better than ±20%.

Organic geochemical results for PARFLUX E sediment trap samples are given in Table 1 as total amounts of material in each trap and as mass fluxes at the depths sampled. The major compositional features of the lipid classes analysed are summarized in Table 2. Further details of compound distributions will be given elsewhere.

Particles <1 mm in size accounted for most of the particulate flux at all depths sampled. The amount of material <1 mm varies little with depth in the water column. Honjo[3] found these particles to be amorphous aggregates of organic matter composed of foraminiferal tests, radiolarian skeletons, small pteropod shells, and faecal pellets. Only in the 389 m trap were particles >1 mm important, these including larger faecal pellets and some intact zooplankton[3].

Bulk organic matter flux decreased rapidly with increasing depth in the mesopelagic zone (389 and 988 m traps), stabilizing in the bathypelagic layer (3,755 and 5,068 m samples). Organic carbon comprised ~50% of the organic matter in the mesopelagic samples and ~35% at the two deeper depths. Of the organic carbon fixed in the euphotic zone at this location[3] (200 mg m^{-2} day^{-1}), ~4–6% reached the mesopelagic traps. Only ~1% arrived in the deep traps. These observations are consistent with a rapid turnover of bulk organic matter in the upper portion of the water column, with a small and highly fractionated amount reaching the sea floor.

Lipids were rapidly depleted in the upper 1,000 m of the water column. Unlike bulk organic matter and organic carbon, lipid fluxes decreased throughout the water column. Lipids became a proportionally smaller fraction of the organic flux (15% at 389 m and 2% at 5,068 m), indicating that they were consumed preferentially compared with other components of the overall organic pool.

Fluxes for specific organic compound classes followed three trends (Table 1): (1) a rapid decrease with depth (hydrocarbons, fatty acids, wax esters, steroid ketones, and lipid-associated amino acids); (2) a rapid decrease between 389 and 988 m followed by a slight flux increase in the 3,755 m trap (free fatty alcohols); (3) a maximum flux at 988 m (free sterols, steryl esters, triacylglycerols). Major aspects of our observations are outlined below and in the tables.

Hydrocarbons of planktonic origin (n-C_{17}, C_{19}, and a lesser amount of pristane) dominated all four traps. Long-chain (C_{25}–C_{31}) hydrocarbons were also present at lower abundances at all depths, indicating long-range transport of continentally derived material. Sterenes were detected, primarily in the 389 and 988 m samples, where they were more abundant than alkanes in the same carbon range. This suggests active microbial transformations of organic matter in or on sinking particles and a relatively fast biogeochemical formation for sterenes[18]. We cannot, however, rule out a planktonic source for these cyclic hydrocarbons.

The flux of total fatty acids (free + esterified) decreased 60-fold with increasing depth. Free fatty acids, a minor fraction of the total acid pool, showed a smaller decrease. The fatty acid composition of the particulates reflects a planktonic source. Recycling and sinking of particles resulted in rapid degradation of all fatty acid moieties, unsaturated compounds being lost more rapidly than saturated ones (for example, saturated/unsaturated acids = 5 and 60 at 389 and 5,068 m respectively). Branched-chain fatty acids, potential markers of microbial contribution[19-22], were minor constituents, and their relative abundance did not increase with depth.

Unsaturated wax esters (for example, $C_{34:1}/C_{34:0} = 40$ at 389 m) dominated the wax ester flux. The composition was indicative of a zooplankton origin[23,24]. Degradation of unsaturated wax esters appeared faster than loss of saturated analogues. However, even at 5,068 m depth, unsaturated compounds dominated the wax ester distribution ($C_{34:1}/C_{34:0} = 15$).

Steroid ketones (stanones + stenones) exhibited a gradual flux decrease with increasing depth. The major ketone in each sample was cholest-4-en-3-one, representing 60% of the ketone flux into the mesopelagic traps and about 35% into the deeper traps. *In situ* production of steroid ketones, possibly through microbial transformations of sterols, may have occurred as the particles sank. The gradual flux decrease of ketones compared to sterols (see below) could be due to differing degradation rates.

Amino acids associated with the lipid fraction in the mesopelagic traps were similar in composition to the protein amino acid composition of plankton. Such distributions were also found in suspended particulate matter filtered from seawater in the Pacific[25]. In contrast, only glutamic acid, aspartic acid, alanine, serine and glycine were detected in the deeper traps. These are the major amino acids in bacterial cell walls[26] and may reflect bacterial input.

Free fatty alcohols of 14, 16 and 18 carbon atoms were associated with particles in all four traps. Only about 10% of the alcohols in the 389 m trap were found in the 988 m trap. On the other hand, we observed a significant enrichment of fatty alcohols at 3,755 m. The several compounds responsible for this increase remain unidentified at present, but they are neither straight-chained molecules nor phytol.

The free sterol flux maximized at 988 m, where cholest-5-en-3β-ol accounted for 95% of the sterol composition. In contrast, at 389, 3,755 and 5,068 m, a wide range of planktonic sterols were present.

Steryl ester fluxes and molecular distributions correlate well with free sterols, although the relative flux increase at 988 m over 389 m was about an order of magnitude greater for the esters. In the 389 m sample, steryl esters were composed of a range of sterols (Table 2) and primarily $C_{16:0}$ and $C_{18:0}$ fatty acids. However, esters of cholest-5-en-3β-ol predominated at 988 m.

Triacylglycerols in the 389 m trap were composed primarily of $C_{18:0}$, $C_{18:1}$ and $C_{16:0}$ fatty acids, resulting in a C_{45}-C_{63} carbon range. Polyunsaturated fatty acid moieties ($C_{22:6}$ and $C_{20:5}$) were more abundant in the 988 m sample than saturated or monounsaturated acids.

Our results suggest that significant alteration of organic compounds produced by phytoplankton and zooplankton[21,23,24,27–29] in the upper water column takes place even before the particles reached the shallowest trap. For example, *n*-C_{17}, C_{19}, and pristane were depleted relative to other alkanes in the 389 m trap compared with freshly sampled indigenous zooplankton collected at 300 m at the PARFLUX E site (our analyses). Unsaturated fatty acids and wax esters in this trap were apparently degraded more rapidly than saturated acids and esters. On the other hand, sterenes and steroid ketones were generally absent from the plankton lipid but were abundant in the trap samples.

Details of food web dynamics, microbial transformations and biochemical reactions in the open ocean are poorly understood. However, it is apparent that many of the organic compounds we analysed are consumed (recycled and/or remineralized) in the mesopelagic layer in this part of the ocean. Only a few per cent of these compounds are associated with particles reaching the bathypelagic zone. Nevertheless, alterations of the composition of extractable organic matter on the sinking particles occur throughout the water column and significant amounts of labile organic material reach the sea floor. Many of the compositional changes we observed take place below the ~300 m depth below which Menzel[30] thought most organic compounds were refractory.

We cannot preclude that vertically migrating zooplankton were not entrapped in the mesopelagic sediment traps. However, it is unlikely that the flux maxima at 988 m for sterols, steryl esters, and triacylglycerols are due to such entrapment. Only in the 389 m trap did particles >1 mm contribute

Table 2 Composition of lipid classes in PARFLUX E sediment traps

Compound class	Range	Compound distribution
Hydrocarbons	C_{15}–C_{32}	n-C_{17}, C_{19} dominate all depths, CPI_{23-29} = 1.2–1.4 sterenes (such as, cholest-2-ene, 3,5-cholestadiene) abundant
Fatty acids	C_{14}–C_{26}	$C_{16:0}$*, $C_{18:1}$, $C_{18:0}$ dominate all depths†
		$C_{20:5}$, $C_{22:6}$—10–20% of total acids in mesopelagic traps, 1–2% in bathypelagic traps
		Iso, anteiso C_{15}, C_{17} minor (<2%) at all depths
Wax esters	C_{26}–C_{44}	$C_{34:1}$, $C_{32:1}$ dominate all depths (~75% of total wax ester at 389 m; ~50% at 988 and 5,026 m, 25% at 3,755 m depth)
		Fatty acids. C_{14}–C_{26}; $C_{16:0}$, $C_{22:0}$, $C_{18:1}$ major
		Fatty alcohols: C_{14}–C_{26}; $C_{16:0}$, $C_{18:1}$, $C_{16:1}$, $C_{18:0}$ major
Steroid ketones	—	Cholest-4-en-3-one dominates (>60% of total ketones in mesopelagic traps, ~35% in bathypelagic traps)
Amino acids	—	Typical planktonic amino acids in upper traps
(extractable)		Glutamic acid, aspartic acid, alanine, serine, glycine only in deeper traps suggesting bacterial input (?)
Free fatty alcohols	C_{12}–C_{24}	$C_{16:0}$, $C_{18:1}$, $C_{18:0}$, $C_{16:1}$ dominate
Free sterols	—	Cholest-5-en-3β-ol dominant sterol at all depths (95% of sterol distribution at 988 m; 20–50% in other depths)
		Cholesta-5,22(E)-dien-3β-ol, 24-methylcholesta-5,22(E)-dien-3β-ol, 4,23,24-trimethyl-5α-cholest-22-en-3β-ol abundant
Steryl esters	—	Fatty acids. 389 m $C_{16:0}$, $C_{18:0}$ major 988 m $C_{16:0}$, $C_{14:0}$, $C_{18:0}$, $C_{18:1}$ major
		Sterols: 389 m cholest-5-en-3β-ol (60%), cholesta-5,22(E)-dien-3β-ol, 24-methylcholesta-5,22(E)-dien-3β-ol, 5α-cholestan-3β-ol. 988 m cholest-5-en-3β-ol (85%), 5α-cholestan-3β-ol, cholesta-5,22(E)-dien-3β-ol
Triacylglycerols	C_{45}–C_{57}‡	C_{51}, C_{53}, C_{55}, C_{57} compounds predominate
		Fatty acids: 389 m $C_{18:0}$, $C_{18:1}$, $C_{16:0}$ major 988 m $C_{22:6}$, $C_{20:5}$ also dominant

* Shorthand notation denotes number of carbon atoms: number of double bonds.

† For each category, compounds are listed in order of decreasing relative abundances.

‡ Total carbon number (acyl carbons + glycerol carbons).

significantly to the flux of organic compounds (Table 1). Furthermore, at 988 m the individual molecular constituents of the sterol, steryl ester, and triacylglycerol fractions were vastly different compared with both shallower and deeper samples (Table 2). Two hypotheses may be proposed to account for these maxima. First, differences in biological communities populating this region of the water column may be responsible for the different inputs of these organic compound classes at depth compared to shallower than 389 m. Alternatively, organic matter produced in the euphotic zone may be compartmentalized and transported through 389 m, followed by the release of these compounds below the 389 m trap.

Our interpretations are constrained by the limited data set—a single set of samples from one location in the World's ocean. In addition, our lipid analyses account for only ~15–20% of the total organic flux. However, we are pursuing a better understanding of the cycling of organic matter in the oceans by continuing detailed organic analyses of particulate matter collected in sediment traps in both open ocean (North central Pacific) and coastal (Peru upwelling, Panama Basin, and coastal California) areas. Interpretation of all sediment trap results are complicated by questions of differential settling rates, resuspension of bottom sediments and horizontal transport processes, trapping efficiencies, and the potential for chemical and biochemical reactions after particles have been intercepted.

Several authors have focused on the measurement of total organic carbon associated with particles caught in sediment traps[2–5,8–10]. Our results, however, show for the first time that while total organic carbon fluxes in the deep ocean decrease only slightly throughout the water column, the composition of portions of this material changes dramatically. These changes reflect processes acting on the particles during transport through the water column, and they are important to the composition of the organic matter being deposited at the sediment–water interface.

The discovery of Lower Llandovery (Silurian) graptolites in Peary Land, near the top of the sequence in the central part of the North Greenland foldbelt, shows that the rocks in this sequence are mostly pre-Silurian. It also permits correlation of the lithostratigraphic units in the central foldbelt[1] with those on the margin[2] and on the unfolded platform to the south[3,4]. This places constraints on the timing of the Innuitian orogeny in North Greenland.

A 600 km long east–west trending Palaeozoic foldbelt forms the Arctic coastal area of North Greenland[3] (Fig. 1). The foldbelt continues to the west as the Innuitian mobile belt of the Canadian Arctic islands[5]. In Greenland the belt is up to 100 km wide and the degree of deformation and metamorphism increases from south to north[1]. The folded sequence includes Upper Precambrian to Lower Palaeozoic rocks of a northern clastic trough and the adjacent part of a southern carbonate platform.

The evolution of the platform–trough system started in the late Precambrian with the development of an incipient east–west trending trough. Faulting and subsidence continued through Cambrian, Ordovician and Silurian times. The trough was formed by rifting and the southern margin was controlled by major faults. The northern margin is not known in Greenland as it was probably situated under the present Arctic Ocean. The trough expanded in several episodes by southwards shift of the southern margin to new fault systems. During this process, the older fault systems became intrabasinal and largely inactive (Fig. 2).

The first Precambrian?–Cambrian phase of trough fill mainly comprised turbidites, dark mudstones, light lime mudstones and resedimented conglomerates (quartzite and Paradisfjeld Groups; Fig. 3) reflecting the incipient nature of the rift. Subsequently, Cambrian turbidite sedimentation reflects deeper water and a greater differentiation of shelf and trough. Transport was both lateral from south and north and longitudinal from the east. At the end of this phase turbidite sedimentation was punctuated by several episodes of conglomeratic gravity flows initiated on the platform margin and upper slope. The turbidites and conglomerates represent the Polkorridoren Group[1] and formation A (ref. 2) (Fig. 3).

The supply of coarser clastics dramatically decreased in the latest Cambrian, and the Ordovician was characterized by slow deposition of black mudstones and cherts, (bulk of the Sydgletscher Group[1] and formation B (ref. 2)) probably in a deeply submerged narrow rift. Thick resedimented conglomerates derived from the margin of the carbonate platform and the upper slope were deposited along the southern margins of the trough.

The transition from Ordovician to Silurian was marked by a new phase of turbidite sedimentation and a sequence several kilometres thick was deposited in the trough during the Silurian (formation C (ref. 2) and 'Un-named Silurian flysch formation'[4]). Silurian turbidites from eastern Peary Land to Hall Land (Fig. 1) were transported longitudinally from the east.

Contemporaneously, a variety of shallow marine limestones and dolomites with minor intercalations of terrigenous clastics were deposited on the platform to the south (Figs 2 and 3).

During the Llandovery–Wenlock transition the platform margin collapsed. The position of the new border fault is not precisely known, but in the Peary Land area the onlapping turbidite sequence can be followed several hundred kilometres to the south[6].

Silurian turbidite sedimentation was periodically interrupted by deposition of resedimented conglomerates derived from the upper slope and platform margin. The youngest preserved deposits of the North Greenland trough are turbidites and chert conglomerates.

Subsequently, orogenic deformation of the sequence is assumed to be of Devonian–early Carboniferous age[3]. Foldbelt strike is east–west parallel to the strike of the platform trough boundary. The southern margin of the foldbelt (Fig. 1) roughly coincides with this boundary and three major tectonic zones are recognizable in the Peary Land region. The platform carbonates are mainly undeformed whilst the trough clastics adjacent to the platform are folded. Northwards deformation increases and in Johannes V. Jensen Land the trough sediments are metamorphosed to amphibolite facies along the northern coast[1].

In the past, three independent stratigraphies have been put forward for each of these zones. To the south a comprehensive scheme covers the generally richly fossiliferous carbonates[3,4,7–9]. The overlying Silurian turbidite sequence is lithologically monotonous and poorly fossiliferous and has not received the same detailed study. However, three formations can be recognized, comprising a basal mainly shaly unit of Llandovery to Wenlock age, a middle sandy turbidite unit of Wenlock age and an upper conglomerate unit of Wenlock age (Fig. 3).

The sequence of the foldbelt margin was subdivided into three formations[2]. These include formation A, a sandy turbidite sequence capped by a major resedimented conglomerate unit. This is overlain by formation B, mainly a mudstone and chert sequence with wedges of resedimented conglomerate. Finally, formation C is the basal part of a major sandy turbidite unit. There are a few sporadic biostratigraphic dates from these sequences but there is no comprehensive zonation. Formation A is bioturbated in several horizons and it is underlain by units containing abundant trace fossils. The base of formation B contains graptolites of earliest Ordovician (early Canadian) age[10]. Consequently, formation A is probably Cambrian age throughout. Formation B has yielded graptolite faunas from the lower half indicating an early to middle Ordovician age. The graptolites *Climacograptus miserabilis* Elles & Wood and *Orthograptus* sp., resembling *O. quadrimucronatus* (Hall) indicating a late Ordovician (Cincinnatian) age, have been

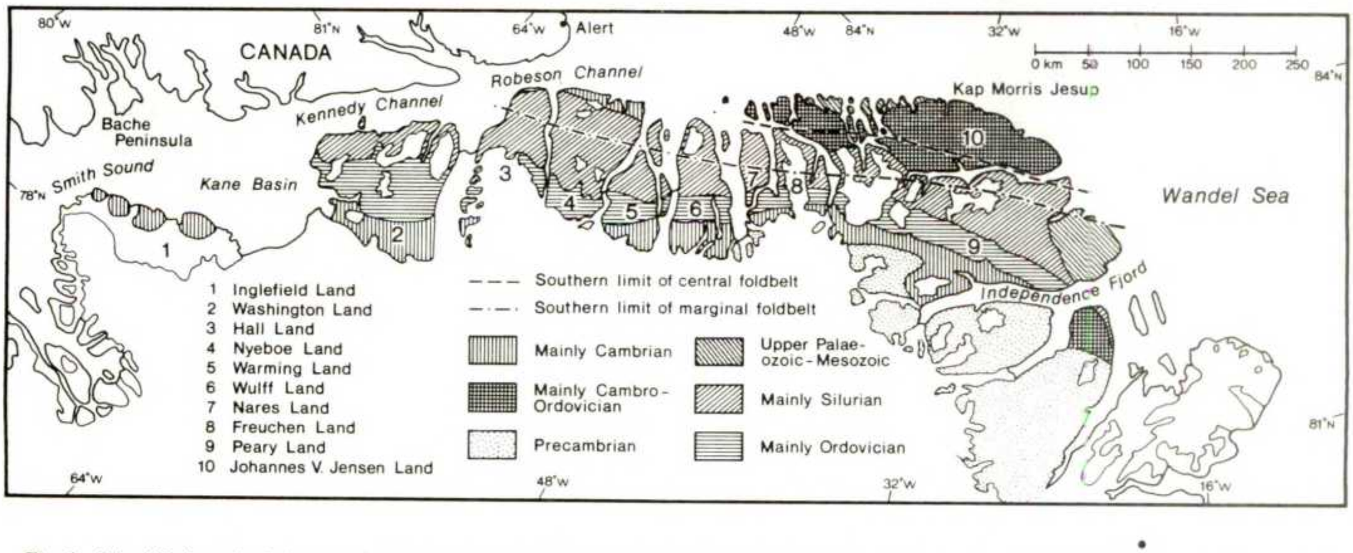

Fig. 1 Simplified geological map of North Greenland. Based on refs 3, 8 and unpublished observations. The southern limit of the central foldbelt corresponds to the Harder Fjord fault. The southern limit of the marginal foldbelt roughly corresponds to the Navarana Fjord fault.

obtained from the top of formation B. Formation boundaries are diachronous particularly between formations B and C, which fall within the Upper Ordovician to Lower Silurian range.

Until now, no age-diagnostic fossils have been obtained from the central part of the foldbelt, but unidentifiable graptolite fragments were reported from the upper part of the sequence[1]. The first lithostratigraphic scheme for this area[11] was subsequently revised[1] and comprises three groups subdivided into informal formations (Fig. 3). A fourth group was recognized[12] in 1979. These comprise from below: an un-named quartzite group, and the Paradisfjeld, Polkorridoren and Sydgletscher Groups[12]. Previously, correlation between the three independent stratigraphic schemes of the central foldbelt, foldbelt margin and unfolded carbonates and clastics to the south was speculative. This was due to lack of faunas and to lateral facies changes.

Two formations were recognized in the Polkorridoren Group[1], of which the upper characteristic turbidite unit was tentatively correlated with formation C of the foldbelt margin and the Silurian turbidites of the unfolded areas to the south[3]. This correlation was based primarily on lithological resemblance. By implication the overlying Sydgletscher Group was assumed to be of late Silurian to Devonian age[2,3]. This group which is more than 1 km thick is divided into five formations[1,12]. An assemblage of graptolites was found 142 m above the base of the penultimate formation, termed upper Sydgletscher shales (3d)[1]. These graptolites, the first age-diagnostic fossils derived from the central part of the foldbelt (Fig. 4), provide a correlation link with areas to the south, considerably revising earlier schemes.

The graptolites appear as flattened carbon films with inconspicuous thecal structures and some are tectonically compressed. The material comprises about 10 incomplete biserial and 15 monoserial fragments. Three specimens can be referred to *Climacograptus rectangularis* (M'Coy)? and four monoserial fragments to *Atavograptus* aff. *atavus* Jones (Fig. 4). *C. rectangularis* has generally been reported from the *atavus* to *cyphus* Zones of the Lower Llandovery[13] and recently at least up to the *triangulatus* Zone[14]. *A. atavus sensu lato* has been reported from the *atavus* to *magnus* Zones[13]. However, *A.* aff. *atavus* is very similar to specimens described from the *atavus* Zone of Bornholm[15] and the sample is probably referable to a stratigraphical level around the *atavus–cyphus* Zones in the Lower Llandovery.

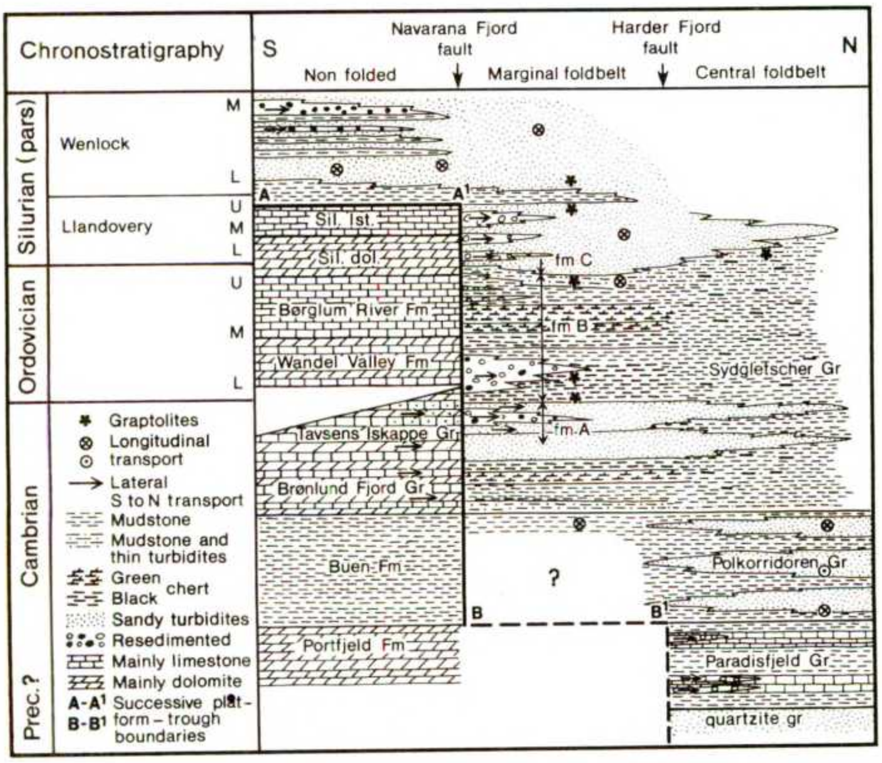

Fig. 3 Stratigraphy and facies distribution of a north–south transect through the Lower Palaeozoic carbonate platform–clastic trough system of Peary land. Based on refs 1, 4, 22 and unpublished observations.

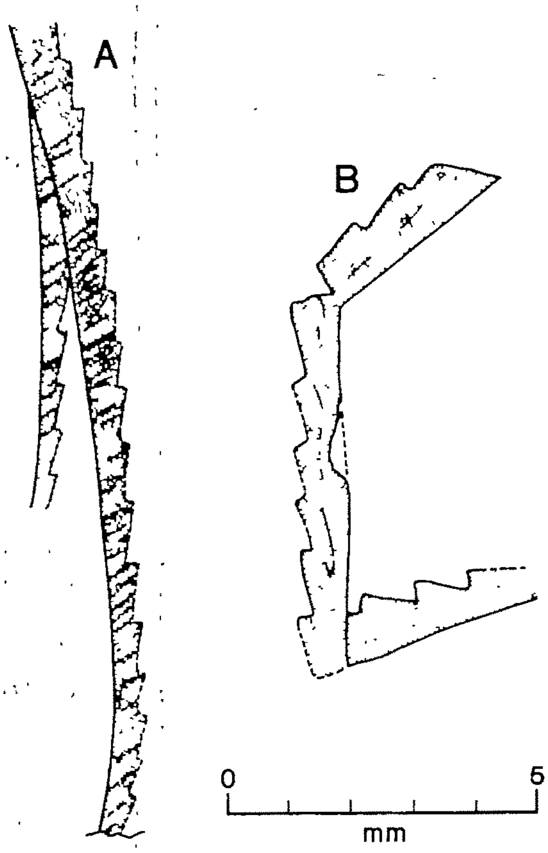

Fig. 4 First age diagnostic fossils from the central North Greenland foldbelt. *a*, *Atavograptus* aff. *atavus* (Jones). Two proximal fragments. *b*, *Atavograptus* aff. *atavus*. One distal fragment. Both specimens are from the upper Sydgletscher shales. MGUH 15077 and MGUH 15078. GGU sample 230273.

This indicates the bulk of the Sydgletscher Group is of pre-Lower Llandovery, *atavus* Zone age, and thus mainly of Ordovician age and that it is broadly contemporaneous with formation B of the foldbelt margin (Fig. 3). The correlation between the Sydgletscher Group and formation B is strongly supported by lithological evidence as both units are characterized by black cherts and mudstones. The graptolite-bearing formation is overlain by a several hundred metres thick formation consisting of extremely thick turbidite beds. Individual beds are structureless and reach thicknesses of 30 m suggesting a rapid depositional rate for the formation.

This formation is the youngest rock unit of the central foldbelt and it is unlikely to be much younger than early Llandovery.

The three stratigraphic schemes used to describe the trough sediments of the central foldbelt, foldbelt margin and unfolded area can now be combined into a single stratigraphic scheme (Fig. 3). The scheme which is informal, shows the main facies types and their spatial distribution. A formal comprehensive stratigraphy will be published elsewhere.

In spite of the new biostratigraphic data, it is still difficult to date precisely the orogenesis. The youngest folded rocks within the central foldbelt are of Llandovery or only slightly younger age. Towards the south and west in the marginal parts of the foldbelt, the top part of the Silurian turbidite sequence yields graptolites of Ludlow (late Silurian) age (our unpublished observations). The presence of earliest Devonian has been suggested for a single locality in western Hall Land on the basis of one specimen of the graptolite *Monograptus* cf. *aequabilis*[16]. It was recently reidentified by Jaeger (personal communication) as *Monograptus* cf. *transgrediens* Perner and probably of Pridoli (latest Silurian) age. The graptolite bed was overlain by strata containing alleged Devonian vertebrates[17] assigned a Devonian age partly on the basis of the underlying graptolites. There is thus no evidence of Devonian rocks in North Greenland.

In eastern Peary Land the folded sequences are overlain with angular unconformity by Upper Pennsylvanian and younger rocks[3,18–20]. Reliable isotopic ages have not yet been obtained. Therefore, the diastrophism can only be loosely dated as Devonian to early Pennsylvanian. Comparison with Arctic Canada fails to yield more definitive evidence regarding time of diastrophism. In Ellesmere Island the most extensive and intensive deformation in the history of the Innuitian mobile belt commences not later than middle Devonian and was completed before the late early Pennsylvanian[21].

Structure of supernumerary limbs

M. Maden

The National Institute for Medical Research, Mill Hill,
London NW7 1AA, UK

The generation of supernumerary limbs by rotation of amphibian limb buds or regeneration blastemas is a phenomenon well known to embryologists[1,2]. The recent revival of interest in this aspect of limb morphogenesis has been largely due to the stimulus provided by the polar coordinate model for control of limb outgrowth and pattern[3] and subsequent efforts to test its validity. The geometrical rules postulated in the polar coordinate model make precise predictions about the handedness of supernumerary limbs. Following antero-posterior (AP) or dorso-ventral (DV) inversions, they should be of the same handedness as the stump, whether single or in pairs, but after inversion of both axes (APDV) pairs should be of opposite handedness[3]. It is surprising, therefore, that the structure of supernumerary limbs has never been studied in sufficient detail to report whether they really are normal limbs, for only the skeletal elements are examined in cleared whole mounts (see Fig. 1). This only allows an assessment of the AP axis, and to determine the dorsal and ventral surfaces (and hence the handedness), the curvature of the digits is noted. I therefore decided to study the muscle patterns of all types of supernumeraries, and report here that, contrary to expectation, the majority of APDV supernumeraries are not normal limbs but are mirror-image duplications in the dorso-ventral axis, that is, either double-dorsal or double-ventral. This presents problems for contemporary models of pattern formation in the limb, and issues a warning to those who use supernumerary limbs as an experimental tool to investigate other areas of developmental biology.

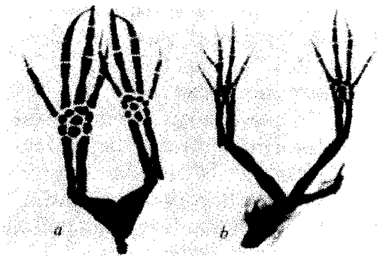

Fig. 1 *a*, Supernumerary limb generated by grafting a left blastema to a right stump. On the left is the right graft, on the right the perfect right-hand supernumerary limb which appeared at the posterior pole of the stump and bifurcates in the stylopodium. *b*, Supernumerary limb generated by rotating a right blastema 180° and replacing it on the same stump. On the right is the graft, on the left the supernumerary which appeared at the dorsal pole of the stump and bifurcated in the stylopodium. The similarity between this supernumerary and that in *a* is striking and it would normally have been identified as a left limb. In fact, on sectioning it was discovered to be double-ventral in structure (see Figs 2*c*, 3*e*). Victoria blue staining.

The experiments were carried out on young *Ambystoma mexicanum*, 80–140 mm long, whose limbs had been amputated through the mid-stylopodium level. At the late cone/early palette stage, blastemas were cut off and either placed on the contralateral stump (AP or DV inversions) or replaced upside down on the same stump (APDV rotations). Such grafted blastemas continue their own development into normal limbs as well as participating in the generation of supernumerary limbs at the graft–stump boundary. When they had fully developed, the muscle patterns of 20 of these grafts were examined and they revealed a completely normal anatomy[4]. The most characteristic features of normal limbs are to be found at the carpal and digit level, where the dorsal extensors have separated into four crescent-shaped muscles, the extensores digitorum breves (Fig. 2*a*). The flexors, comprised of about 16 separate muscles[4], form a large mass of tissue on the ventral surface of the hand which in the digits, splits into four semi-circles of muscle (Fig. 2*a*). A three-dimensional reconstruction of the normal muscle pattern (Fig. 3*a*) shows that the sparser dorsal muscles terminate in the metacarpals (tendons travel distally to the tips of the digits) whereas the ventral muscles themselves extend right to the last phalanx.

The first series consisted of 11 limbs whose AP axis had been reversed, yielding a total of 12 supernumeraries. Ten limbs developed single supernumeraries, all at the posterior side of the host limb (Fig. 1*a*), and one a double supernumerary (Table 1). It is interesting that this striking bias towards the production of supernumeraries at the posterior pole after upper arm inversions is also apparent from other studies[5,6], but it disappears when blastemas from the lower arm are inverted. All the supernumeraries produced in this series were perfect limbs whose digits curved ventrally and from an examination of the skeletal structure (Fig. 1*a*) would be considered normal limbs. Analysis of the muscle patterns of each of these 12 supernumeraries confirmed that they were indeed completely normal (Fig. 3*b*, Table 1) and that all were of stump handedness.

The second series comprised seven limbs whose DV axis had been reversed. This yielded a total of 10 supernumeraries, 4 single and 3 double (Table 1). These were more equally distributed between the two poles than in the previous series–55% dorsal, 45% ventral. One was slightly displaced in the antero-dorsal quadrant. Apart from their position, these supernumeraries were in every respect identical to those in the first series and an analysis of the muscle pattern confirmed that they were completely normal limbs (Fig. 3*c*, Table 1). Again, they were all of stump handedness.

The third series comprised 12 blastemas rotated 180° (APDV). These were a group of limbs from a previous series[7] and were selected for analysis here because of a good separation of graft and supernumerary(ies). For instance, the example shown in Fig. 1*b* bifurcates in the humerus. Eight limbs had single supernumeraries and four had double supernumeraries, making 16 in all, whose position of origin was random (Table 1). These all looked normal when stained with Victoria blue (Fig. 1*b*) although in some cases their digits did not curve. An analysis of their muscle patterns revealed that 5 of the 16 (Table 1) had at the carpal level separate crescent-shaped extensores digitorum breves both dorsally and ventrally (Fig. 2*b*), terminating at the metacarpals. These limbs had no ventral flexor muscles extending to the tips of the digits and were thus identified as double-dorsal limbs. The three-dimensional reconstructions supported this conclusion (Fig. 3*d*). A further six supernumeraries had an uncharacteristically excessive amount of muscle on their dorsal surfaces which did not separate into small crescent-shaped elements (Fig. 2*c*). Instead of the dorsal muscles terminating in the metacarpals, they continued to the end of the digits and, together with the normal ventral muscles, formed thick circles of muscle surrounding each digit (Fig. 2*c*). These limbs were thus identified as double-ventral (Fig. 3*e*, Table 1). The third category of APDV supernumeraries contained five limbs which were completely normal (Fig. 2*d*, Table 1).

Thus, the AP and DV supernumeraries examined here were normal in every respect and were of stump handedness as had been previously supposed. In contrast, the APDV supernumeraries had an equal chance of being double-dorsal, double-

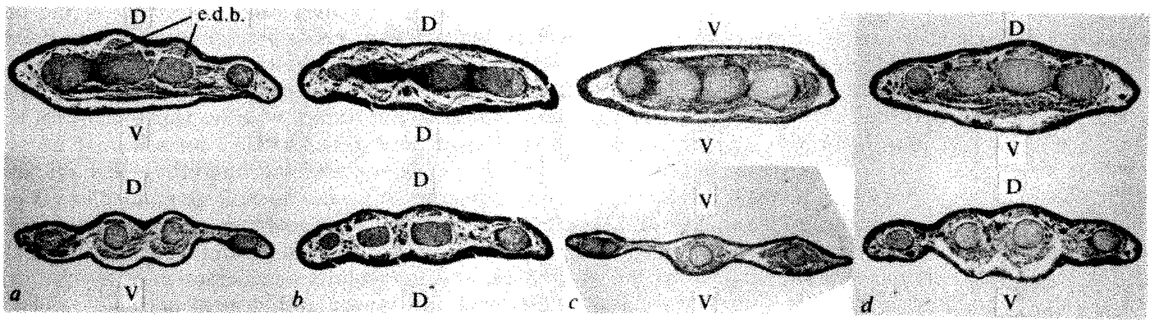

Fig. 2 Sections through the carpal/metacarpal level (upper sections) and distal metacarpal level (lower sections) of various types of limb. Stained with haematoxylin and eosin. The dorsal (D) and ventral (V) surfaces are marked. *a*, A limb which developed from a grafted blastema. This shows completely normal muscle patterns[4]. In the upper section note that the first (left) and fourth (right) digit extensors have already terminated, leaving only those of the second and third digits (e.d.b.). These are crescent-shaped and sit on the flat tops of the basal carpals. The ventral flexor muscles extend right across the hand and are composed of about 16 separate muscles[4]. The lower section through the digits shows the ventral muscles separated into large semi-circles. ×175. *b*, An APDV supernumerary. Clearly, the muscle patterns have mirror-image symmetry, as small, crescent-shaped muscles appear at the top and bottom of the limb. This is a double-dorsal limb, the three-dimensional reconstruction of which is shown in Fig. 3*d*. Note also that, particularly in the lower section, the cartilages seem to be mirror-images—both surfaces of the middle two elements are flat-topped. ×168. *c*, Another type of APDV supernumerary. As in *b* the muscles are mirror-images and in the digits they form complete circles of muscle around the phalanges. This is a double-ventral limb, the three-dimensional reconstruction of which is shown in Fig. 3*e*. Again, particularly in the upper section, the carpals appear mirror-images. ×120. *d*, Another type of APDV supernumerary. This, in contrast to the previous two, was a completely normal limb (compare with *a*). ×190.

ventral or normal. As emphasized above, only well separated, four-digit supernumeraries were selected for study and the typical hypomorphic structures produced in any series of rotations—spikes, fused supernumeraries or ones with fewer digits than normal—were ignored. These are clearly abnormal in the AP axis and perhaps also in the DV axis. Furthermore, it may well be that other classes of APDV supernumeraries will be found, those appearing at frequencies of less than 1 in 16, and this possibility is now being investigated. Nevertheless, the generation of mirror-image limbs has two significant implications for theories of pattern formation. First, it adds to the growing body of results which present severe difficulties for the polar coordinate model and is contrary to the prediction that pairs of APDV supernumeraries should be of opposite handedness. The concept of handedness is meaningless when applied to mirror-image limbs, and pairs were not even of opposite mirroring (Table 1). The only other model which attempts to describe the generation of supernumerary limbs in such detail is the serial threshold model[8], which ascribes the formation of mirror-image limbs to different rates of intercalation in each of the three axes. However, theories based solely on local cell–cell interactions cannot, at their present stage of development, provide a satisfactory explanation for the appearance of APDV supernumeraries because, whatever their structure, there will always be large areas of gross discrepancy either between the supernumerary and the stump or between the supernumerary and the blastema. This problem is not solved by the discovery of mirror-image limbs because a double-dorsal limb at, say, the dorsal pole of the stump will abut directly on to the ventral pole of the rotated blastema. This should, according to local intercalation rules, generate more supernumeraries *ad infinitum*. Clearly, such simplistic descriptions cannot explain these phenomena and new models must be devised which incorporate more global field constraints.

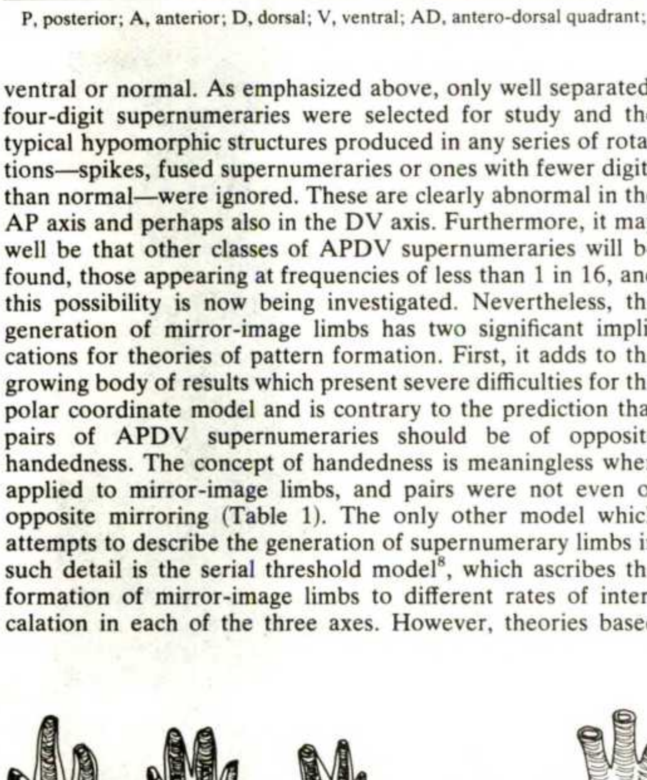

Fig. 3 Three-dimensional reconstructions of muscle patterns from serial sections of various limbs. Every 10th section was drawn with a camera lucida. These drawings were then projected 1 cm apart on to another piece of paper and the surface configurations of the muscles were then drawn. Each reconstruction drawn above is to the same scale to show the variation in proximo-distal extent of muscles. They are all viewed from the dorsal (extensor) surface with flexors underneath and all have a break in the wrist to help visualize their internal structure. *a*, Grafted limb. The blastema, grafted at the late cone/early palette stage, develops into a normal limb despite having at least one axis inverted relative to the stump. The dorsal extensor muscles (dotted) terminate at the carpal/metacarpal level whereas the ventral flexor muscles (cross-hatched) continue to the ends of the digits. This is the normal muscle pattern in the axolotl forelimb[4]. *b*, An AP supernumerary limb. This shows the same features as *a*—short extensors (dotted), long flexors (cross-hatched). *c*, A DV supernumerary limb showing normal muscle patterns as in *a* and *b*. *d*, An APDV supernumerary. In this case, the ventral muscles (clear) do not extend to the tips of the digits, but form a mirror-image pattern of the dorsal muscles (dotted) and terminate at the carpal/metacarpal level. This is a double-dorsal limb, the histology of which is shown in Fig. 2*b*. *e*, An APDV supernumerary. Here both dorsal (cross-hatched) and ventral muscles are much more profuse; they continue to the tips of the digits and form complete circles of muscle. This is a double-ventral limb, the histology of which is shown in Fig. 2*c*.

These present results also suggest that deterministic models be replaced by those with a more probabilistic nature, however unsatisfying this may be. The polar coordinate model is a highly deterministic model in which the cells can only show one particular behaviour following one particular experimental interference. The result is a strict series of predictions. This is clearly not the case for APDV supernumeraries; each class of structure—double-dorsal, double-ventral or normal—had an equal chance of appearing. This probabilistic concept has been considered previously in connection with the induction of supernumeraries at angles of rotation other than 180° (ref. 7). Further work has revealed a frequency distribution in which the angle of rotation is directly related to the likelihood of supernumerary induction[9].

It is to be hoped that this finding of mirror-image supernumeraries is a universal phenomenon in both regeneration and development. In support of this, I have carried out 180° rotations of developing limb buds in *Rana temporaria* and nearly all of the supernumeraries so generated were double posterior in structure. This may indicate that the plane in which APDV supernumeraries are duplicated is species dependent, but that the general principle remains the same. If this is so, it has implications for the other developing system commonly studied, the chick limb bud. It means that a graft of the zone of polarizing activity (ZPA) in normal dorso-ventral orientation (equivalent to an AP inversion) should generate a different type of reduplicate from a ZPA graft with reversed dorso-ventral orientation (equivalent to an APDV rotation). How current models of ZPA activity can cope with this situation remains to be seen.

I thank Katriye Mustafa for technical assistance in all aspects of this work.

A one-dimensional pattern in the cellular slime mould *Polysphondylium pallidum*

F. W. Spiegel & E. C. Cox

Department of Biology, Princeton University, Princeton, New Jersey 08544

The cellular slime mould *Polysphondylium pallidum* has a fruiting body with whorls of branches spaced at regular intervals along the stalk (Fig. 1). The spacing between successive whorls is quite regular and under genetic control[1]. Because stalk cell number per interval correlates strongly with interval length, we have studied the influence of ploidy on the distance between whorls to determine if cell counting could account for the spacing. It is known that diploid spores and amoebae of *Dictyostelium discoideum* and *Polysphondylium violaceum* are roughly twice the size of their haploid parents[2,3], and we find that stalk cells in *P. pallidum* follow the same pattern. Our results show that the number of stalk cells between successive whorls in haploids is approximately twice the number in diploids, while the spacing remains the same. This clearly indicates that spacing is not achieved by a cell counting mechanism. Instead, it appears to depend on distance.

Cells were grown and diploids were constructed by previously published methods[3] using genetically marked parent strains. In every case diploid clones were shown to segregate the appropriate recessive genetic markers. Two- to three-day-old fruiting bodies cultured on water agar in the presence of activated charcoal were either photographed directly (Fig. 1) or trapped under a cover slip for photography at higher magnification (Fig. 2). Figure 1 compares developing and mature diploid fruiting bodies to the two haploid parents. It is quite clear that whorl spacing in diploids is very similar to that in haploids. Quantitative measurements of large numbers of sorocarps bear out this impression: spacing in five independently isolated diploids is indistinguishable from the haploid parents (Table 1).

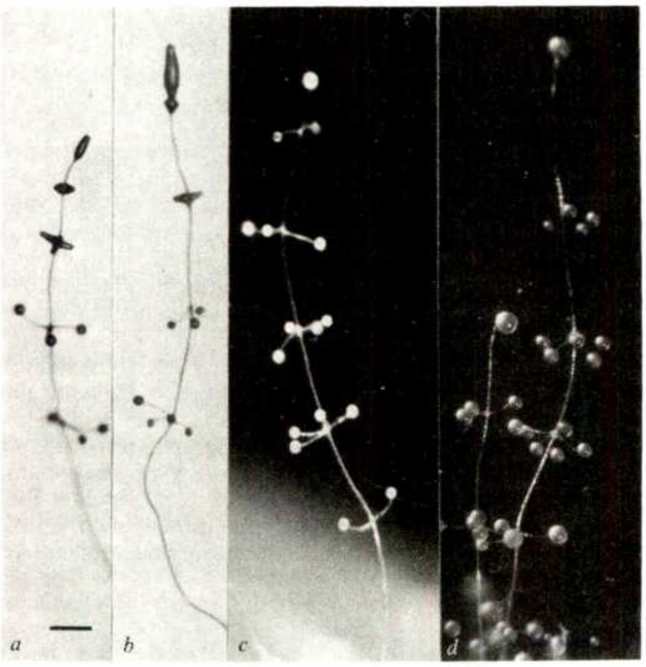

Fig. 1 Comparison of haploid and diploid *Polysphondylium pallidum* fruiting bodies. *a*, Culminating sorogen of haploid PN519; *b*, culminating sorogen of diploid 95a; *c*, mature sorocarp of haploid PN525; *d*, mature sorocarp of diploid 95a. The larger sori in *d* are the result of absorption of water in humid culture conditions. Scale bar, 100 μm.

The most striking feature of whorl spacing in diploid sorocarps is that spacing does not depend on a cell counting mechanism. This conclusion follows from the results shown in Fig. 2 and Table 1. It is qualitatively evident from Fig. 2 that the number of cells between whorls is larger in the two haploid parents than in diploid progeny, even though the distance between whorls is very similar. This impression is borne out by the detailed quantitative measurements summarized in Table 1. The average number of cells per interval in the haploid strains PN519 and PN525 is almost exactly twice the number in the diploid isolates 95a to 95e, while the cell length is approximately one half. The size and shape of diploid spores, shown clustered about the stalks in Fig. 2, bears the same relationship to haploid spore shape in *P. pallidum* as it does in *D. discoideum* and *P. violaceum*[2,3].

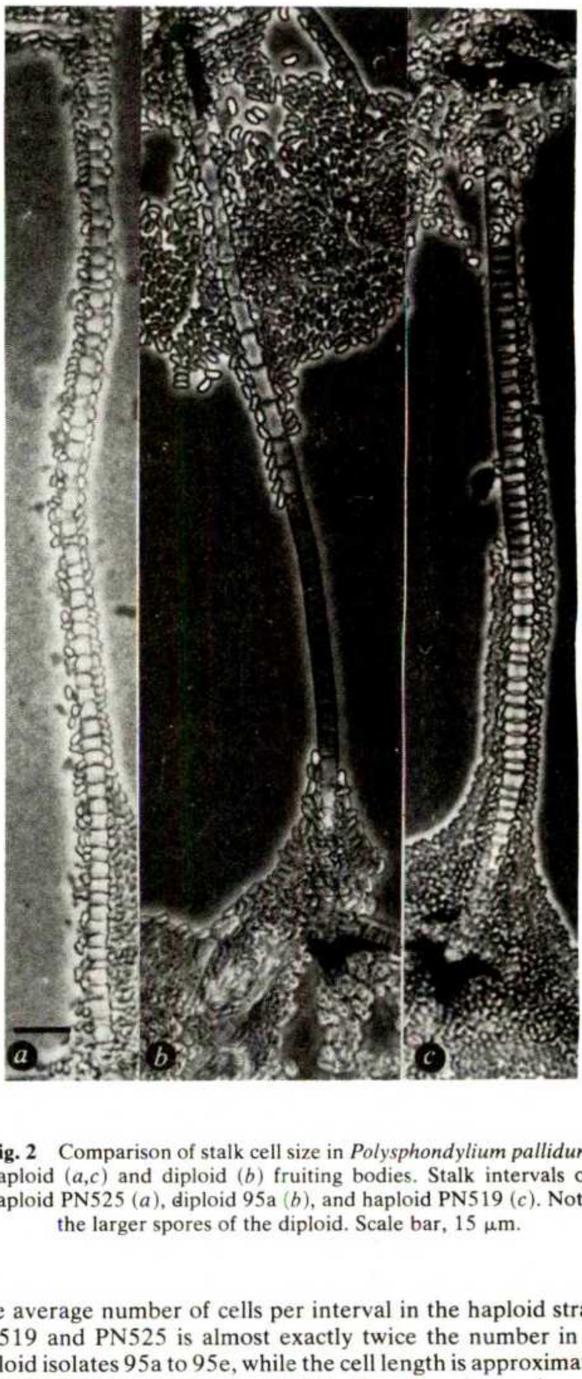

Fig. 2 Comparison of stalk cell size in *Polysphondylium pallidum* haploid (*a*,*c*) and diploid (*b*) fruiting bodies. Stalk intervals of haploid PN525 (*a*), diploid 95a (*b*), and haploid PN519 (*c*). Note the larger spores of the diploid. Scale bar, 15 μm.

These results thus eliminate one simple hypothesis that is *a priori* appealing, and suggest that whorl spacing depends on

0028–0836/80/340806—02$01.00

some mechanism other than cell counting. They are reminiscent of the effect of increasing ploidy on cell number in amphibians, where animals maintain their size and shape by using fewer, larger cells[4]. *P. pallidum* is unlike many higher plants, however, which tend to become proportionately larger following an increase in ploidy[5,6], and unlike bristle spacing along *Drosophila melanogaster* basitarsi, where spacing mechanisms seem to depend on the number of cells in normal diploid and intersex triploids[7].

Table 1 Interval length between whorls and cell number per interval in haploid and diploid strains of *P. pallidum*

Strain	Ploidy	Average interval length (μm)	Average cell number/interval	Average cell length/interval (μm)
PN519	*n*	374 (110)	45.7 (18.5)	8.7 (2.2)
PN525	*n*	354 (79)	40.4 (14.0)	9.5 (2.7)
95a	2*n*	350 (99)	18.4 (8.1)	20.7 (5.8)
95b	2*n*	319 (100)	20.5 (8.0)	16.7 (4.7)
95c	2*n*	349 (87)	21.4 (9.7)	18.1 (5.3)
95d	2*n*	358 (97)	20.5 (7.5)	18.8 (5.3)
95e	2*n*	304 (91)	18.8 (8.3)	17.4 (4.8)

Comparison of interval length between whorls, stalk cell number per interval, and stalk cell length between haploid and diploid strains of *P. pallidum*. A minimum of 100 intervals on a minimum of 20 sorocarps was counted for each strain. Diploids 95a–e were constructed from the parents PN519 and PN525[3]. Values shown in parentheses represent ± s.d.

The developmental history of each whorl in *P. pallidum* is complex. Stalk cells are laid down apically as the sorogen ascends the elongating stalk. At regular intervals masses containing variable numbers of cells pinch off basally from the ascending sorogen (this may be seen clearly in Fig. 1*a*). These cells differentiate into whorls with varying numbers of arms, each arm bearing a terminal sorus of spores[8,9]. The timing of these events clearly determines the spacing frequency. We have determined[1] that the control of spacing in *P. pallidum* is as well defined as heterocyst spacing in the prokaryote *Anabaena cylindricata*[10], even though the distances over which the spacing mechanism must operate are roughly an order of magnitude larger in *P. pallidum*, because spacing mutants can be isolated in *P. pallidum* (our unpublished data). Since a facile genetic system is available[11], and because the spacing may be altered by physiological manipulation[9,12], it may be possible to analyse in some detail the genetic and physical basis for whorl spacing in this simple eukaryote.

We thank David Francis for supplying the genetic stocks used in this study. This work was supported in part by a grant to the Biology Department by the Whitehall Foundation and by USPHS grants AI09392 and CA09167.

Induction of abnormal development and differentiation in cultured mammary glands by cyclic adenine nucleotide and prostaglandins

Frederick V. Schaefer, R. Philip Custer & Sam Sorof

Institute for Cancer Research, Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111

Squamous (epidermoid) metaplasia is a common abnormality of development and differentiation, in which various epithelia are replaced by cells resembling those of the epidermis. The metaplastic cells differentiate into flattened cells that frequently form keratotic flakes and whorls. The cells may regress, remain benignly squamous, or progress to epidermoid carcinoma[1]. Squamous metaplasias have previously been brought about by mechanical injury[2], vitamin A deficiency[3,4] and chemical carcinogens[5–7]. In search of the physiological mediators of abnormal development and differentiation in oncogenesis, we have now discovered that the combination of dibutyryl cyclic AMP, prostaglandins (PGs) E_1, E_2 and B_1, and papaverine (Pap) induces squamous metaplasia with keratin production in the epithelium of cultured mammary glands. The three inducers may act synergistically to elevate the level of intracellular cyclic adenine nucleotide. Removal of these inducers causes the regression of the metaplastic cells. Retinoid does not block the induction of this squamous metaplasia, even though retinoid has previously prevented and reversed the squamous metaplasias caused by vitamin A deficiency or chemical carcinogens in other organs[4,8]. The findings suggest that cyclic adenine nucleotide and the PGs may mediate the squamous metaplasias present in many abnormal, transformed and malignant tissues, and possibly also the normal development and differentiation of epithelia into keratin-producing, stratified squamous cells, as in skin.

The mouse mammary gland can now be manipulated to undergo three courses of development and differentiation *in vitro*. First, normal development and differentiation of mouse mammary glands can be induced in culture[7,9,10]. The glands of hormonally primed female BALB/c mice, 3 to 4 weeks old, consist mainly of ducts with numerous terminal buds. When cultured in serum-free medium containing insulin (I), prolactin (P), aldosterone (A) and hydrocortisone (H), the glands develop lobuloalveoli[7,9,10] and produce casein[11]. Removal of all hormones except I (regression medium) brings about alveolar involution[7,10]. Such mammary glands exhibit no metaplasia (series 1 and 2, Table 1). Subsequent incubation with epidermal growth factor and IPAH induces a second lobuloalveolar development, which can again be involuted in the regression medium[12]. All these processes resemble those that normally occur *in vivo*.

Second, the epithelial cells of the cultured mammary glands can also be transformed by chemical carcinogens, as evidenced by the production of nodule-like alveolar lesions that have escaped the hormonal controls of alveolar development[7,13–15]. The transformed glands are dysplastic, metaplastic[7,15] and tumorigenic[14]. In contrast, chemically analogous noncarcinogens have little or no transforming activity[7,16]. Retinoid can prevent, suppress and apparently reverse the transformations caused by procarcinogens[15,17], which require metabolic activation to become reactive, but not the transformations brought about by many activated carcinogens[17].

A third course of development and differentiation is reported here. The combination of three agents (dibutyryl cyclic AMP, specific PGs and Pap) induces an extensive stratified squamous cell metaplasia with keratin production in cultured mammary glands (Fig. 1). Fresh whole mammary glands of hormonally

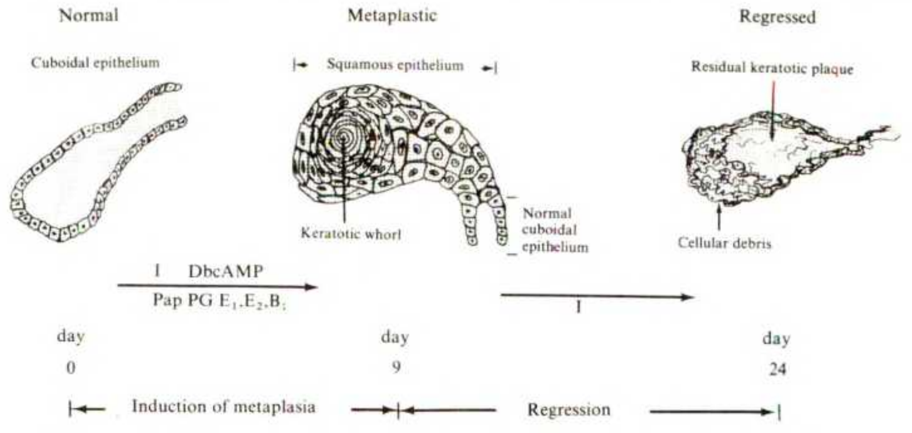

Fig. 1 Abnormal development, differentiation and involution in mouse mammary glands in culture: induction of squamous metaplasia and keratin production by cyclic adenine nucleotide, PGs and Pap. The serum-free whole organ culture system has been described[7,9,10]. Female BALB/c mice, 3–4 weeks old, were primed by subcutaneous injections of β-oestradiol (1 μg) and progesterone (1 mg) for 9 consecutive days. On the day following the last injection (day 0), mice were killed and their entire second thoracic mammary glands were excised and floated in medium on Dacron rafts in 95% O_2 and 5% CO_2 atmosphere. Serum-free keratinizing medium consisted of Waymouth MB752/1 medium (1 ml per gland), 350 $\mu g\,ml^{-1}$ L-glutamine, 35 $\mu g\,ml^{-1}$ penicillin G, and the supplements, dibutyryl cyclic AMP (DbcAMP) (10^{-4} M), Pap (10^{-6} M), (both Sigma), and I (5 $\mu g\,ml^{-1}$ (Calbiochem). 'Enhancing medium' consisted of the keratinizing medium with additions of PGE_1, PGE_2 and PGB_1 (each 5 $\mu g\,ml^{-1}$) (Upjohn). On day 9, the mammary glands exhibited extensive squamous metaplasia and deposits of keratin. Maintenance of the glands for an additional 15 days (days 9–24) in 'regression medium', containing I (5 $\mu g\,ml^{-1}$) as the only supplement, caused the metaplastic foci to involute. Media were renewed every 2 or 3 days as required. Glands were coded, fixed, sectioned at 5 μm, and stained with haematoxylin and eosin for histological analysis, and by Masson's trichrome method for histochemical detection of keratin (bright red colour).

primed BALB/c mice were cultured for 9 days in serum-free 'keratinizing medium', containing dibutyryl cyclic AMP (10^{-4} M), Pap (10^{-6} M) as a phosphodiesterase inhibitor[18], and I (5 $\mu g\,ml^{-1}$). Most (62%) of the mammary glands developed a few foci of epidermoid metaplasia (intensity grade 1) that often differentiated to form keratin (series 3, Table 1). Further, when this medium was supplemented with a mixture of PGE_1, PGE_2 and PGB_1, each at 5 $\mu g\,ml^{-1}$ (enhancing medium) in series 4, there was considerable enhancement of the ability of dibutyryl cyclic AMP to induce the squamous development and differentiation of the epithelium that lined both the mammary ducts and alveoli (Fig. 2*a*,*b*). Virtually all glands (99%) contained numerous foci of metaplasia with central cornification and keratin plaques (intensity grade 4). Mitotic figures were present in both the metaplastic and normal epithelial cells. All three PGs were necessary for maximal effect. Lowering the concentration of each PG to 1 $\mu g\,ml^{-1}$ still invoked the epidermoid metaplasia in all glands, although the foci were fewer and smaller (grade 1–2, not shown). The addition of a mixture of PGF_1 and $PGF_{2\alpha}$, each at 5 $\mu g\,ml^{-1}$, to the keratinizing or enhancing medium did not augment the effect (series 5).

The induction of the epidermoid metaplasia specifically required the presence of cyclic adenine nucleotide. Dibutyryl cyclic GMP at the same concentration (10^{-4} M), or sodium butyrate (cleavage product of dibutyryl cyclic AMP) at twice that concentration, failed to replace the dibutyryl cyclic AMP of enhancing medium (11% and 0% frequencies, respectively; series 6 and 7). Cyclic AMP or 5' AMP had little activity compared to the more lipophilic dibutyryl cyclic AMP; they required the three PGs to reach the level of activity exhibited by the dibutyryl cyclic AMP without PG in keratinizing medium (series 8 and 9). Omission of both dibutyryl cyclic AMP and Pap from enhancing medium caused complete loss of activity in the control series 10 (Fig. 2*c*). A modified enhancing medium lacking only dibutyryl cyclic AMP was partially active (30%, intensity grade 1), presumably because of an inhibition of degradation of endogenous cyclic AMP by Pap (series 11). Comparison of results of series 7 and 11 indicates that the presence of sodium butyrate was mildly inhibitory. The high frequency (100%) and intensity (grade 4) of metaplasia following deletion of Pap from enhancing medium are consistent with the presence of only a low level of endogenous cyclic AMP phosphodiesterase activity in the glands (series 12). The use of IPAH medium or the omission of all supplements except I (regression medium) resulted in no metaplasia (series 1 and 2). Mammary glands of mice not hormonally primed yielded an intermediate level of squamous metaplasia in enhancing medium (each of 26 glands, intensity grade 2).

Table 1 Induction of epidermoid metaplasia in cultured mammary glands

			Metaplastic glands	
Series	Treatment*	No. of glands	Frequency† %	Intensity grade‡
1	I+P+A+H	30	0	0
2	I	30	0	0
3	Dibutyryl cyclic AMP+Pap+I (keratinizing)	31	62	1
4	Dibutyryl cyclic AMP+Pap+I+PGE_1, E_2, B_1 (enhancing)	114	99	4
5	Dibutyryl cyclic AMP+Pap+I+PGE_1, E_2, B_1, $F_{1\alpha}$, $F_{2\alpha}$	34	100	4
6	Dibutyryl cyclic GMP+Pap+I+PGE_1, E_2, B_1	27	11	1
7	Sodium butyrate+Pap +I+PGE_1, E_2, B_1	16	0	0
8	Cyclic AMP+I+ PGE_1, E_2, B_1	21	52	1
9	5'AMP+I+PGE_1, E_2, B_1	28	68	1
10	PGE_1, E_2, B_1+I (control)	46	0	0
11	Pap+PGE_1, E_2, B_1+I	27	30	1
12	Dibutyryl cyclic AMP+I+PGE_1, E_2, B_1	18	100	4

*Whole mammary glands from hormonally primed mice were incubated for 9 d in serum-free medium containing the listed supplements at the following concentrations: dibutyryl cyclic AMP, dibutyryl cyclic GMP, cyclic AMP, and 5' adenylic acid (5' AMP), each at 10^{-4} M; Pap at 10^{-6} M; PGs, I, P, A, and H, each at 5 $\mu g\,ml^{-1}$; and sodium butyrate at 2×10^{-4} M.

†Per cent of multiple of glands with foci of stratified squamous epithelial cells and keratin deposits.

‡Intensity of metaplasia on a scale of 1–4: grade 0, no epidermoid metaplasia; grade 1, minimal epidermoid change. Foci were sparsely distributed and poorly developed. Grades 2 and 3, intermediate grades quantitatively approaching 1 and 4, respectively. Grade 4, well developed foci of epidermoid metaplasia involving the lining of most major ducts and distal ductules. Differentiation of squamous epithelium was partial to complete, the latter forming keratin plaques.

The abnormally developed and differentiated epidermoid cells involuted following the removal of the dibutyryl cyclic AMP, Pap and PGs (Fig. 1). Incubation of the metaplastic glands for an additional 15 days (days 9–24) in the regression medium caused complete involution of both the epidermoid and cuboidal (normal secretory) epithelia, leaving behind a residue of keratin plaques (Fig. 2*d*).

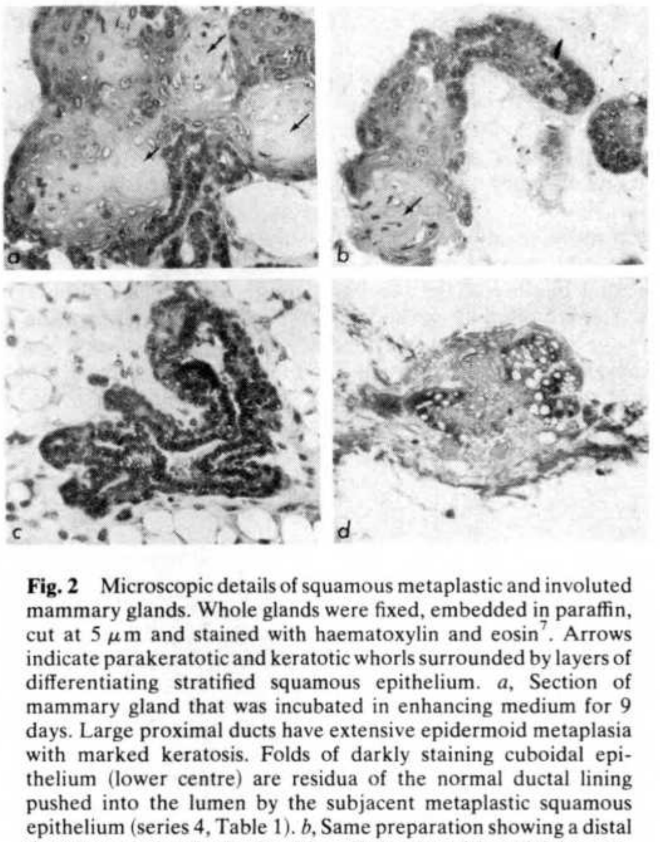

Fig. 2 Microscopic details of squamous metaplastic and involuted mammary glands. Whole glands were fixed, embedded in paraffin, cut at 5 μm and stained with haematoxylin and eosin[7]. Arrows indicate parakeratotic and keratotic whorls surrounded by layers of differentiating stratified squamous epithelium. *a*, Section of mammary gland that was incubated in enhancing medium for 9 days. Large proximal ducts have extensive epidermoid metaplasia with marked keratosis. Folds of darkly staining cuboidal epithelium (lower centre) are residua of the normal ductal lining pushed into the lumen by the subjacent metaplastic squamous epithelium (series 4, Table 1). *b*, Same preparation showing a distal ductule and alveolar buds with well developed keratinizing epidermoid metaplasia. Normal-appearing cuboidal cells are admixed above and to the right (series 4, Table 1). *c*, Section of a control gland that was incubated in the absence of dibutyryl cyclic AMP and Pap in medium containing I and PGE_1, PGE_2 and PGB_1 for 9 days. The appearance is like that of the primed gland at day 0. The ductal system is developed, but there is no lobuloalveolar growth. The epithelium is of the normal cuboidal type and shows no epidermoid metaplasia (series 10, Table 1). *d*, Section of a gland that was incubated in enhancing medium for 9 days, and then kept in regression medium for 15 days. A distal alveolar lobule that was partially metaplastic has involuted, leaving a residue of vacuolated secretory cells and a central plaque of keratin. All squamous cells have disappeared.

The induction of the metaplasia was not blocked by retinoid. The presence of 2-retinylidene-5,5-dimethyl-1,3-cyclohexanedione (retinylidene dimedone) at 10^{-5}, 10^{-7} or 10^{-9} M for 9 days failed to prevent the squamous metaplasia and keratin production brought about by enhancing medium (all 100%, not shown). This retinoid was chosen because it prevents, suppresses and apparently reverses the transformations of the cultured mammary glands caused by procarcinogens[15,17]. The failure of the retinoid to prevent squamous metaplasia in the present study is in marked contrast to the preventions and reversals of squamous metaplasias arising from vitamin A deficiency[3,4] and chemical carcinogens[5–7] in other systems. If these agents are effective in a common pathway, this difference suggests that the cyclic nucleotide, PGs and Pap act at stages after those of vitamin A deficiency and chemical carcinogens. Alternatively, separate pathways may be involved.

The present findings provide the initial indication of the identities of the possible physiological inducers of epidermoid metaplasia. Cyclic adenine nucleotide, certain PGs and Pap specifically and reversibly induce this abnormal development and differentiation in the epithelial cells of cultured mammary glands, endowing them with characteristics of skin. The common denominator among the inducers may be that they act synergistically to elevate the level of intracellular cyclic adenine nucleotide in three ways: first, by the exogenous entry of dibutyryl cyclic AMP, second, by the stimulation of the synthesis of cyclic AMP due to the actions of the PGs on adenyl cyclase[19,20], and third, through an inhibition by Pap of the phosphodiesterase-mediated degradation of the nucleotide[18].

The normal course of lobuloalveolar development and differentiation (casein production) impeded the abnormal course of squamous metaplastic development and differentiation (keratin production). Prior induction of the normal course in whole mammary glands cultured in medium containing IPAH markedly reduces the subsequent induction of the metaplasia in enhancing medium (F.V.S., R.P.C. and S.S., unpublished). Conversely, agents that elevate the intracellular level of cyclic AMP have recently been reported to inhibit the production of α-lactalbumin and casein by mammary glands in fragment culture[21].

The possibility arises that cyclic AMP and PGE_1 and PGE_2 may be the mediators of the squamous metaplasias that occur in many abnormal, transformed and malignant tissues, including mammary glands, of animals and humans[1,7,8,22–26]. Agents that elevate the level of intracellular cyclic AMP have been variously reported either to stimulate or to inhibit the growth of cells of mammary gland[27], epidermis[28] and other organs[28,29]. Further, several types of normal differentiation have previously been elicited by these same inducers in cell cultures of fibroblasts[30–32], skeletal muscle[33], melanoma[34] and other systems[19,20,29]. In addition, the production of keratohyaline granules is stimulated in cultures of human skin by theophylline, an inhibitor of the phosphodiesterase degradation of cyclic AMP[35] and keratin filaments are present in the cytoskeletons of epithelial cells in many organs[36]. It accordingly seems reasonable to investigate whether cyclic adenine nucleotide and specific PGs are the physiological mediators of the normal and abnormal development and differentiation of epithelia into enhanced keratin-producing, stratified squamous cells, as in skin and other organs.

We thank Dr W. Thomas London for critical discussions, Mrs Dovile Cooper for assistance, Mrs Ruth Bender for histological preparations, the Upjohn Company for a gift of PGs and Dr Michael B. Sporn for a gift of retinylidene dimedone, which was synthesized by Drs Nancy Acton and Arnold Brossi. This study was supported in part by NIH grants CA-21522, CA-05945, CA-06927 and RR-05539, and an appropriation from the Commonwealth of Pennsylvania.

† Ciba-Geigy Pharmaceuticals Division, Horsham, West Sussex RH12 4AB, UK

The undecapeptide substance P is a putative neurotransmitter in the mammalian central nervous system (CNS), and may be associated with pain fibres in the spinal cord[1,2]. Radiolabelled derivatives of other neuropeptides havd been used to demonstrate specific interactions with receptor sites on brain membranes[3–6], and this approach has now been explored with substance P. We have now prepared [4-^{3}H-Phe^8]-substance P and we find that it binds reversibly to a saturable population of sites in rat brain particulate fractions. Scatchard analysis of concentration-dependent saturation of binding indicates a single population of non-interacting sites with a high affinity ($K_d = 0.38$ nM) and a low density ($B_{max} = 27.2$ fmol per mg protein). Kinetic analyses indicate an apparent dissociation equilibrium constant of 0.46 nM. A variety of neurotransmitter amines and amino acids, and other peptides do not compete at the substance P sites, but structurally related peptides or shorter C-terminal fragments of substance P are active. The rank order of potency of these substance P-related peptides agrees with that reported for their effects in depolarizing spinal cord neurones[7]. The regional distribution of the specific binding sites for ^{3}H-substance P parallels that of substance P immunoreactivity, being high in the hypothalamus and low in the cerebellum and cerebral cortex. The characteristics of the ^{3}H-substance P binding sites are consistent with those expected for substance P receptors.

^{3}H-labelled substance P was prepared by reductive deiodination of the protected peptide [Boc-Arg^1,Lys(Boc)^3, Phe(I)^8]-substance P with tritium as similarly described for corticotropin-(1-24)-tetracosapeptide[8]. The solid-phase synthesis of the precursor peptide and the tritiation and purification of the radiolabelled substance P will be reported in detail elsewhere. The specific activity of the final product was 23 Ci mmol^{-1}, based on quantitative amino acid analysis and confirmed by radioimmunoassay. The purity was assessed by TLC in three different solvent systems, by isocratic and gradient-elution reverse-phase HPLC in three systems, and by measurements of the immunoreactivity of serially diluted samples against C-terminal sequence- and N-terminal sequence-directed[9] antisera. By all techniques, the purity was $\geq$90%, and the major contaminant was substance P sulphoxide, in which the C-terminal methionine residue was oxidized[10]. Aliquots of ^{3}H-substance P were stored at a concentration of 0.25 mM in 0.01 M HCl in glass vials under liquid nitrogen. For use, samples were diluted to 25 μM with 0.1 M HCl containing 1 mg ml^{-1} bovine serum albumin (BSA; recrystallized, Sigma). In these conditions, the labelled peptide could be stored at −20 °C for up to 10 days, with repeated freezing and thawing, and accumulated <5% of ^{3}H-substance P sulphoxide and negligible amounts of other labelled products. On the guinea pig ileum, ^{3}H-substance P had contractile activity equipotent with that of synthetic unlabelled substance P.

^{3}H-substance P was rapidly degraded when incubated at 37 °C with a crude synaptic membrane preparation from rat brain (see Fig. 1 legend for procedure). For this reason, all incubations included the peptidase inhibitors bacitracin (300 μg ml^{-1}), phenylmethylsulphonyl fluoride (0.1 mM), and *p*-chloromercuribenzoate (0.1 mM), and the incubations were performed at 4 °C. ^{3}H-substance P was stable to enzymatic digestion in these conditions as determined by HPLC analyses of acid extracts of membrane-bound radioactivity after various intervals (5–60 min). Control experiments indicated that none of these additions interfered with ^{3}H-substance P binding.

At low concentrations of ^{3}H-substance P(<1 nM), 50–60% of the total binding of the labelled peptide to brain membranes could be inhibited by the addition of 10μM unlabelled peptide. The specific component of binding, defined in this way, was saturable, whereas the nonspecific binding (in the presence of 10μM substance P) was linearly dependent on ligand concentration (Fig. 1*a*). The specific and nonspecific components were both linearly dependent on the amount of tissue present in the

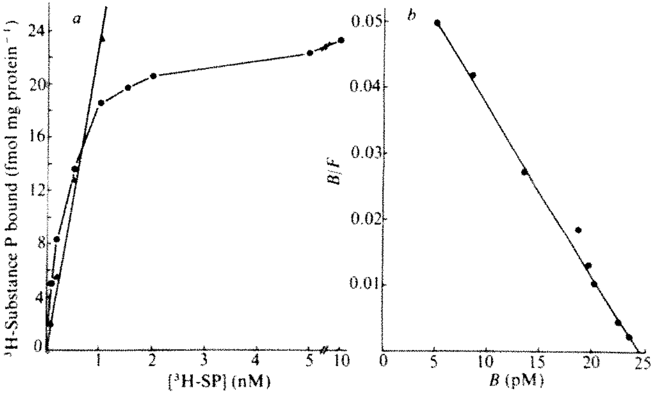

Fig. 1 *a*, Concentration dependence of specific (circles) and nonspecific (triangles) ^{3}H-substance P binding to rat brain membrane fractions. Whole brains minus cerebral cortex and cerebellum were dissected on ice from adult male Sprague–Dawley rats and homogenized in 10 vol ice-cold 10% sucrose/20 mM HEPES (*p*H 7.4) with a Teflon–glass homogenizer. The homogenate was centrifuged at 1,000*g* (5 min, 4 °C) to remove cellular debris. The supernatant was centrifuged at 11,000*g* (20 min, 4 °C) to prepare a crude mitochondrial pellet. The pellet was lysed by resuspension in 10 vol of ice-cold 5 mM HEPES (*p*H 8.1). The lysate was centrifuged at 100,000*g* (30 min, 4 °C). The resulting pellet was resuspended with a Teflon–glass homogenizer in 5 vol of 20 mM HEPES (*p*H 7.4) and stored frozen at −20 °C. For binding assays, 50 μl of the thawed membrane suspension were added to 430 μl of incubation medium (20 mM HEPES *p*H 7.4 containing 0.5% recrystallized BSA, 300 μg ml^{-1} bacitracin, 0.1 mM phenylmethylsulphonyl fluoride, 0.1 mM *p*-chloromercuribenzoate) in small plastic tubes kept on ice. The tubes were preincubated for 60 min before further additions. Drug, radiolabel and blank additions were made in 10-μl aliquots so that the final volume was 500 μl. Nonspecific binding was defined by adding substance P to a final concentration of 10 μM. In all cases, total and nonspecific binding determinations were made in triplicate. The ^{3}H-substance P was diluted from a 25 μM stock solution with incubation medium. Incubations were performed for 20 min on ice, and were terminated by dilution with 2.5 ml of ice-cold 20 mM HEPES/1% BSA (HEPES/BSA). Membrane-bound ^{3}H-substance P was measured by rapid filtration of the diluted samples through Millipore EGWP (0.2 μm) filters pre-equilibrated with ice-cold HEPES/BSA for 3h. Filters were rinsed with 3 × 2.5 ml of ice-cold HEPES/BSA. Filtration and rinsing were completed in <1 min. Filters were clarified by the addition of 4 ml ethoxyethanol and counted by the addition of 10 ml toluene scintillant. The data points are the means of triplicates in a single experiment. These results have been replicated in four separate experiments by the same technique. In three additional experiments using a centrifugation assay to measure binding, the specific binding data were reproduced, but nonspecific binding represented a greater proportion of the total (70–80%). *b*, Scatchard plot of the specific binding data in *a*.

0028-0836/80/340810—03$01.00

incubation. A Scatchard analysis (Fig. 1*b*) of the saturation curve for specific binding yielded a single straight line from which the density of the sites (B_{max}) was 27.2 fmol per mg protein and the dissociation constant (K_d) was calculated as 0.38 nM. Addition of a large molar excess of unlabelled substance P to membranes previously incubated with ^3H-substance P led to an exponential decay of specific binding (Fig. 2*b*). These data, when analysed by a semi-log plot, gave a straight line with a slope of $-0.15\ min^{-1}$, corresponding to a half time of dissociation of 4.6 min, and a dissociation rate constant (k_{off}) of $2.5\times10^{-3}\ M^{-1}\ s^{-1}$ (Fig. 2*b*). The time course for association of 2 nM ^3H-substance P reached a plateau for nonspecific sites at 2 min (data not shown) and for specific sites at 10 min (Fig. 2*a*). Plotting these data according to a first-order reaction gave a straight line with a slope of 0.47. The association rate constant (k_{on}) determined from the slope was $5.4\times10^6\ M^{-1}\ s^{-1}$. Using the equation $K_d = k_{off}/k_{on}$, an equilibrium dissociation constant of 0.46 nM was calculated, in good agreement with that determined from saturation data.

Table 1 Inhibition of specific ^3H-substance P binding to rat brain membranes by related peptides

Peptide	Rat brain binding inhibition IC_{50}(nM)*	Relative potency	Rat spinal cord depolarization (ref. 7) (relative potency)
Substance P (SP)	3	1.0	1.0
SP_{2-11}	10	0.3	0.6–0.9
SP_{3-11}	36	0.08	0.4–1.0
SP_{4-11}	64	0.05	0.8–1.0
SP_{5-11}	6	0.5	2–12
SP_{6-11}†	1.8	1.7	5–12
SP_{7-11}	220	0.01	<0.02
SP free acid	100	0.03	ND
Eledoisin	11	0.3	ND
Physalaemin	1.6	1.9	ND

* Determined from Hill plots of inhibition of binding of 2 nM ^3H-substance P. Data were generated from the means of triplicates of at least three separate experiments. For experiments with C-terminal fragments of substance P, 1 mM puromycin was added to the incubation medium to protect against aminopeptidase degradation. All peptides were commercial products (Peninsula) and were checked for purity by HPLC.

† Pyroglutamyl N-terminal form. Negative at 10 μM: angiotensin II and III, apamin, bombesin, bradykinin, α-bungarotoxin, carnosine, cholecystokinin-8 (non-sulphated), cholecystokinin-33, leucine-enkephalin, methionine-enkephalin, β-endorphin, β-lipotropin, neurotensin, SQ-20881, thyrotropin-releasing hormone, vasoactive intestinal peptide, vasopressin. Negative at 100 μM: aspartic acid, baclofen, capsaicin, carbamylcholine, dopamine, γ-aminobutyric acid, glutamic acid, glycine, histamine, serotonin, noradrenaline.

The sites were inhibited by structurally related analogues and by C-terminal fragments of substance P but not by a range of other neurotransmitters or peptides (Table 1). The rank order of potencies for a series of C-terminal fragments of substance P was hexapeptide > substance P > heptapeptide > decapeptide > nonapeptide > octapeptide > pentapeptide. Physalaemin and eledoisin, naturally-occurring substance P-related peptides[11], were also effective in competing for specific sites. Substance P free acid, in which the C-terminal methionine amide is replaced by a methionine, was about 30 times less active than substance P. Baclofen, a putative susbstance P antagonist[7], had no effect on ^3H-substance P binding. The IC_{50} for nonradioactive substance P (against 2 nM ^3H-substance P) was 3 nM, corresponding to an apparent K_d of 0.48 nM, in close agreement with both kinetic and equilibrium measurements of the dissociation constant.

A preliminary survey of the regional distribution of ^3H-substance P binding in rat brain was performed, using a single radioligand concentration (2 nM). ^3H-substance P binding sites were unevenly distributed among rat brain regions (Table 2). The density of specific sites was highest in substance P-rich areas such as hypothalamus and midbrain, and lowest in cerebral cortex and cerebellum, which contain only small amounts of substance P[12].

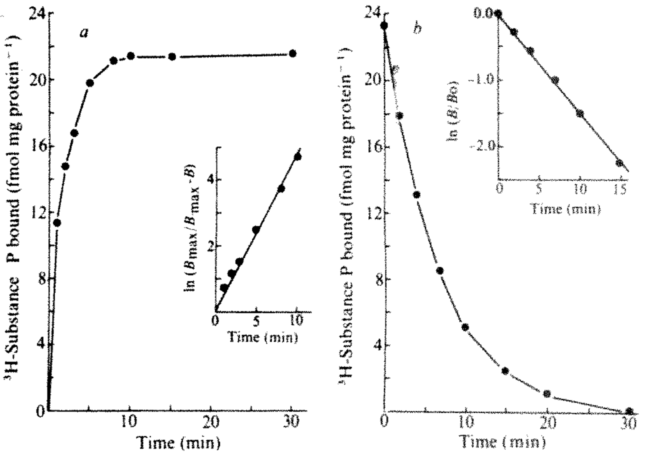

Fig. 2 *a*, Time course of specific ^3H-substance P binding at 4 °C. 2 nM ^3H-substance P was incubated with rat brain membrane fractions, and total and nonspecific binding were determined at the indicated intervals to generate the specific binding. The points are the means of triplicates in three separate experiments. Insert: Linearization of the time course curve for calculation of k_{on} as described elsewhere[6]. *b*, Dissociation time course of specific ^3H-substance P binding at 4 °C. 2 nM ^3H-substance P was incubated on ice for 20 min with rat membrane fractions. Substance P was then added to a final concentration of 10 μM at time zero. Samples of total and nonspecific binding were filtered at the indicated intervals afterwards. The results are the means of triplicates in three separate experiments. Insert: Linearization of the dissociation curve for calculation of k_{off} as described elsewhere[6].

The structural specificity of the high affinity binding sites in rat brain resembles that determined by measurements of the biological activity of substance P and related peptides[13]. Most studies have focused on the actions of substance P on peripheral tissues, but Otsuka and Konishi[7] examined the potencies of substance P and shorter fragments in depolarizing motor neurones after bath application to newborn rat spinal cord, and their results (summarized in Table 1) are in agreement with the present binding data. In particular, it is noteworthy that the hexapeptide fragment is more potent than the native peptide, both in its activity on spinal cord and in inhibiting ^3H-substance P binding, whereas the C-terminal pentapeptide fragment shows a marked reduction in activity. Piercey and Einspahr[14] have also shown a marked reduction in activity of the C-terminal pentapeptide electrophysiologically on dorsal horn neurones.

Table 2 Regional distribution of specific ^3H-substance P binding to rat brain membrane fractions

Region	Binding (fmol per mg protein)
Brainstem	15±5
Cerebellum	6±3
Hypothalamus	36±9
Midbrain	29±6
Striatum	17±4
Temporal cortex	4±2

Individual regions were dissected on ice and crude mitochondrial fraction membranes prepared as in Fig. 1. The specific binding of 2 nM ^3H-substance P was determined using membrane fractions stored frozen at −20 °C as described in Fig. 1 legend. The protein content was determined by the Lowry technique. The results are means ±s.e.m. for triplicate measurements of total and nonspecific binding in four separate experiments. In preliminary experiments substance P-displaceable binding was observed in the cerebellum, cerebral cortex and hippocampus that could also be inhibited by angiotensin II and SQ-20881 (0.1–10 μM), unlike the binding in other regions or in total brain (minus cerebellum and cortex). The nature of this unselective peptide-binding site is not known, but the incubation medium was routinely supplemented with 10 μM angiotensin II to eliminate its contribution.

Although data for the substance P-related peptides physalaemin and eledoisin are not available for rat spinal cord, these substances are approximately equipotent with substance P in a number of other test systems[13,15], and they had a similar potency to substance P in the binding assay. Removal of the C-terminal amide in substance P free acid greatly reduces biological potency in a number of test systems[13,16], and was also found markedly to reduce potency in the binding assay.

Although there have been other published reports of high-affinity binding of radioactively labelled substance P derivatives to brain membrane preparations[17,18], we believe that the present results reflect most closely the known biological activity of substance P. Thus, Nakata *et al.*[17] described the binding of ^{3}H-substance P to rabbit brain membrane preparations, but observed no antagonism by physalaemin. Furthermore, we have been unable to replicate their measurement technique as we observe large amounts of ^{3}H-substance P binding to the type of membrane filters used by these authors, even in the absence of tissue. From the present results, it seems unlikely that the specific binding of ^{3}H-substance P could have reached equilibrium during the 1 min incubation period at 0 °C used by these authors. Mayer *et al.*[18] studied the binding of [^{125}I-Tyr^8]-substance P to a synaptic vesicle fraction from rat brain. Although the labelled peptide exhibited high affinity binding ($K_d = 0.32$ nM), and the regional distribution of binding sites in brain resembled that of endogenous substance P[19], the specificity of this binding bore little relation to biological activity, since C-terminal fragments of substance P inhibited binding only at micromolar concentrations, and physalaemin enhanced rather than inhibited binding of the labelled analogue. Putney *et al.*[20] and Jensen and Gardner[21] have described the use of ^{125}I-physalaemin to label substance P receptors in dispersed parotid acinar cells and dispersed pancreatic acinar cells respectively. In each case, the authors described specific high-affinity binding sites that were present in unusually low density. It is interesting that the density of ^{3}H-substance P sites in rat brain is lower than that seen for many conventional amine or amino acid neurotransmitter receptor sites[22], but is similar to the values reported for other brain peptide-binding sites[3-5].

The characteristics and regional distribution of the high affinity binding sites for ^{3}H-substance P described here are in close correspondence with those expected for substance P receptors in the CNS. The radioligand binding assay offers an important new tool for investigating the occurrence and pharmacological properties of such substance P receptors.

β-Endorphin alters luteinizing hormone secretion via the amygdala but not the hypothalamus

N. Parvizi & F. Ellendorff

Institut für Tierzucht und Tierverhalten, FAL, Mariensee, 3057
Neustadt 1, FRG

Morphine and enkephalins are able to alter pituitary hormone secretion[1-3]. It has been postulated that they do not act directly at the pituitary[4], but rather that the hypothalamus is the site at which inhibition or stimulation of pituitary hormone secretion is initiated[4]. On the other hand, endogenous opiates have been located in distinctly different neuronal regions, including areas outside the hypothalamus[5]. The effects of β-endorphin on plasma luteinizing hormone (LH) levels have not been explored, and the present experiments attempt to elucidate the contribution and the possible site of action of β-endorphin in the control of LH secretion. The results show that β-endorphin inhibits pituitary LH secretion if applied into the amygdala but not when given into the hypothalamus.

Stainless steel guide tubings (22 gauge) containing inner 28-gauge tubing were implanted bilaterally in the basolateral

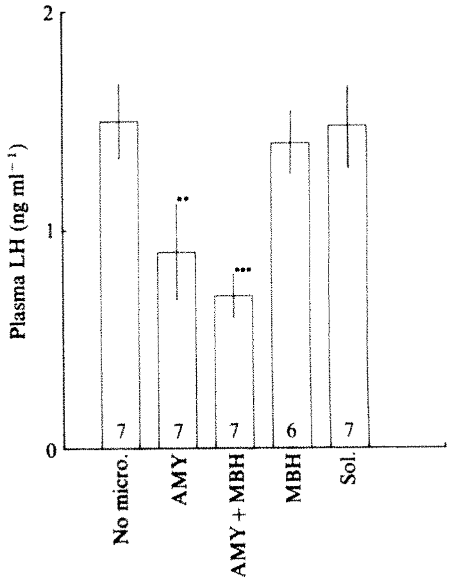

Fig. 1 Decrease of plasma LH levels 100–180 min after microinjection of 30 ng β-endorphin into the amygdala (AMY) or mediobasal hypothalamus (MBH) and amygdala of ovariectomized miniature pigs. 'No micro', control blood sampling without any treatment; 'Sol.', microinjection of 1 μl of 0.7% saline. Numbers in the bars represent the number of animals. For statistical analysis the period of sampling was divided into three blocks each of nine successive samples taken at 10-min intervals. The mean LH value for each animal within each block was calculated. A one-way analysis of variance was then carried out to detect differences among mean LH values of treatments and time blocks. ** $P \leq 0.01$; *** $P \leq 0.001$; $\bar{x} \pm$ s.e.m.

0028-0836/80/340812—02$01.00

hypothalamus and amygdala of seven adult, ovariectomized miniature pigs. The tips of the tubing ended 3 mm above the desired depth. Two weeks later and 5 days before the beginning of the experiment, a silastic catheter was placed in the external jugular vein. During the recovery period, the animals were familiarized with the manipulations of the implant. The experiment was designed so that each animal served as its own control. A control period preceded the treatment on each experimental day. Saline (solvent), 1 µl, β-endorphin (Serva cat. no. 52558), 30 ng, were microinjected on 4 different days at 3-day intervals into either the basolateral hypothalamus or amygdala, or simultaneously into the two tissues. The sequence of treatment was randomly assigned for each animal. Microinjections were given through a 28-gauge tubing connected to a Hamilton syringe as described[6,7]. Blood samples (2 ml) were collected at 10-min intervals from 90 min before to 180 min after microinjection. On one day, blood samples were taken without any treatment. Thus, a double control system allowed us to consider the animals as a group and individually. Plasma LH was estimated by radioimmunoassay[8].

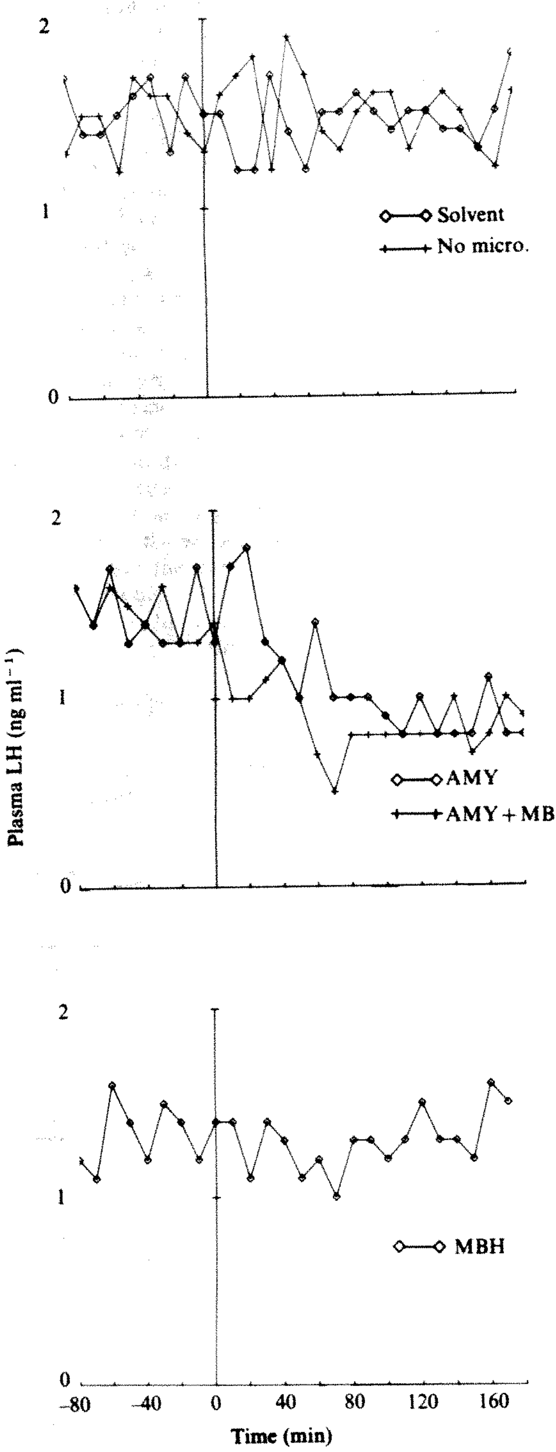

Fig. 2 Point by point presentation of plasma LH levels before and after microinjection of 30 ng β-endorphin into the mediobasal hypothalamus (MBH), amygdala (AMY) or both tissues. 'Solvent' indicates microinjection of 1 µl 0.7% saline into the hypothalamus and amygdala at time 0; 'No micro' indicates control blood sampling without any microinjection; each point represents seven (AMY, control or solvent) or six (MBH, AMY + MBH) animals. For clarity the s.e.m. values are omitted.

Histological verification at the end of the experiment indicated that in six out of seven animals the tips of the tubing were located in the basolateral hypothalamus, and in all seven animals the tips were within the amygdala. Microinjection of β-endorphin into the basolateral hypothalamus had no significant effect on LH secretion, but microinjection into the amygdala of the same animals decreased plasma LH levels significantly ($P \leq 0.01$; for statistical analysis see Fig. 1 legend). The onset of inhibition occurred within 60 min of microinjection (Fig. 2). The simultaneous microinjection of β-endorphin into the hypothalamus and amygdala resulted in a decrease in plasma LH levels similar to that seen with microinjection into the amygdala alone (Fig. 2). This would be expected if β-endorphin were priming the hypothalamus to incoming signals.

The application of other substances, such as steroids[6,7,9] or catecholamines[9], directly into the basolateral hypothalamus causes dramatic changes in LH secretion. Hence the absence of any changes in plasma LH after β-endorphin microinjection into the hypothalamus was unexpected. It suggests, among other possibilities, that hypothalamic LH-releasing hormone (LH-RH) secreting cells are not directly sensitive to β-endorphin and that β-endorphin-induced changes in LH originate from extra-hypothalamic neurones, thereby in some way inhibiting LH-RH. Thus, the high number of β-endorphin receptors in the hypothalamus[10] must be involved in mechanisms not related to LH-RH secretion. The amygdala, on the other hand, must now be considered as one site where β-endorphins, among other substances, induce changes that eventually result in altered LH-RH discharge and thus inhibition of pituitary LH secretion. Although we do not know how this is brought about, the amygdala has been identified as a preferred site of endogenous opiate accumulation[5,10]. However, the effect on plasma LH that we have observed is probably only one effect of amygdala-β-endorphin interplay. For example, it is known that the amygdala and β-endorphin[12,13], as well as LH-RH[14,15], are involved in controlling a wide range of behavioural patterns.

Genetic alteration of nerve membrane excitability in temperature-sensitive paralytic mutants of *Drosophila melanogaster*

Chun-Fang Wu*†‡ & Barry Ganetzky*§

* Division of Biology, California Institute of Technology, Pasadena, California 91125
† Department of Zoology, University of Iowa, Iowa City, Iowa 52242
§ Laboratory of Genetics, University of Wisconsin, Madison, Wisconsin 53706

Single mutations that disrupt basic physiological processes such as axonal conduction and synaptic transmission provide one means to study the membrane components and mechanisms that underlie these processes[1–8]. Temperature-sensitive paralytic mutants of *Drosophila melanogaster* which behave normally at a permissive temperature (23–25 °C) but become paralysed at a restrictive temperature (usually 29–37 °C) have been utilized in such studies. An example is *nap*^{ts} (no action potential, temperature-sensitive), a recessive second-chromosome mutation that causes paralysis of larvae and adults at 37 °C. Electrophysiological recordings have demonstrated that *nap*^{ts} specifically affects a component of axonal membranes[5]. Here we show that axonal conduction in *nap*^{ts} larvae is abnormally sensitive to tetrodotoxin (TTX), a specific blocker of voltage-sensitive sodium channels[9], and that the refractory period of action potentials differs from wild type, consistent with the idea that *nap*^{ts} alters the function of sodium channels. It is further shown that *para*^{ts} (paralysed, temperature-sensitive), a recessive *X*-linked mutation[1], also specifically disrupts axonal conduction and that the two mutations affect functionally related membrane components. Identification of other mutants defective in associated components of nerve membranes is made feasible by using techniques described here.

The TTX sensitivity of nerve conduction was measured in both mutant and normal (Canton-S) larvae. The postsynaptic excitatory junctional potentials (e.j.ps) were recorded intracellularly from medioventral longitudinal muscles in the larval neuromuscular preparation[5,10]. In *Drosophila*[10] and other dipteran[13,14] larvae, these muscles are innervated by two multiterminal axons with multiple branches and lack regenerative action potentials under physiological conditions[10]. Blockage of axonal conduction causes the loss of the evoked e.j.p. For the *nap*^{ts} larva shown in Fig. 1*a*, 5nM TTX has diminished the e.j.p. appreciably and at 10 nM the e.j.p. is completely gone. Axonal conduction but not synaptic transmission is blocked because a graded postsynaptic potential with short latency distinct from the normal e.j.p. can be evoked by electrotonically depolarizing the nerve terminal with high intensity stimuli[5,11,12]. The wild-type e.j.p. is only slightly affected by 10 nM TTX, diminishing at 20 nM TTX, and finally disappearing at 40 mM TTX, at which point a graded response can be evoked electrotonically (Fig. 1*b*).

In any given larva, we found little variation in the dose of TTX required to block the e.j.p. in different body segments. For the different *nap*^{ts} larvae tested, the effective concentration ranged from 5–15 nM (9.8 ± 4.4 nM; $\bar{x} \pm$ S.D.; $n = 11$ larvae). For wild type the range was 20–65 nM (40.3 ± 11.1 nM; $n = 9$ larvae). The difference in TTX sensitivity was confirmed by direct recording of nerve compound action potential. This result also indicates that *nap*^{ts} affects the TTX sensitivity of both the sensory and motor axons in the nerve bundle.

The observed difference in TTX sensitivity is not a consequence of differences in genetic background other than the *nap*^{ts} mutation responsible for the paralytic phenotype. By using a translocation which inserts the *nap*$^{+}$ locus into the *Y* chromosome[5], the TTX sensitivity of *X*/*Y*; *nap*^{ts}/*nap*^{ts} and *X*/*Ynap*$^{+}$; *nap*^{ts}/*nap*^{ts} larvae were compared. These larvae are essentially identical in genetic background, but the former have the behavioural phenotype of *nap*^{ts} whereas the latter are *nap*$^{+}$. The e.j.p. in these control larvae was blocked at a TTX concentration of 32.5 ± 10.9 nM ($n = 4$ larvae), comparable to the effective dose for Canton-S (40.3 ± 11.1 nM).

The altered TTX sensitivity is consistent with the idea that *nap*^{ts} alters the function or number of sodium channels[5]. Biochemical analysis of nerve membrane properties in *Drosophila* has begun[7,15] and can provide independent evidence. Preliminary results from competible, saturable binding of ^{3}H-TTX to a crude particulate fraction prepared from adult heads indicate different binding properties between normal and *nap*^{ts} extracts[15].

A possible alteration in the density and/or kinetics of voltage-dependent ionic channels in *nap*^{ts} is also suggested by an abnormal refractory period of the compound action potential. The axonal refractory period is determined by the kinetics of activation of sodium and potassium channels and the inactivation of sodium channels[16]. For each axon in a nerve bundle there is a definite refractory period during which a second stimulus cannot elicit another propagated response. The second compound action potential gradually recovers as the interval between two stimuli increases, because an increasing number of axons are again able to generate a propagated response (Fig. 2*a*). The second response recovers more rapidly in control than in *nap*^{ts} larvae even though the stimulus strength relative to the threshold is the same. We defined $\tau_{1/2}$ as the interval between stimuli needed to obtain a second response with amplitude 50% of the first. The $\tau_{1/2}$ decreases for both mutant and control larvae as the stimulus intensity increases (Fig. 2*b*). However, at almost every relative stimulus strength, the mutant requires a longer interval for recovery than does the control. The minimum $\tau_{1/2}$ is

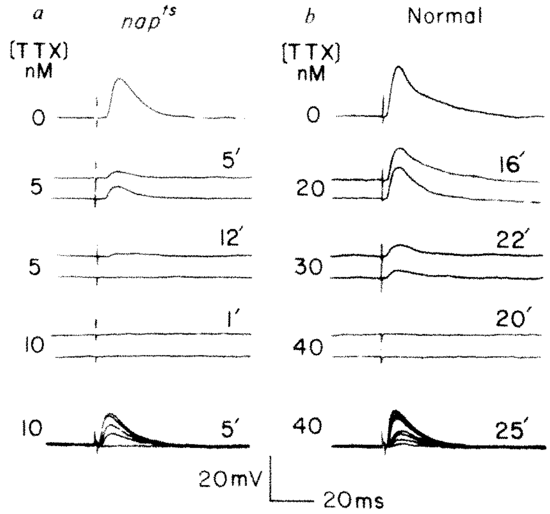

Fig. 1 Continuous recordings (23 °C) from ventrolateral longitudinal muscles in the mutant *nap*^{ts} and the normal (Canton-S) larvae showing e.j.ps at different TTX concentrations shown to the left of each trace. Segmental nerve bundles were severed close to the ventral ganglion and stimulated (0.2 ms duration) via a glass suction electrode. E.j.ps were recorded intracellularly using glass microelectrodes filled with 3M KCl (30–60 mΩ). TTX was added to the bath solution to change concentrations in increments of 5–10 nM. Solutions were mixed and enough time allowed for equilibration. Traces were made at different times after change of TTX concentration as marked on the right of each trace. *a*, *nap*^{ts} larva. At 5 nM TTX, the e.j.p. is almost entirely blocked within 12 min. Synaptic transmission is not affected by TTX because graded potentials (bottom trace, superimposed recordings) can still be evoked electrotonically by strong stimuli (1.0 ms duration) even at 10 nM TTX when active conduction is blocked. *b*, Normal larva. The e.j.p. is lost only after 25 min in 40 nM TTX. At this point graded responses could be evoked electrotonically. The bath solution[5,10] contains 0.8 mM Ca^{2+}.

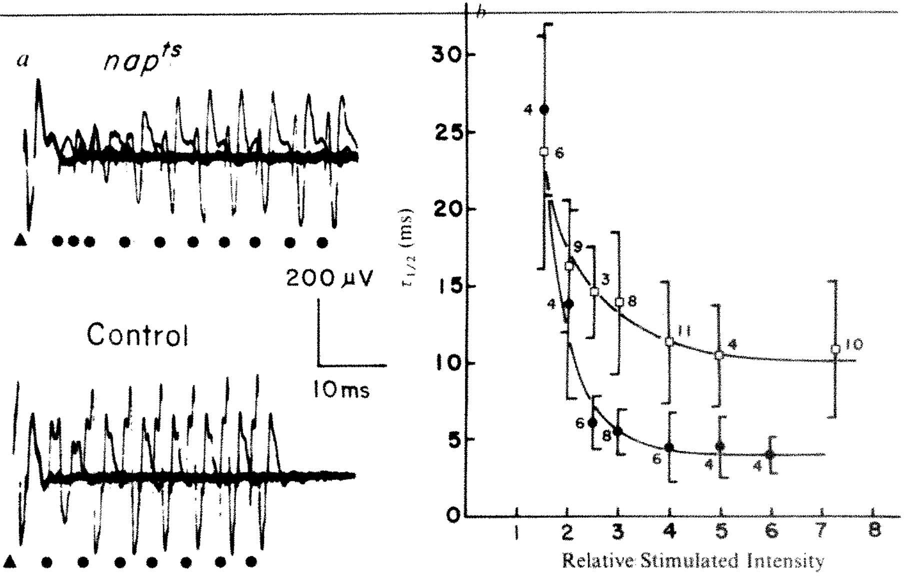

Fig. 2 *a*, Compound action potentials of *nap*^{ts} and control larvae at 23 °C showing refractory period. The segmental nerve bundles were cut close to the ganglion and stimulated at the cut end with a suction electrode. A second suction electrode drew up a loop of nerve near the distal end and recorded the response[5]. Responses to twin stimuli with increasing interval between them are superimposed. In *nap*^{ts} larva the second response attains complete recovery after an interval of 20–25 ms following the first stimulus. Stimulus intensity was 4 V; threshold was 1 V; stimulus duration was 0.2 ms. For control larvae the second response has recovered within 10 ms following the first stimulus. Stimulus intensity was 5.2 V; threshold was 1.3 V; stimulus duration was 0.2 ms. In these superimposed traces triangles mark the first stimuli and dots mark the second stimuli. *b*, Refractory period of compound action potential for *nap*^{ts} (□) and control (●) larvae at different stimulus intensities determined from experiments like those shown in Fig. 2*a*. The interval ($\tau_{1/2}$) between stimuli necessary to produce a second response with an amplitude 50% of the first response was determined at different stimulus intensities relative to threshold. $\tau_{1/2}$ decreases as the stimulus intensity increases. The minimum attainable $\rho_{1/2}$ is more than twice as long in *nap*^{ts} larvae as in control larvae. Each point represents an average from the number of nerves indicated. Error bars represent standard deviation.

about 4 ms in control larvae but is close to 10 ms in the mutant. This suggests that in *nap*^{ts} each axon contributing to the compound action potential has a longer than normal refractory period. Another less likely possibility is that *nap*^{ts} has a specific effect only on those axons with a short refractory period.

These effects of *nap*^{ts} on nerve conduction at permissive temperatures are unlikely to be due to a defect in a passive electrical property of excitable membranes such as increase in leakage conductance. Computer simulations of active conduction in a Hodgkin-Huxley model axon[16] of the size found in *Drosophila* showed that the observed increase in refractory period and the conduction block at the restrictive temperature cannot be accounted for solely by an increase in leakage conductance (Joyner and Wu, unpublished data).

If *nap*^{ts} does affect the sodium channel, it will be of interest to identify other mutations with similar properties. Of eight other temperature-sensitive paralytic mutants on the *X* and second chromosomes that we recently examined, only *para*^{ts} shows behavioural and physiological phenotypes like those of *nap*^{ts}. Adult *para*^{ts} flies show rapid reversible paralysis at 29 °C (ref. 1). Simultaneous recording of the e.j.p. and nerve compound action potential indicates that the e.j.p. and compound action potential disappear at 37 °C but return when temperature is lowered (Fig. 3). In normal larvae, the e.j.p. and the compound action potential persist up to at least 40 °C (ref. 5). Synaptic transmission is not blocked in *para*^{ts} larvae because a graded e.j.p. could still be elicited electrotonically after failure of active conduction. Therefore, *para*^{ts}, like *nap*^{ts}, specifically blocks axonal conduction at high temperature, as originally suggested by Siddiqi[17].

The *nap*^{ts} and *para*^{ts} gene products may share a related function because the double mutant is lethal even at temperatures permissive for each single mutant as shown in Table 1. A comparison of progeny classes 2 or 3 with 1 indicates that *nap*^{ts} or *para*^{ts} can cause a slight reduction in viability. However, the striking result is the complete failure to recover any double mutant progeny at all (class 4). The same is true for other *para* alleles in combination with *nap*^{ts} (Ganetzky and Wu, unpublished data). The lethality appears specific for the combination of *para* with *nap*, since other *X*-linked temperature-sensitive paralytic mutants show no such synergistic interaction with *nap*^{ts}.

In other examples of synthetic lethality in *Drosophila*, it has been possible to demonstrate at the biochemical level that the mutations involved have related functions[18]. If *nap*^{ts} is shown to disrupt the assembly or function of sodium channels, a similar defect for *para*^{ts} might be indicated. However, the two mutants do not appear to act identically because at room temperature *para*^{ts}, unlike *nap*^{ts}, did not appear to differ significantly from wild type in TTX sensitivity or refractory period. One interesting possibility is that sodium channels are comprised of at least two different protein subunits—one altered by *nap*^{ts} and the other by *para*^{ts}.

Whether or not this notion proves correct, it is certainly the case that the gene products specified by the *nap* and *para* loci play essential roles in membrane excitability. By utilizing genetic and physiological techniques, it should be possible to identify other genes in *Drosophila* that control primary events of excitability in the nervous system. Moreover, we wish to emphasize that analysis of double mutants, as in the case of *nap*^{ts} and *para*^{ts}, can reveal functional relationships between gene products in excitable membranes that would be difficult to detect in any other way.

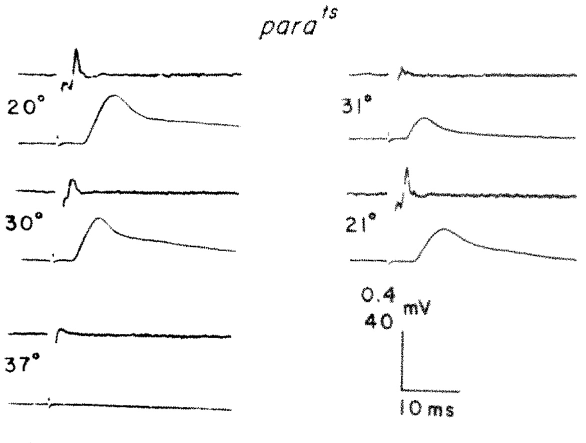

Fig. 3 Continuous recording of compound action potential and evoked e.j.p. from a *para*^{ts} larva at various temperatures. The e.j.p. (bottom trace in each panel) was recorded intracellularly from the same ventrolateral longitudinal muscle fibre. The compound action potential (top traces) was recorded from the nerve bundle containing the motor axons innervating the impaled muscle fibre. As the temperature is raised from 20° to 37 °C, both the e.j.p. and the compound action potential disappear (left). They reappear when the temperature is lowered back to 21 °C (right). The calcium concentration in bath solution was 0.8 mM.

Table 1 Progeny resulting from cross of $\frac{para^+}{Y}\,\frac{nap^{ts}}{nap^{ts}}$ ♂♂ × $\frac{para^{ts}}{para^{ts}}\,\frac{Cy}{nap^{ts}}$ ♀♀ at 23 °C

Cy (Curly) is a dominant wing marker located on a multiply inverted chromosome that does not undergo genetic exchange with its nap^{ts} bearing homologue. The *Cy* chromosome carries a normal allele of nap^{ts}. Four classes of progeny are expected to emerge from the above cross with equal frequencies. The four classes are distinguishable by sex and wing phenotype. Because both nap^{ts} and $para^{ts}$ are recessive, only the last class of progeny among the four is mutant for both $para^{ts}$ and nap^{ts}.

Non-uniform Ca^{2+} buffer distribution in a nerve cell body

D. Tillotson & A. L. F. Gorman

Department of Physiology, Boston University School of Medicine,
80 E. Concord Street, Boston, Massachusetts 02118

In nerve cells, Ca^{2+} influx through voltage-dependent channels in the membrane causes a transient rise in the intracellular, free Ca^{2+} concentration[1-3]. Such changes have been shown to be important for the release of transmitter at the axon terminal[3,4] and for the control of the movement of ions through channels in the soma membrane[5,6]. The transient behaviour of the rise in Ca^{2+} concentration can, in part, be explained by the presence of sequestering systems in the cell which tend to limit the magnitude and duration of changes in internal Ca^{2+} (refs 7–10). It is possible that systems involved in buffering changes in internal Ca^{2+} are not distributed uniformly throughout the cell. This is particularly likely in the cell body, where a significant portion of the cytoplasm is occupied by the nucleus, whose buffering capacity may differ from that of other cellular regions. We report here that in the soma of a molluscan pacemaker neurone, the machinery responsible for short-term buffering of Ca^{2+} ions is localized near the inner surface of the plasma membrane.

The pacemaker neurone R-15 in the abdominal ganglion of *Aplysia californica* was used, and experiments were carried out in artificial seawater which contained (in mM) 500 NaCl, 10 KCl, 10 $CaCl_2$, 50 $MgCl_2$ and 10 Tris at *p*H 7.7, and at a temperature of 16 °C. In some experiments, Na^+ was completely replaced by Tris. The procedures for iontophoretic injection of ions or pressure injection of purified arsenazo(III), voltage clamping the soma membrane and monitoring changes in intracellular Ca^{2+} with differential absorbance micro-spectrophotometry were similar to those described previously[11,12].

The experimental design is shown in Fig. 1*a*. Arsenazo(III) was injected and its intracellular concentration (about 200 µM) was determined using a small light-accepting probe (~150 µm diameter) which was about half the cell diameter. Starting near the inner membrane surface, an electrode containing 0.2 M $CaCl_2$ was advanced through the cytoplasm in 20-µm increments in a neurone clamped at a holding potential of about −40 mV, and absorbance changes associated with small test Ca^{2+} injections were measured at each increment. A fourth electrode containing 0.5 M EGTA was used to inject EGTA iontophoretically into the cell. The small light-accepting probe, used previously[11,12] for measuring absorbance changes produced by Ca^{2+} injection from a microelectrode, has the disadvantage that

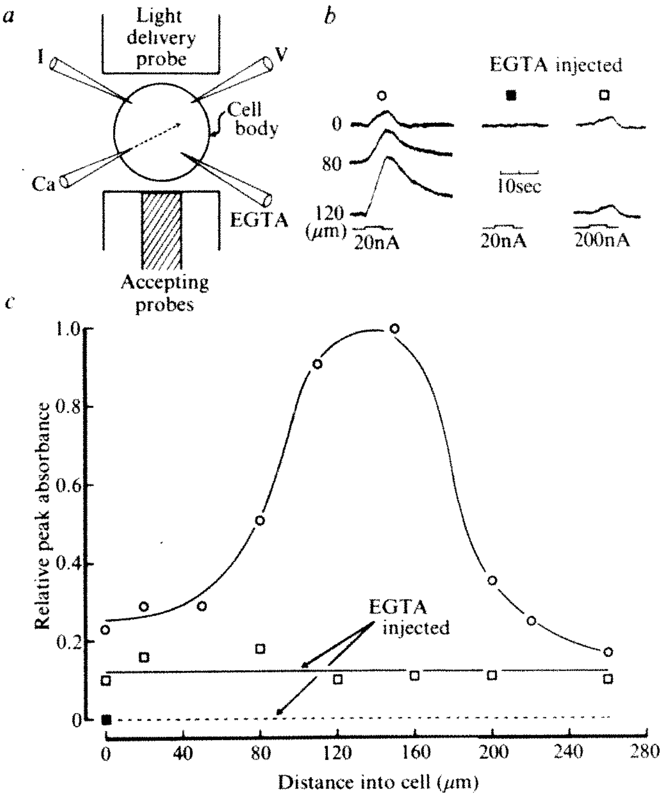

Fig. 1 Effects of Ca^{2+} injections at various distances in the soma cytoplasm on the free, intracellular Ca^{2+} concentration measured with arsenazo(III). *a* Shows the experimental arrangement. The nerve cell soma (cell body) was impaled with voltage (V), current (I), Ca^{2+} injection (Ca) and EGTA injection (EGTA) electrodes and positioned between a pair of fibre optic probes. Large and small (hatched lines) light-accepting probes are shown. *b* Shows the differential absorbance changes at 660–690 nm during Ca^{2+} injections for 5 s (20 or 200 nA) at the indicated distances into the cytoplasm from the cell membrane before (left column) and after injection of EGTA for 5 min (200 nA) (middle and right columns). The arsenazo(III) was 98.6% pure and its intracellular concentration was estimated to be about 200 µM. *c* Shows a plot of the normalized absorbance changes produced by Ca^{2+} injections (5 s, 20 nA) at various distances into the cell from the membrane before (open circles) and after (closed square) EGTA injection. The open squares plot the absorbance changes produced by a 10-fold increase in Ca^{2+} injection intensity (5 s, 200 nA) after EGTA injection. All data are from the same cell.

0028-0836/80/340816—02$01.00

part of the cytoplasm and the plasma membrane are not directly in the light path. With all other factors equivalent, a test Ca^{2+} injection just outside the light path will produce a distorted absorbance signal, with slower rising kinetics and a reduced peak amplitude relative to those produced by an identical injection within the light path. To examine the localization of the Ca^{2+} buffer system, we replaced the small light-accepting probe (after injection of arsenazo(III)) with a probe of 400 μm diameter, which was larger than the average cell diameter (~300 μm), thus rendering all points inside the cell equivalent. This system was tested experimentally using a 300-μm diameter droplet of solution (containing 300 mM KCl and 0.2 mM arsenazo(III) and buffered to a *p*H of 7.3 with 100 mM MOPS) in place of the neurone and injecting Ca^{2+} at different distances within the droplet. The changes in absorbance produced by Ca^{2+} injections were identical at all points within the droplet even at short times (within a few seconds of the injection), when elementary diffusion considerations dictate that the injected Ca^{2+} cannot have equilibrated throughout the droplet. This indicates that the sensitivity of the measurement system does not depend significantly on the position at which the injection is made. The use of a larger light probe, however, results in the transmission of a significant fraction of the incident light around the cell and hence severely limits our ability to quantify absorbance changes in terms of changes in internal Ca^{2+} concentration[12,13], although changes in the relative peak absorbance and in the kinetics of the absorbance can be determined.

Dye absorbance changes associated with small test Ca^{2+} injections (20 nA, 5 s) at different points in the cytoplasm are shown in the first column in Fig. 1*b* and a full set of measurements from the same cell are plotted in Fig. 1*c*. The amplitude of the absorbance signal is taken as an index of the buffering capacity of a region of the cytoplasm near the electrode tip. As the Ca^{2+} microelectrode was advanced into the centre of the cell, the amplitude of the absorbance signal increased and its kinetics decreased, indicating a diminution of buffering strength relative to the cell boundary, but as the electrode tip was moved towards the opposite membrane, the signal amplitude and kinetics returned to control values. Similar results were found in three other cells. The results from all four cells suggest that there may be a cytoplasmic layer near the cell membrane (0–50 μm) which has a different buffering capacity from that found in the centre of the cell.

To control for the possibility that the apparent Ca^{2+} buffering localization at the cell boundary is caused by a peculiarity of the absorbance recording arrangement, the Ca^{2+} chelating agent EGTA was injected iontophoretically into the cell for 5 min at 100 nA. An injection of this duration and intensity is more than sufficient to abolish all absorbance changes in cell R-15 produced by Ca^{2+} influx into the cytoplasm from the external medium during 0.5 s voltage-clamp pulses to all positive membrane potentials. We reasoned that a high internal EGTA concentration, if uniformly distributed throughout the cytoplasm, would render the whole cell equivalent with respect to buffering capacity, and that in these conditions Ca^{2+} injections at various distances through the soma would give absorbance changes of equal amplitude. The localization experiment was repeated after EGTA injection using a 10-fold greater injection current (200 nA, 5 s), because the previous injection level produced no measurable change in absorbance. The predicted result of equivalent intracellular buffering is shown in Fig. 1*b* and *c*. We conclude, therefore, that in normal circumstances the capacity to buffer Ca^{2+} is differentially distributed in the soma, being greatest in a cytoplasmic layer near the cell plasma membrane.

In most cells, buffering of intracellular Ca^{2+} is thought to be controlled by both sequestration by internal organelles and extrusion by systems in the plasma membrane[7–9]. In nerve cells, a membrane-bound Na–Ca exchange system has been suggested as playing a significant part in the maintenance of intracellular Ca^{2+} levels[14] and could explain the observed buffering localization, as Ca^{2+} near the membrane, and hence near the Na–Ca exchange sites, would be extruded more quickly than Ca^{2+} in the cell interior. To test for this possibility, we examined the effect of removal of extracellular Na^+ on the absorbance change associated with Ca^{2+} injection near the inner membrane surface. Removal of external Na^+ should stop the exchange process[1,14], but it had no significant effect on the amplitude or time course of the absorbance change. This result agrees with previous findings from molluscan neurones[15] and suggests that short-term Ca^{2+} buffering may not depend on the Na^+-dependent transport of Ca^{2+} out of the cell. However, the situation with Ca^{2+} influx through the plasma membrane may be entirely different and membrane extrusion systems may be very much more important.

In nerve cells, changes in the total internal Ca^{2+} concentration are caused primarily by influx from the external medium, and evidence from squid axon suggests that the rise in free intracellular Ca^{2+} concentration is confined to the cell periphery[1,16]. The localization of the machinery responsible for Ca^{2+} removal near the inner membrane surface may provide a physical basis for this confinement. It is well known that the nuclear membrane is freely permeable to large molecules and that the cytoplasm is continuous between the nuclear and non-nuclear regions of the cell; the localization of the buffer at the cell periphery therefore suggests that the buffering apparatus may be attached to some structural element in the cytoplasm. The identity of the systems responsible for this localization is uncertain, but could include membrane sites and cytoplasmic proteins which bind Ca^{2+}, and those intracellular organelles (such as mitochondria, endoplasmic reticulum) which sequester Ca^{2+} near the membrane.

Ouabain stimulation of noradrenaline transport in guinea pig heart

Virendra K. Sharma, Lorelle A. Pottick & Shailesh P. Banerjee

Department of Pharmacology and Toxicology, University of Rochester School of Medicine and Dentistry, Rochester, New York 14642

Cardiac glycosides such as ouabain inhibit Na^+-dependent high-affinity noradrenaline uptake in sympathetic nerve terminals by interacting with $(Na^+ + K^+)$ATPase located in the neuronal membrane[1–3]. It has been suggested that the augmentation of noradrenaline concentration at the neuromuscular junctions following the inhibition of its uptake may contribute to the ouabain-induced cardiac arrhythmia seen with toxic doses of the drug[4,5]. Although it is generally accepted that the biochemical basis for the pharmacological response of cardiac glycosides must involve specific interaction of this class of drugs with the cardiac cell membrane Na^+, K^+-exchange pump, the precise molecular mechanism for the improvement of muscle performance by ouabain is controversial[6,7]. Many investigators

claim that cardiac glycosides increase myocardial force of contraction by inhibiting $(Na^+ + K^+)$ATPase[8-10]. According to this hypothesis, such an inhibition might increase the intracellular concentration of Na^+, which may augment the activity of the transmembrane Na^+, Ca^{2+}-exchange pump described by several workers[11-14]. We have found that ouabain stimulates Na^+-dependent transport of noradrenaline by guinea pig heart sympathetic nerve terminals.

There is increasing evidence that low doses of cardiac glycosides increase the contractility of the myocardium and stimulate the active transmembranous transport of monovalent cations[15-18]. Such a conclusion has been vigorously challenged by Michael and co-workers[19,20]. It is possible that the stimulation of cation transport by cardiac glycosides may be observed in intact cells as opposed to broken cell membrane preparations. Thus, Michael and his co-workers[19,20], who used an isolated purified enzyme system, were unable to observe any stimulation of $(Na^+ + K^+)$ATPase activity by ouabain. We decided to investigate this possibility by examining the effects of different concentrations of ouabain on Na^+-dependent noradrenaline transport in sympathetic nerve terminals of cardiac muscle. If the noradrenaline uptake system is tightly coupled to $(Na^+ + K^+)$ATPase[1-5], and low doses of ouabain can stimulate cation transport[15-18], then these low concentrations of this cardiac glycoside must increase velocity of Na^+-dependent noradrenaline uptake into the cardiac sympathetic nerve terminals.

The Na^+-dependent $[^3H]$noradrenaline uptake in guinea pig heart slices was measured as described previously[2,5]. The effect of several concentrations of ouabain on Na^+-dependent $[^3H]$noradrenaline uptake is shown in Table 1. Although 1×10^{-10} M ouabain produced a small stimulation of the Na^+-dependent $[^3H]$noradrenaline uptake, 1×10^{-9} M and 5×10^{-10} M increased the initial velocity of $[^3H]$noradrenaline transport into the cardiac sympathetic nerve terminals by about 28% and 63%, respectively. When the concentration of ouabain was raised to 5×10^{-9} M, a significant inhibition of uptake was observed. Several experiments with different concentrations of ouabain (between 2×10^{-10} M and 8×10^{-10} M) indicated that maximal stimulation of Na^+-dependent $[^3H]$noradrenaline uptake is seen at 5×10^{-10} M ouabain.

Table 1 Effect of different concentrations of ouabain on high-affinity noradrenaline uptake in guinea pig heart slices

Concentration of ouabain (pM)	Specific $[^3H]$noradrenaline uptake (pmol g^{-1} h^{-1})*
0	83.8 ± 2
1	77.1 ± 1
50	79.1 ± 6
100	96.6 ± 7
500	136.7 ± 3‡
1000	107.8 ± 6†
5000	37.2 ± 4†

Male guinea pigs were killed by a blow on the head. Ventricle of the heart was removed immediately and placed in modified Krebs solution (4 °C) and cleared of extraneous tissues as described previously. Modified Krebs solution had the following composition (mM): NaCl, 118; KCl, 4.7; $CaCl_2$, 2.5; $MgCl_2$, 0.54; $NaHCO_3$, 25; NaH_2PO_4, 1; and glucose, 11. EDTA (20 $\mu g\ ml^{-1}$), ascorbic acid (200 $\mu g\ ml^{-1}$) and nialamide (1.25×10^{-5} M), were added to retard the spontaneous oxidation of noradrenaline. Ventricle slices were prepared with a Stadie–Riggs tissue microtome. The slices were weighed and immersed in 10 ml beakers containing 3.8 ml of Krebs solution. All data were obtained from triplicate slices and each experiment was repeated at least once more. Varying concentrations of ouabain (0.1 ml volume) and 26 nM $[^3H]$noradrenaline were added and the slices were shaken in a Dubnoff metabolic incubator at 37 °C in an atmosphere of 95% O_2 and 5% CO_2 for 10 min. Preliminary experiments indicated that the rate of $[^3H]$noradrenaline uptake remained linear for at least 10 min when the weight of the slices was between 20 and 40 mg. Nonspecific accumulation of radioactivity or blanks was routinely determined in triplicate by parallel incubation at 4 °C for 10 min. After incubation, slices were rinsed three times with ice-cold Krebs solution, blotted on filter paper, and placed in 1 ml of ice-cold 0.4 N perchloric acid. Tissues were extracted in the acid for 21 h at 4 °C and this was followed by centrifugation at 3,000g for 10 min in a Sorvall centrifuge (Model GLC-2). An aliquot (0.5 ml) of each sample was transferred to a vial containing 9.5 ml of Scintiverse (Fisher) and counted in a Packard Tri-Carb liquid scintillation spectrometer (Model 3380) at 30% efficiency as determined with internal standards. Tissue/medium ratios for $[^3H]$noradrenaline uptake were calculated as (c.p.m. per g wet weight tissue)/(c.p.m. per ml of medium). Results shown are averages of four experiments and each experiment was run in triplicate.

* Mean ±s.e.m.

† $P < 0.01$ compared with control.

‡ $P < 0.001$ compared with control.

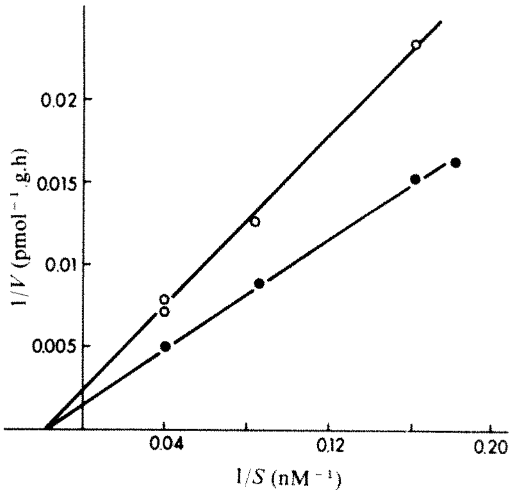

Fig. 1 Reciprocal plots of initial velocity of high-affinity noradrenaline uptake in guinea pig heart slices either in the presence (●) or absence (○) of 0.5 nM ouabain. Each point represents the mean of four determinations. Slopes and intercepts of the lines were determined by the method of least squares.

This increase of $[^3H]$noradrenaline uptake in sympathetic nerve terminals by ouabain may be due to an enhancement of the maximal velocity or apparent affinity of the uptake system for noradrenaline. The biochemical mechanism for the augmentation of $[^3H]$noradrenaline uptake in guinea pig slices by ouabain was evaluated by kinetic analysis. Results shown in Fig. 1 indicate that the maximal velocity (V_{max}) for $[^3H]$noradrenaline uptake into the nerve endings of guinea pig heart slices is 444 pmol per g tissue per h, with the apparent affinity constant (K_m) for noradrenaline being 5.6×10^{-8} M. The presence of 5×10^{-10} M ouabain increased the maximal velocity for $[^3H]$noradrenaline uptake to 667 pmol per g tissue per h without altering the K_m for the neurotransmitter (Fig. 1). These results indicate that ouabain may stimulate $[^3H]$noradrenaline uptake in cardiac sympathetic nerve terminals by increasing the V_{max} without affecting K_m.

There are several implications arising from this observation of stimulation of Na^+-dependent noradrenaline transport in guinea pig heart sympathetic nerve terminals by ouabain. First, there is some controversy on the involvement of $(Na^+ + K^+)$ATPase in the transport for noradrenaline[21]. Recent evidence from several laboratories indicates an intimate relationship between these two transport systems[1-5]. For example, ouabain has been found to show identical species sensitivity for the inhibition of $(Na^+ + K^+)$ATPase and noradrenaline uptake in heart and spleen slices[1-3]. Again, in regenerating sympathetic nerve terminals, ouabain binding sites appear before noradrenaline uptake systems can be detected[5]. As the low concentration of ouabain that is known to stimulate the Na^+, K^+-exchange pump[15-18] activates noradrenaline uptake (Table 1), these two transport systems must be coupled. Second, there is some dispute regarding the mechanism by which ouabain alters the level of noradrenaline at the neuromuscular junction. It has been suggested that ouabain may stimulate release of noradrenaline from sympathetic nerve terminals without affecting the uptake mechanism[22,23]. As ouabain cannot stimulate noradrenaline uptake by augmenting the release of accumulated noradrenaline, there has to be some direct effect of ouabain on high-affinity noradrenaline uptake mechanisms.

In conclusion, this report describes for the first time a stimulation of Na^+-dependent noradrenaline uptake in myocardial sympathetic nerve terminals by ouabain. Since ouabain selectively interacts with cell surface $(Na^+ + K^+)$ATPase, the results of this report provide further insight into the relationship between the monovalent cation transport pump and the noradrenaline uptake system.

Removal of sialic acid from cardiac sarcolemma does not affect contractile function in electrically stimulated guinea pig left atria

S. E. Harding & J. Halliday

Department of Pharmacology, King's College, London WC2R 2LS, UK

Calcium is essential for the maintenance of contraction in the heart, and it has been suggested that the glycoprotein matrix on the external surface of cardiac cells is a critical factor in the supply of 'activator' calcium to the beating heart[1]. Sialic acid residues are important calcium-binding sites in the matrix and treatment with neuraminidase, an enzyme which cleaves sialic acid from oligosaccharide chains, has been reported to abolish spontaneous contraction in cultured heart cells, without causing general breakdown in the plasma membrane[2,3]. However, we report here that in intact, electrically stimulated guinea pig atrial preparations, neuraminidase treatment produces no significant changes in resting tension or force of contraction. It is also without effect on the response to calcium removal and replacement, and inotropic or toxic concentrations of cardiac glycosides. In these experiments, up to 79% of the total tissue sialic acid was removed, and electron microscopy studies showed that this removal was accompanied by marked reduction of lanthanum binding to the sarcolemma. We therefore conclude that the calcium-binding sialic acid residues in the external matrix of the cardiac cells are of little importance in the maintenance of contractile function in these intact atrial preparations.

In preliminary determinations of the total sialic acid content of guinea pig heart, by incubation of the tissue in 0.05 M H_2SO_4 at 80 °C for 1 h (a modification of the method of Bers[4]), the content in nmol sialic acid per mg wet weight was 1.64 ± 0.12 for atria ($n = 6$) and 1.49 ± 0.14 (s.e.m.) for ventricles ($n = 4$). Although these values are not significantly different, the time course of sialic acid release by neuraminidase was found to be much slower in ventricles than in atria. By method (1) (see Table 1 legend), neuraminidase treatment freed 79% of total sialic acid from the atria within 5 h, whereas the corresponding release from ventricles was only 24%. We therefore decided to use atria in all further experiments.

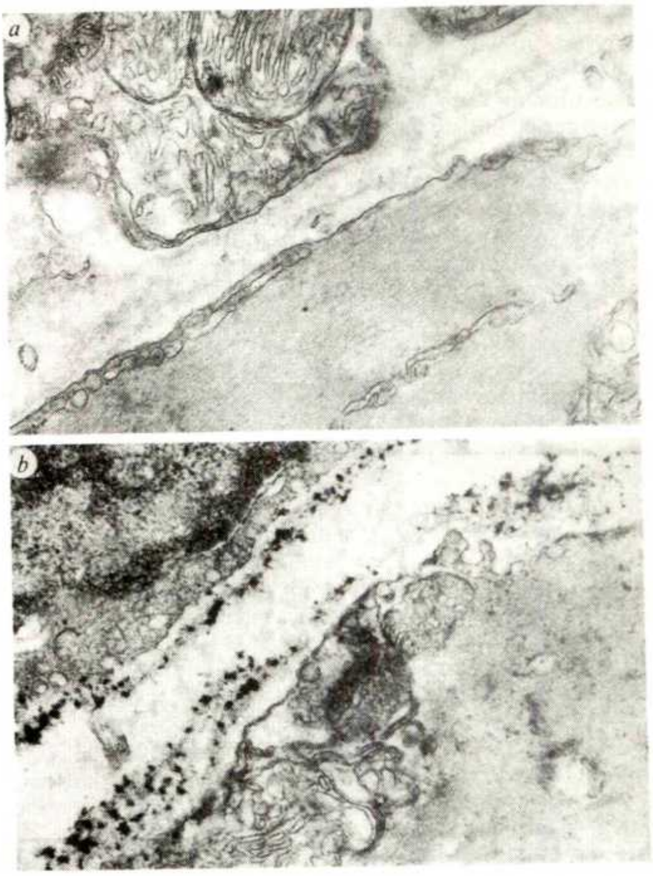

Fig. 1 Electron micrographs of neuraminidase-treated (*a*) and control (*b*) guinea pig left atria. Fixation and lanthanum staining were as described in the text. Note the heavy deposits of lanthanum on the external matrix of control cells, and their absence in neuraminidase-treated atria. ×30,000.

For the experiments in which the force of contraction was monitored, two methods were used for the incubation of the tissue with neuraminidase (see Table 1 legend). The first, in which the atrial strip was detached from the electrodes and incubated in a concentrated enzyme solution, had the advantage that all the neuraminidase-sensitive sialic acid, 1.30 ± 0.06 nmol per mg wet weight ($n = 5$), was removed in the 5-h period (the mean percentage difference between the amount released at 5 h and that at 6 h was $2.4 \pm 1.5\%$, and was not significant). This lack of further release was not due to deterioration of the enzyme, because the 5-h incubation medium was as effective as fresh neuraminidase solution in releasing sialic acid from *N*-acetylneuramin-lactose (from bovine colostrum, Sigma). The second method, in which the enzyme was added to the Krebs solution in the organ bath, enabled the force of contraction and resting tension to be monitored throughout the incubation. However, the sialic acid content of the bath could not be measured directly with this method because the volume of dilution was too great; parallel incubations in small volumes, but with the same ratio of enzyme to Krebs, were required to estimate the release. The amount released by this procedure was 1.07 ± 0.04 nmol sialic acid per mg wet weight ($n = 5$). This represents 65% of the total (82% of the neuraminidase-sensitive) sialic acid content, which is less than that achieved with method (1), but still higher than the 61% removal shown to cause disruption of the external matrix of cultured heart cells[3].

Electron microscopy studies were done to confirm visually that neuraminidase treatment was removing sialic acid residues from the external matrix. Tissues were exposed to concentrated neuraminidase (1 unit ml^{-1}) for 5 h, then transferred to HEPES buffer, composition (mM) 133 NaCl, 3.6 KCl, 1.0 $CaCl_2$, 0.3

$MgCl_2$, 16.0 glucose, 3.0 HEPES (*p*H 7.1), containing 5 mM $LaCl_3$ for 2 h. The temperature was maintained at 37 °C and the solutions were continuously bubbled with 100% O_2. Control tissues were exposed to the acetate buffer alone (see Table 1 legend) during the first 5 h. The tissues were fixed as described in ref. 3.

Preliminary results showed that in neuraminidase-treated tissues, lanthanum binding is greatly reduced in all areas (Fig. 1*a*). Control tissues, however, demonstrate the normal pattern of lanthanum binding described by other workers[3]; that is, large accumulations of lanthanum at the external matrix of the sarcolemma (Fig. 1*b*). This finding supports the biochemical data suggesting that neuraminidase treatment of whole atria is effective in removing at least part of the glycocalyx.

As may be seen in Table 1, the force of contraction of the control atrial preparations declines over the time course of these experiments. This is a well reported phenomenon, termed 'ageing', which Carrier *et al.* have suggested[5] is due to a decrease in calcium binding at the external surface of the sarcolemma; however, sialic acid removal neither enhanced nor attenuated this fall in force, casting some doubt on this hypothesis. In addition, sialic acid removal did not alter the resting tension, indicating that the capacity of the heart to relax was unchanged, and implying that the systems involved in the maintenance of low intracellular calcium between beats had not been affected.

We were particularly interested in the effect of neuraminidase treatment on the response to ouabain, as several reports have suggested that positive inotropic concentrations of cardiac glycosides increase external calcium binding. Ouabain, for example, increased both the density of the negative charges on the cardiac membrane[6] and the amount of La^{3+}-displaceable calcium bound to this surface[7]. We found, however, that neuraminidase treatment had no effect on either the positive inotropic response to 0.2 μM ouabain or the maximum rise in force evoked by a higher concentration. The toxicity of ouabain was assessed by the time to onset of arrhythmias after administration of a toxic concentration, and the rise in resting tension 30 min after this administration. Neither parameter was altered by sialic acid removal (see Table 1).

In the experiments with cultured heart cells, it was reported that neuraminidase treatment increased the amount of ^{45}Ca taken up[2], and the speed of uptake and washout[8]. This observation suggested that the external matrix might in some way regulate calcium entry to or exit from the cell. We therefore examined the effect of neuraminidase on the rate of fall in force of atrial preparations after removal of calcium from the bathing medium, and the subsequent rise on calcium replacement. The method, and the procedure for calculating half-times, are given in Table 2 legend. No differences in rates of decline and recovery of force of contraction between control and neuraminidase-treated preparations could be detected; a slight decrease was seen in the time taken for the force to fall, but the control also showed this change. It was possible to resolve the fall in force after calcium removal into two exponential decay processes[9], and therefore, in case there had been opposing changes in the two processes that were not apparent in the overall half-times, each curve was analysed, and the intercept on the ordinate and the half-life calculated for both the fast and slow decays. Once again, there was no significant difference between control and neuraminidase-treated preparations, indicating that there had been no change in the rate of loss of calcium from, or return of calcium to, those pools associated with maintenance of contraction.

Table 2 Effects of neuraminidase treatment on rates of decrease or recovery of force with calcium removal or replacement, respectively

	Half-time (s) for decrease in force of contraction following Ca^{2+} removal		Half-time (s) for increase in force of contraction following Ca^{2+} replacement	
	Before 5 h incubation	After 5 h incubation	Before 5 h incubation	After 5 h incubation
Control (*n* = 6)	22.9 ± 2.7	16.4 ± 1.1	45.5 ± 3.1	57.5 ± 6.9
Neuraminidase-treated (*n* = 6)	21.3 ± 2.2	18.2 ± 1.1	57.4 ± 4.9	58.3 ± 5.8

Method (2) (see Table 1 legend) was used for neuraminidase treatment of the atrial strip. For calcium removal, the organ bath was drained, then washed through with prewarmed, pre-oxygenated, calcium-free Krebs (calcium not osmotically replaced). Half-time for the decrease in force of contraction was taken as the time for the force to decrease to 50% of that immediately before draining the bath. After 2 min, calcium was re-introduced by injection of 100 mM $CaCl_2$ solution to give a bath concentration of 2.5 mM. Half-time for recovery was the time to reach ½(max-min) force, where max = maximum force of contraction attained within 10 min of calcium replacement, and min = force immediately before replacement. This procedure was repeated three times before and three times after neuraminidase treatment. All values are mean ± s.e.m.

In our experiments, therefore, removal of a large proportion of sialic acid from the membrane had no detectable effect on the function of the intact myocardium. These results are difficult to reconcile with those obtained in cultured cells, where spontaneous beating ceased and calcium exchangeability rose after neuraminidase treatment[2]. A possible explanation for this difference is that the culturing of the cells, which includes trypsin

Table 1 Effect of neuraminidase treatment on resting tension and force of contraction and response to ouabain in guinea pig atria

			Response to ouabain

Method (1) (*n* = 4)						
Control	13.5 ± 7.1	—	173 ± 10.3	218 ± 37.0	—	—
Neuraminidase-treated	18.5 ± 5.3	—	163 ± 22.1	292 ± 19.8	—	—
Method (2) (*n* = 8)						
Control	41.9 ± 4.3	28.5 ± 14.2	157 ± 7.2	204 ± 8.9	11.8 ± 4.2	7.5 ± 3.4
Neuraminidase-treated	46.8 ± 2.7	43.0 ± 14.2	153 ± 5.5	211 ± 11.6	18.8 ± 4.5	10.2 ± 6.1

Left atria were halved and mounted in contact with platinum electrodes in a 10-ml organ bath containing Krebs (119 mM NaCl, 4.7 mM KCl, 0.94 mM $MgSO_4.7H_2O$, 1.2 mM KH_2PO_4, 25 mM $NaHCO_3$, 11 mM glucose, 2.5 mM $CaCl_2$) bubbled with 95% O_2/5% CO_2, and stimulated at 3 Hz, 500 μs, supramaximal voltage. In method (1) the tissue was then unhooked from the electrode and placed in 1 ml acetate buffer (50 mM Na acetate, 154 mM NaCl, 9 mM $CaCl_2$, 5 mM KOH and 100 mM Tris-HCl, *p*H 7.4) containing 1 unit ml^{-1} neuraminidase (Behringwerke: 1 unit will split off 1 μmol *N*-acetylneuraminic acid from human α_1-acid glycoprotein in 1 min at 37 °C and *p*H 5.5), and bubbled with 100% O_2. Aliquots (0.2 ml) of the incubation medium were assayed for free sialic acid by the Warren method[10]. After 5 h, when all the neuraminidase-sensitive sialic acid had been split off, the preparation was removed, resuspended in the organ bath and stimulation restarted. After a period of equilibration, ouabain was added to the bath to a concentration of 0.2 μM and the positive inotropic effect allowed to develop for 30 min. In method (2) neuraminidase was added directly to the organ bath to give a concentration of 0.1 units ml^{-1}, and the tissue kept beating throughout the incubation. Parallel experiments using smaller volumes were done to estimate release of sialic acid by this method. After 5 h the neuraminidase was removed by washing the tissue six times with Krebs solution; ouabain was then added to a bath concentration of 0.2 μM as before. After 30 min the concentration was raised to 1 μM and the force of contraction and resting tension were monitored for a further 30 min. The time to onset of arrhythmias and increase in resting tension were taken as indices of ouabain toxicity. Control tissues were treated similarly to test ones, except that neuraminidase was omitted from the acetate buffer. All values given are the mean ± s.e.m. No neuraminidase-treated values differ significantly from control ($P < 0.05$).

* Expressed as a percentage of that immediately before incubation with neuraminidase.

† Expressed as a percentage of that immediately before addition of ouabain.

digestion, may have in some way increased the susceptibility of the matrix to disruption by sialic acid removal. Alternatively, it is just possible that similar changes in calcium permeability did occur in our preparations, but that the reserve capacity of the calcium-sequestering systems of the cell was sufficient to compensate for the extra influx.

The cessation of beating in the neuraminidase-treated, cultured cells might not be due to failure of contraction mechanisms as such, but to a disturbance of pacemaker mechanisms; this could explain why our preparations, which were electrically stimulated, continued to beat after a similar treatment. However, preliminary experiments with spontaneously beating right atria have shown that contractile activity is maintained throughout 5 h incubation in concentrated neuraminidase (1 unit ml^{-1}) at 37 °C. It therefore seems unlikely that sialic acid removal results in a disruption of pacemaker mechanisms.

We have thus shown that treatment of guinea pig atria with neuraminidase can remove up to 79% of tissue sialic acid and strip lanthanum-binding sites from the external sarcolemma. This disruption of the external glycocalyx, however, has no detectable effect on the force of contraction of electrically stimulated atria or the response of these atria to ouabain or calcium-free media. It seems, therefore, that the contribution of the sialic acid residues in the external glycoprotein matrix to contractile function in the guinea pig atrium is negligible.

We wish to thank Mr G. Morgan and Miss K. Bugg for the electron microscope studies, and Drs I. K. M. Morton and J. Littleton for their helpful discussion. S.H. is an MRC student.

Covalent linking of photoreactive insulin to adipocytes produces a prolonged signal

Dietrich Brandenburg, Cornelia Diaconescu, Derek Saunders & Peter Thamm

Deutsches Wollforschungsinstitut, Veltmanplatz 8,
D-5100 Aachen, FRG

The first step of insulin's many cellular functions is specific binding to receptors on the plasma membrane of target cells. The subsequent molecular basis of insulin action, particularly the coupling mechanism(s) involved in transmitting the biological message, remains largely unknown[1]. Our approach to the problem centres on the application of a series of well characterized photo-insulins carrying an aryl–azido or nitro–aryl–azido group in positions A1, B1, B2 or B29 (refs 2–4). Specific binding to membrane components could be demonstrated with B1-, B29- (ref. 5) and A1-photo-insulins[6] as well as a B2-derivative[7]. We now report that lipogenesis is increased to, and maintained at, near-maximal levels for several hours after photoinduced covalent binding of B2- (2-nitro,4-azidophenylacetyl)-des-Phe^{B1}-insulin (Napa-DP-insulin[3]) to living adipocytes.

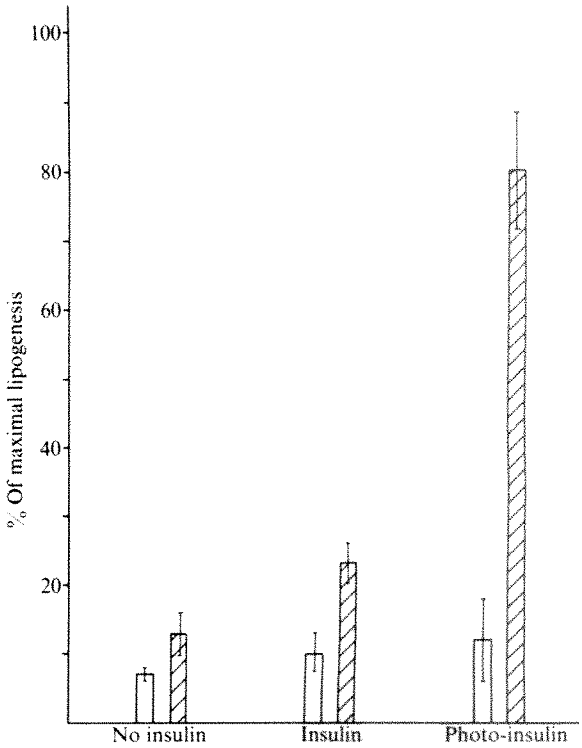

Fig. 1 Effect of covalent binding of photolabelled insulin on lipogenesis in adipocytes. Experiments were carried out with irradiation (▨) and without irradiation (☐) with the indicated preincubations. Per cent values (height of columns) are the ratios of basal lipogenesis (c.p.m. without added insulin) to maximal response (c.p.m. at 10 ng insulin per ml) and represent averages from three independent experiments. Adipocytes were prepared[13] from epididymal fat tissue of four Sprague–Dawley rats (130–160 g) and resuspended in 90 ml of Krebs–Ringer–HEPES buffer, *p*H 7.4, containing 1% bovine serum albumin[14]. Three lots of 25 ml (2–4 × 10^5 cells per ml) were transferred to thermostatted (37 °C) Millipore ultrafiltration chambers (47 mm internal diameter) equipped with boiled Millipore-MF-filters (8 μm pore size) and Teflon-coated stirrer bars. All subsequent operations up to the irradiation period were carried out in light of long wavelength (λ 500 nm). No addition was made to the first chamber (blank). Insulin (monocomponent pork, Novo; 14 pmol ml^{-1}) was added to the second chamber and Napa-DP-insulin (14 pmol ml^{-1}) to the third. The suspensions were equilibrated under slow ~100 r.p.m.) stirring for 5 min. Each chamber was then irradiated from above for 1 min with a Philips HPK 125 W/L UV lamp equipped with a black glass filter (UVW-55, Hanau Wertheim). The lamp was 8 cm from the surface of the stirred adipocyte suspension. After irradiation, the Millipore chambers were sealed. Warm (37 °C) Krebs–Ringer–HEPES buffer (300 ml) was run through in a constant volume washing procedure at a flow rate of 10 ml min^{-1}. After washing, 1-ml aliquots (quadruplicates) of the suspensions were used in a lipogenesis assay according to ref. 8. The incubation time was 2 h. Control experiments were carried out as above, but without irradiation.

A fat cell assay[8] was used to determine the biological effects of Napa-DP-insulin. Adipocytes were first incubated with Napa-DP-insulin (80 ng ml^{-1}) to obtain a receptor occupancy of more than 90% (ref. 9). The photoreactive group was activated by short exposure to UV light of wavelengths 300–400 nm. Cells were then washed for 30 min by a mild constant-volume procedure which diluted the insulin concentration by 1 : 3 × 10^4. The wash period was sufficient to allow for dissociation of the non-covalently bound insulins from the receptor. These adipocytes were then used in a standard lipogenesis assay to determine the effect of prebound and added insulin. In control experiments, adipocytes were incubated in the dark or under UV light with or without unmodified insulin.

It was important to find conditions of activation which would not damage the adipocytes. Appropriate experiments in which

0028–0836/80/340821—02$01.00

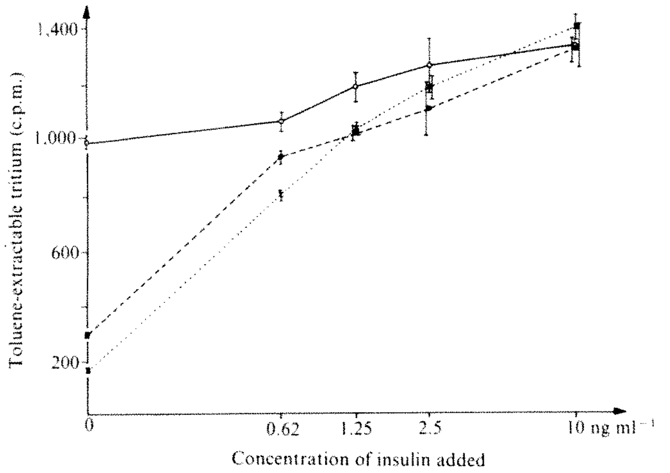

Fig. 2 Insulin-stimulated incorporation of tritium from D-[2-^{3}H] glucose into toluene-extractable lipids of isolated rat fat cells after the following pretreatment: curve 1 (· · · · ·), irradiation only; curve 2 (– – – – –), preincubation with insulin (14 pmol ml^{-1}) + irradiation; curve 3 (———), preincubation with Napa-DP-insulin (14 pmol ml^{-1}) + irradiation.

adipocytes were irradiated for various periods showed that there was no appreciable loss in lipogenic viability after 1 min of irradiation. This represents twice the half life of the photo-label in the same conditions, an activation of about 75% (ref. 4).

Adipocytes preincubated with high concentrations of insulin and subsequently washed gave basal values which were only slightly higher than normal (Fig. 1), and to a somewhat greater extent in the case of Napa-DP-insulin. Adipocytes responded normally to increasing concentrations of insulin in the subsequent lipogenesis assay (data not shown). The higher basal values may be related to the memory effect described by Gliemann[10].

Irradiation of adipocytes which had been preincubated with insulin caused basal lipogenesis to increase from 11 to 23% (Fig. 1). However, the concentration dependence and maximal stimulation in the lipogenesis assay were similar to those of cells preincubated without insulin (see curves 1 and 2 in Fig. 2). A considerable increase in basal lipogenesis was observed after irradiation of adipocytes preincubated with photoreactive insulin (Fig. 1 and Fig. 2, curve 3). This amounted to 75% of the maximal stimulation in two experiments and to 90% in a third. The difference between the experiments was probably due to small uncontrollable variations in the conditions of irradiation.

The addition of progressively higher concentrations of insulin to the medium resulted in a further incorporation of tritium into lipids until maximal response was reached. In all three experiments, the maximal stimulation of lipogenesis in adipocytes preincubated with or without insulin or Napa-DP-insulin was identical within experimental error. Maintenance of normal insulin sensitivity in the latter case indicates that the adipocytes were still fully viable and that the effects were not due to specific damage through photo-sensitization.

Our study demonstrates that photoreactive insulin can be activated without interfering with the viability of isolated adipocytes. Furthermore, covalent binding indeed generates a biological response. This response lasts for a considerable period. The photo-insulin-treated cells are handled for a period of 0.75 h (washing and pipetting) before the 2-h incubation with ^{3}H-glucose, so that the covalent hormone–receptor complex must be functional over at least 2.75 h. However, it is not inconceivable that the complexes are functional as long as they are intact.

Specific covalent binding of insulins with photoreactive groups at the N-terminus of the B-chain to cell membrane preparations has been demonstrated[6,7,11]. Therefore, we deduce that the effect we observed was due to specific linkage to the adipocyte receptor. It is interesting that the N-terminus of the B-chain has previously not been included in the putative receptor-binding region of the hormone[12]. The irreversible complex that is formed is obviously able to elicit the subsequent events of glucose transport and metabolism. Experiments are under way to determine whether a given population of covalently bound hormone–receptor complexes has the same ability to stimulate lipogenesis and glucose transport as the same population of noncovalently linked hormone–receptor complexes.

The insulins of New World hystricomorph rodents exhibit many novel amino acid changes in primary structure when compared with other mammalian insulins[1–3]. These changes give rise to unusual properties (low potency, failure to self-associate[4–6]) not shared by other naturally-occurring insulins. We report here on the primary structure, zinc-binding properties and circular dichroism (CD) of porcupine insulin (*Hystrix cristata*), the first Old World hystricomorph insulin to be investigated, and discuss the changes in primary structure of the hormone in relation to its properties. Residue B_{22} is strongly implicated as being responsible for the unusual properties of porcupine insulin.

Porcupine insulin differs at seven residues from bovine insulin (Fig. 1) and is unable to bind zinc (Fig. 2). Such behaviour has been noted only in hagfish[7], guinea pig[4] and casiragua[6] insulins. These latter insulins lack the zinc-coordinating B_{10} His together with several other residues on the dimer–dimer interface of bovine insulin which have been implicated in zinc binding and hexamer formation[8]. As these residues are conserved in porcupine insulin, an alternative explanation is required to account for its failure to bind zinc.

The CD spectrum of porcupine insulin shows concentration independence in both the near and far UV (Fig. 3). The intensity of the tyrosyl CD band of bovine insulin at 275 nm has been shown to be dependent on concentration and has been largely

assigned to perturbation of the tyrosines at B$_{26}$ and B$_{16}$, which become buried as the hormone dimerizes (W. Strassbürger, J. Fleischauer and A.W., unpublished results). Because these residues are conserved in porcupine insulin, one would expect a concentration dependence at 275 nm if dimerization occurred. Therefore, the lack of concentration dependence is further proof of the inability of porcupine insulin to dimerize. As porcupine insulin is monomeric, its CD spectrum is compared with that of monomeric bovine insulin (that is, at concentrations below 10^{-6}M). The CD spectra of the two insulins can be seen to be more similar at 275 nm (Fig. 4). However, the positive band at 196 nm in bovine insulin is blue-shifted to 193 nm in porcupine insulin and is reduced in ellipticity. The negative extremum found at 208 nm in bovine insulin also shows reduced ellipticity in porcupine insulin. The ellipticity of the bands at 196 and 208 nm are dependent on backbone conformation rather than on side-chain chromophores and have been largely assigned to α-helix. These data suggest that at *p*H 8.4 the tertiary structures of porcupine and bovine insulins are different. On acidification to *p*H 2, the CD spectrum of porcupine insulin more closely resembles that of bovine insulin measured at neutral *p*H; at 275 nm the two spectra are almost indistinguishable, although differences at 196 nm are still apparent (Fig. 4). The acidification of porcupine insulin seeks to alter its tertiary structure towards a more 'bovine-like' insulin conformation.

We explain these observations as follows. In bovine and most other insulins the conformation of the hormone may be stabilized by a complementarity of charge betwen B$_{22}$ Arg guianidinium group and A$_{21}$ Asn carboxylate[8]. Both enzymatic cleavage of the A$_{21}$ Asn (ref. 9) and substitution of the B$_{22}$ Arg (ref. 10) result in a modification of the tertiary structure of the hormone and affect its ability to aggregate[5,9,10]. The substitution B$_{22}$ Arg by Asp in porcupine insulin (Fig. 1) will bring two negative charges into close proximity unless there is a change of conformation, which may also result in a loss of zinc binding and self-association. At low *p*H, protonation of either B$_{22}$ Asp or the A$_{21}$ α-carboxylate may remove charge–charge repulsion and allow a close approach of the B$_{22}$–A$_{21}$ residues, resulting in the change of tertiary structure of porcupine insulin towards the conformation of the bovine molecule. A similar mechanism has been suggested for the effect of acidification of guinea pig insulin[11].

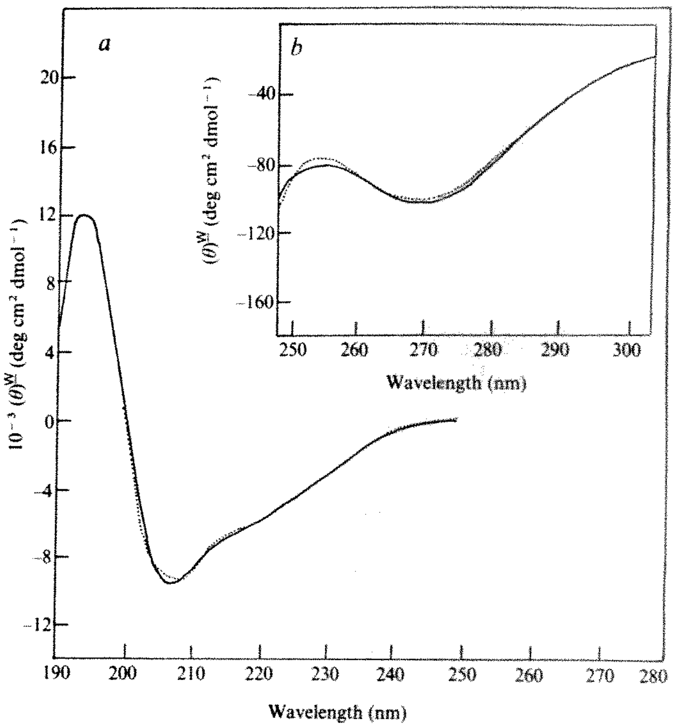

Fig. 3 Circular dichroism spectrum of porcupine insulin as a function of concentration. ——, 4×10^{-5}M porcupine insulin; · · · ·, 4×10^{-6}M porcupine insulin in 0.025 M Tris buffer, *p*H 8.4, zinc free. Bovine insulin has a concentration-dependent CD spectrum at both 222 nm and 275 nm (ref. 5).

The affinity of binding of porcupine insulin to rat liver plasma membrane insulin receptors and its ability to stimulate the conversion of [3-^{3}H]glucose into lipid by isolated rat fat cells were determined. The most notable property of porcupine insulin revealed by these assays, apart from the decrease in biological potency of the hormone, was the discrepancy between the receptor binding affinity, 25%, and the biological activity, 4%, of the hormone (both relative to bovine insulin). Similar discrepancies have been found in hagfish insulin[12] and in several

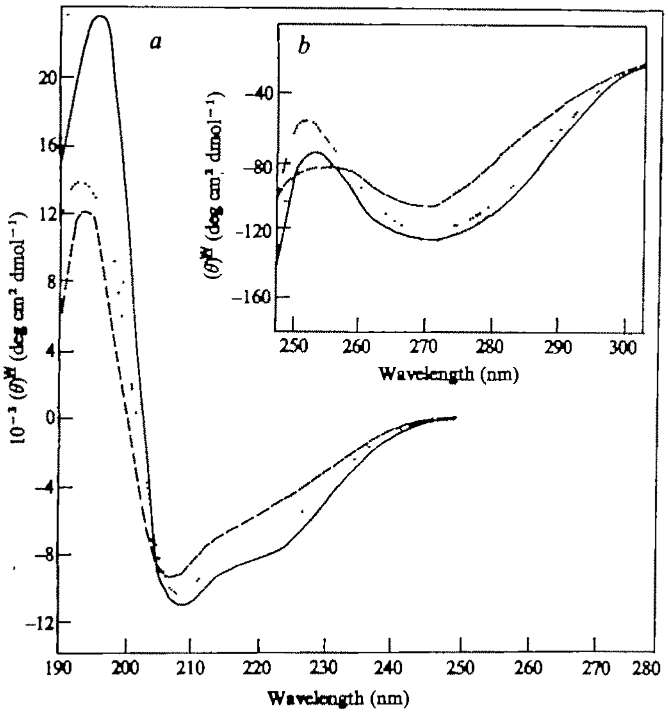

Fig. 4 Circular dichroism spectrum of porcupine insulin at *p*H 2.0 and 8.4 and of bovine insulin at *p*H 7.8. – – –, Porcupine insulin 4×10^{-5}M, *p*H 8.4; · · · ·, porcupine insulin 4×10^{-5}M, *p*H 2.0; ——, bovine insulin 4×10^{-6}M, *p*H 7.8. All are in 0.025M Tris buffer at the *p*H indicated, zinc free.

insulin analogues[13]. We are unable to detect a common factor between these insulins and cannot explain the discrepancy. The decrease in potency of porcupine insulin is probably due to the substitution of the B_{22} Arg, because this is the only residue not conserved in the putative receptor binding site proposed by Pullen *et al.*[14]. A similar substitution, B_{22} Arg to Asp, arises in guinea pig insulin and has been cited by Zimmerman *et al.*[15] as being responsible for the low potency of this insulin. A recently synthesized analogue of bovine insulin substituted only at B_{22} Arg to Asp has been reported to have a reduced potency (K. Yueh-ting, personal communication).

Other substitutions in the sequence of porcupine insulin which might also contribute to its decrease in binding affinity are at A_4 Glu to Asp, B_{21} Glu to Asn, and B_{27} Thr to Arg, all of which lie on the periphery of the receptor binding region of the hormone[14]. Note also that hagfish insulin, which also has a substitution at B_{21} Glu (Glu to Val), has a greatly reduced potency[12]. This insulin has conserved all the residues involved in receptor binding and has a nearly identical conformation to that of bovine insulin[16]. Thus, it is likely that the substitution at B_{21} makes an important contribution to the decrease in potency of porcupine insulin.

Examination of the primary structure of four New World hystricomorph insulins reveals no one amino acid substitution that is characteristic of this suborder[3]. All the insulins share the property of low potency (blood glucose lowering, or [3-^{3}H]glucose conversion into lipid) when compared with bovine or porcine insulin. Scrutiny of the porcupine insulin sequence also fails to show any characteristic amino acid substitutions. Low potency persists. We speculate that hystricomorph rodents, both New and Old World[17], have low-potency insulins because of a common evolutionary pressure. This pressure has resulted in a reduction of the role of insulin as a modifier of glucose metabolism, as well as a change in the insulin receptor[3]. We speculate that another function of insulin has been consequently upgraded. One such function could be its mitogenic activity.

We thank Professor S. Gombe for organizing the collection of porcupine pancreas, and Drs A. J. B. Haigh and D. G. Rae (Wellcome Kenya Ltd) for maintaining contact and successfully preserving and despatching the glands. R.H. thanks the SRC for a CASE Studentship.

Crystal structure of a ribosomal component at 2.6 Å resolution

Marie Leijonmarck, Stig Eriksson & Anders Liljas

Institute of Molecular Biology, Uppsala University, Box 562,
S-751 22 Uppsala, Sweden

Structural information about the ribosomes has been sought in many ways[1,2]. It is known that the 50S subunit of *Escherichia coli* ribosomes contains four copies of the ribosomal protein L7/L12 (refs 3–7) in a unique region[8,9]. A complex can be isolated consisting of those four copies bound to another ribosomal protein, L10 (refs 10–13). L7/L12 aggregates into elongated dimers in solution[14,15]. Ribosomes deprived of L7/L12 have a reduced affinity for supernatant factors such as EF-Tu and EF-G and almost no capacity for factor-dependent GTP hydrolysis[16–18]. The sequence of the 120 amino acid residues in L7/L12 from *E. coli* has been determined[19], and two domains of L7/L12 (residues 1–36 and 53–120, respectively) have been crystallized separately[20]. We now report the first crystal structure of a ribosomal component, a C-terminal fragment (CTF) of the protein L7/L12 from *E. coli*, determined to 2.6 Å resolution. The CTF has a compact, plum-shaped tertiary structure with a high content of secondary structure. The three α-helices and three β-strands in CTF account for 32% α-helix and 14% β-structure in the intact L7/L12 protein. A binding site for anions shows some resemblance to the known nucleotide binding site in many proteins.

Ribosomes, subunits, the protein L7/L12 and its fragments were obtained as described earlier[11,20]. The crystallization of CTF started with a solution containing 0.2 M citrate *p*H 3, 10 mM $MgSO_4$, 0.8 M $(NH_4)_2SO_4$ and 2–10 mg ml⁻¹ protein. Crystals were obtained in hanging drops at 20 °C by vapour diffusion against 4 M $(NH_4)_2SO_4$. These bipyramidal crystals grew to a maximum length of about 0.4 mm over a period of 1–2 months. Before use the crystals were washed in 4 M $(NH_4)_2SO_4$. Native data were collected on a crystal in 4 M $(NH_4)_2SO_4$ at *p*H 4.2. Two heavy atom derivatives were used: 2 mM *p*-chloromercuribenzene sulphonic acid (PCMBS) at *p*H 5.2 and 1 mM $KAu(CN)_2$ at *p*H 4.2. They were soaked for 3 days. These crystals belong to the space group $P4_32_12$ with cell dimensions $a = b = 54.7$ Å and $c = 42.5$ Å and contain one molecule of CTF (molecular weight ≈ 6,900) per asymmetric unit. X-ray intensities were collected at +4 °C on a Philips-Stoe computer-controlled 4-circle diffractometer[21]. The 2,218 independent reflections in the 2.6-Å resolution sphere were collected on one native crystal. For the heavy atom derivatives, Friedel pairs were measured at ±2θ in blocks of 100 reflections. Data were cor-

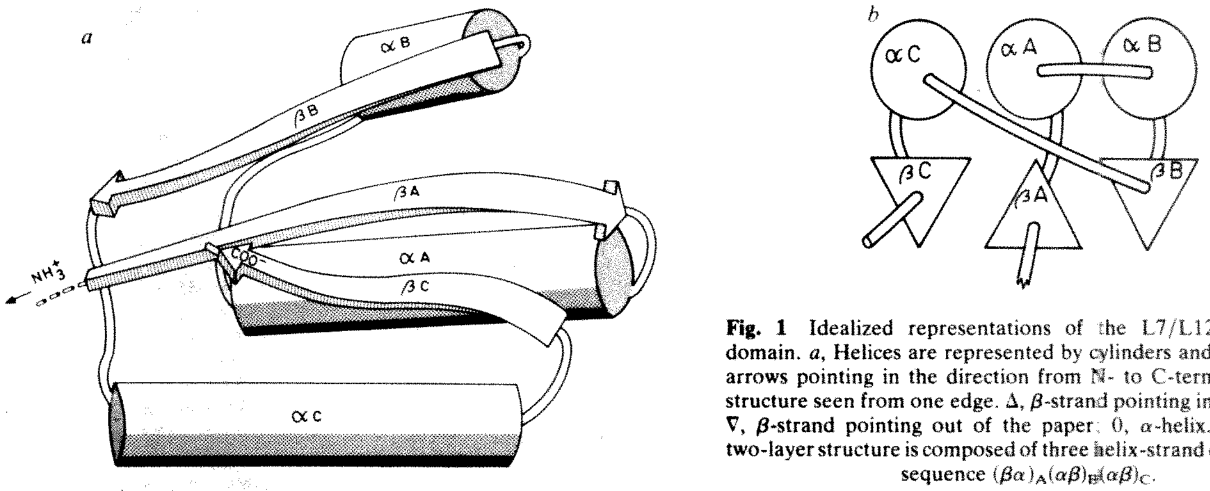

Fig. 1 Idealized representations of the L7/L12 C-terminal domain. *a*, Helices are represented by cylinders and β-strands as arrows pointing in the direction from N- to C-terminus. *b*, The structure seen from one edge. Δ, β-strand pointing into the paper; ∇, β-strand pointing out of the paper. 0, α-helix. This simple two-layer structure is composed of three helix-strand couples in the sequence $(\beta\alpha)_A(\alpha\beta)_B(\alpha\beta)_C$.

rected for Lorentz-polarization effects and for radiation damage and a semi-empirical absorption correction was applied[22].

The heavy atom positions were determined from three-dimensional difference Patterson functions, calculated with coefficients including the anomalous scattering[23]. The Patterson map of the PCMBS derivative was interpretable in terms of a single PCMBS site with the Hg atom as well as the S atom on the crystallographic 2-fold axis. The major site of the gold derivative was obvious from the Patterson map, whereas minor sites were derived from cross-phased difference Fourier maps. With phase angles in the two enantiomorphic space groups derived from the PCMBS derivative alone, two difference Fouriers of the gold cyanide derivatives were calculated. The clear difference in peak height showed the space group to be $P4_32_12$. The final state of the least squares refinement is shown in Table 1. Using the phase angles obtained, a 'best' native Fourier[24] was calculated.

The electron density map shows a clear distinction between solvent and protein. The protein part was interpreted as a single continuous polypeptide chain. A unique alignment could be made of the amino acid sequence (residues 53–120) with regard to the chain tracing. Rough coordinates were measured from the map as a guideline for the model building on a Vector General 3404 graphical display unit. The program package FRODO by Jones[25] was used.

The C-terminal fragment of L7/L12 is a plum-shaped molecule of approximate dimensions 20×20×35 Å. It is composed of three α-helices and three β-strands, all lying roughly along the long axis of the molecule (Fig. 1). The three helices form one layer and the antiparallel β-strands form a second layer with the usual twist[26]. We have found no other protein containing this simple arrangement of secondary structure elements.

L7/L12 has a high proportion of charged residues. Nevertheless, all the residues between the two layers of secondary structure are hydrocarbon side chains (Fig. 2). These residues are never exchanged for polar residues in any of the three known sequences (Fig. 3).

A surprisingly large surface area on the β-sheet side of the CTF molecule is composed of only hydrophobic side chains (Ile 57, Ala 61, Leu 78, Ala 90, Pro 91 and Ala 93). This hydrophobic surface may ultimately be found to be a surface for contact of CTF with other regions of the L7/L12 polypeptide or for other proteins[27]. The hydrophobic surface of CTF is lined by acidic residues, Asp 55, Glu 82, Asp 85, Glu 96 and Glu 118 and the C-terminal carboxyl group.

CTF obviously has a compact domain structure. This agrees well with the following observations: the spontaneous cleavage[20] seems to have occurred where the polypeptide enters into the domain; limited proteolysis experiments also yield a very similar fragment[27]; a comparison of the L7/L12 sequences from three species shows that the region just before residue 53 is hydrophilic, highly variable and has frequent deletions[5].

CTF has about 38 residues (56%) in α-helices and 17 residues (25%) in β-strands, 32% and 14%, respectively, of the 120 residues in L7/L12. A high helical content for L7/L12 has been observed by many investigators from circular dichroism (CD) spectra[3,28–31]. Two groups have observed 10–20% β-structure[3,31] by analysis of the entire far-UV region of the CD spectrum. With so much β-structure in CTF, there would be

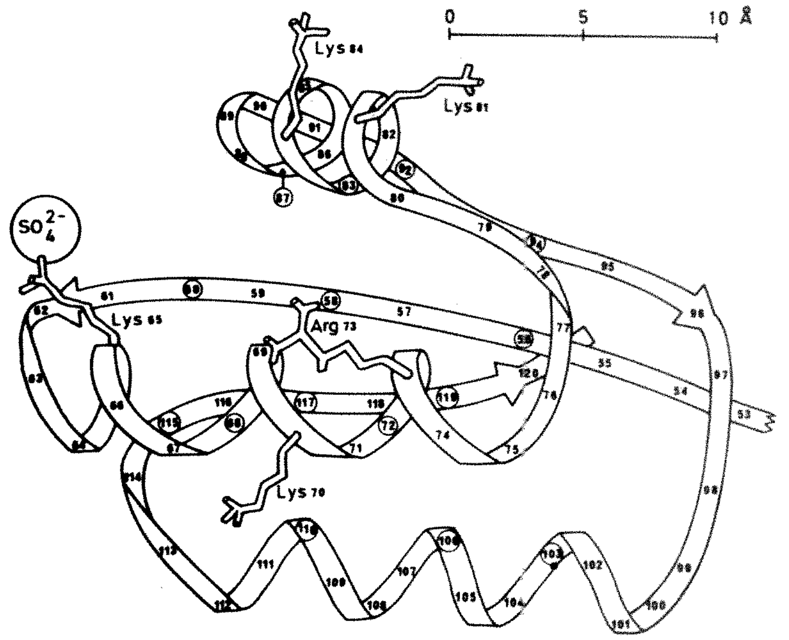

Fig. 2 The structure of the L7/L12 C-terminal domain shown as a ribbon. The approximate location of each residue is indicated. This view of the molecule is opposite to the one in Fig. 1. The residues pointing into the hydrophobic core are in circles. This side of the molecule has five basic residues specially indicated here, without counter ions from the protein. A very significant electron density, best interpreted as a bound sulphate ion, is observed near Gly 62. This binding has some similarities to the nucleotide binding family of proteins.

little, if any, β-structure in the N-terminal part of the L7/L12 protein.

Several predictions of the secondary and tertiary structure of L7/L12 have been made[32-35], all inconsistent with the CTF structure in Fig. 2. For example, Ptitsyn *et al.*[32] predicted the three α-helices but missed the three β-strands. All other attempts overestimated the α-helical content. Even when the occurrence of β-structure was considered (ref. 35 and Argos and A.L., unpublished work), a correct assignment of the β-strand was impossible.

An unusual feature of L7/L12 is its resistance to complete denaturation, for which one domain of the protein seems to be responsible[29,31]. As this contains the β-structure it must be the C-terminal domain. Two reasons for this stability must be the high amount of residues in secondary structure and the extremely hydrophobic interior. A domain with this stability would be unlikely to adopt different conformations in ribosomes, solution or crystals. Several observations suggest that the C-terminal domains of the four L7/L12 molecules are located at the tip of one of the protruberances on the 50S particle[8,27].

A globular electron density, best explained as a sulphate, is located near the turn between the β_A-strand and the α_A-helix. This site is analogous to that found in a large family of enzymes that bind nucleotides or other anions at the junction between the C-terminal side of a β-strand and the N-terminal of a helix[36]. The sulphate ion is bound close to residues Ala 61, Gly 62 and Lys 65, all three being conserved in the three known sequences (Fig. 3).

The protein L7/L12 must be present for optimal function of the ribosome[16,37]. One of the functions of the protein is to mediate the EF-Tu- and EF-G-dependent GTP hydrolysis[18]. The complete C-terminal domain seems to be required for this function[38,39]. Several pieces of evidence[27] make it tempting to believe that the EF-Tu molecule is bound to the ribosome with phosphates of the GTP molecule at the anion binding site of the L7/L12 C-terminal domain.

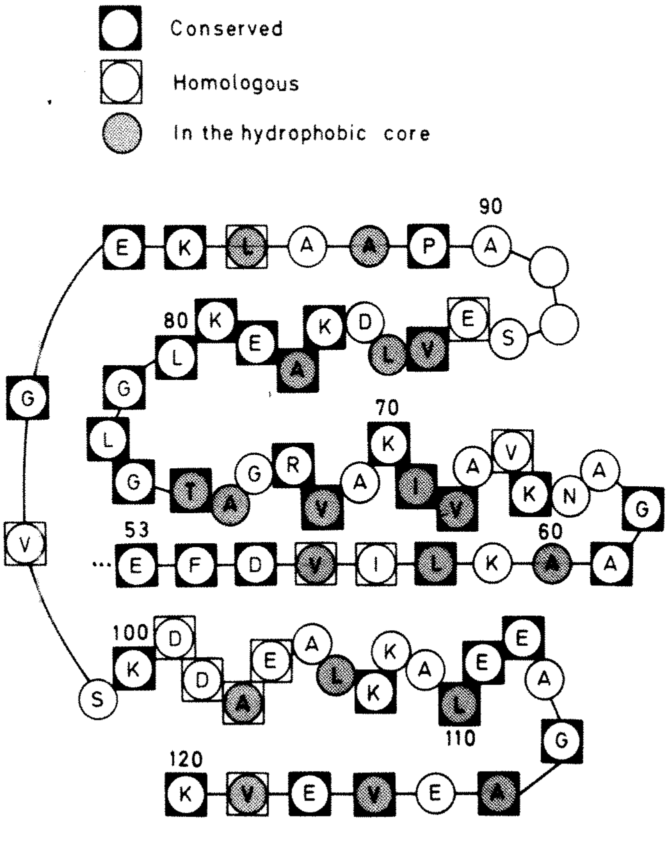

Fig. 3 The C-terminal amino acid sequence[19] arranged into the various secondary structure elements. Amino acids in helices are in a wavy arrangement without connecting lines, and residues in β-strands are connected with horizontal lines. Invariant and homologous residues between the three complete sequences known[5] are enclosed in shaded or light boxes. The shaded circles indicate residues being part of the hydrophobic core. The two empty circles before residue 90 indicate that the sequence from *Bacillus subtilis* has two more residues in this region. The one-letter code for amino acids is used[40].

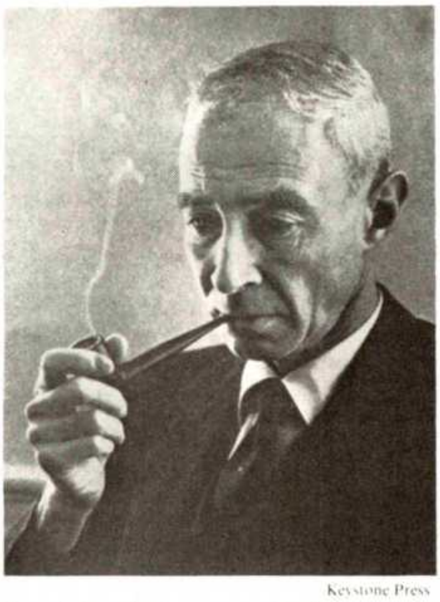
BOOK REVIEWS

The growing pains of Robert Oppenheimer

Rudolf Peierls

Frank Oppenheimer

Robert Oppenheimer, 1926 or 1927 — "the young researcher whose professors had doubts about his scientific future . . .".



Keystone Press

Oppenheimer in later years, after his success as director of Los Alamos and the ordeal of the "Oppenheimer Trials".

Robert Oppenheimer: Letters and Recollections. Edited by Alice Kimball Smith and Charles Weiner. Pp.250. (Harvard University Press: 1980.) $20, £12.

ROBERT Oppenheimer was one of the most famous scientists of his time, not so much for his contributions to theoretical physics, although these were substantial enough, but as mentor of a large number of successful theoreticians, and above all for his direction of the Los Alamos Laboratory at which the atom bomb was developed and produced during the Second World War.

The impressions he made on superficial acquaintance were very different at different times and on different occasions, and sometimes appeared hard to reconcile. The shy and introverted young boy and student became the successful director of a vast enterprise, successful very largely by his skill in dealing with people. The young researcher, whose professors had doubts about his scientific future because he had difficulty in expressing himself in writing, became famous for always finding the *mot juste* to sum up a situation. His lightning speed of understanding, which often produced the answer or a comment before his questioner had completed half his explanation, would on occasions make him miss the point of an important new idea, and he could meet presentations of such ideas by young colleagues with withering criticism. The ivory-tower scholar who did not know or care much about public affairs found his social conscience in the late 1930s by taking an interest in liberal and left-wing groups (an interest which formed part of the accusations in the security hearings against him), and later became a national figure in the debates about international relations and defence policy.

The present volume traces the development of this complex personality. The editors, Alice Kimball Smith and Charles Weiner are singularly well qualified for their task. Mrs. Smith was at Los Alamos from the start until the end of the War, and therefore well acquainted with the atmosphere of the place and with many of its members. She later made a study of the part played by scientists in the post-war period in influencing legislation towards civilian control of atomic energy. Dr Weiner is a physicist concerned with recent scientific history, who has recorded interviews with many distinguished physicists.

In describing themselves as editors of Oppenheimer's letters and recollections, they do not really do justice to their work. The letters are supplemented, where there are gaps, not only by passages of Oppenheimer's recollections taken from later interviews, but also by comments from friends, colleagues and pupils, painstakingly collected and sensitively evaluated. In many places the editors' comments, based on this material, are more informative than the letters. They not only identify many of the people and events referred to in the letters, but also summarize events and developments not mentioned in the letters or which took place in periods from which no letters have survived. The book is therefore really intermediate between edited correspondence and a serious biography.

The young Oppenheimer was not the type to keep copies of his letters, and not many of the recipients preserved them. The fact that there remain enough letters from the pre-War period to provide a clear picture of Oppenheimer's attitudes and development during that time is largely due to the few friends who kept the letters and made them available. One of these is Herbert W. Smith, his English teacher in the Ethical Culture School; letters to him are most numerous of any of the correspondents. In the earlier part Oppenheimer sends him essays and verse; his evident desire for approval makes Smith a kind of father figure.

Almost as numerous are the letters to Oppenheimer's brother, Frank, in which the elder brother gives much advice and exhortation, and shows great warmth and affection, though sounding a little patronizing at times. Amongst other sizeable collections of letters are those to Francis Ferguson, whom he first met in his final year at the Ethical Culture School and with whom a close and sometimes tempestuous friendship developed. Of a later period, the physicist George Uhlenbeck, who was a close friend, preserved many interesting letters.

The first three chapters are based on these letters and a few others, supplemented by other information collected by the editors. From his home background we follow Robert to the Ethical Culture School, where he was an excellent scholar in all subjects, and where his interest in science was first aroused through mineralogy. After leaving school and after a year's convalescence from dysentery contracted during a trip to Europe, he visited New Mexico in the summer with his teacher, Herbert Smith. This was the beginning of his deep attachment to the south-west. In 1922, aged 17, he entered Harvard. He spread his studies over a wide range of subjects, mostly on the literary side but including chemistry, in which he graduated in 1925, and some physics. The number and diversity of courses, and the amount of reading he managed, must have meant hard work; at the same time he learned to make contact with people and form friendships.

In his final year at Harvard an important influence was Percy Bridgman, in whose laboratory Oppenheimer did some experimental work, and his decision to go for postgraduate study in physics probably owed much to Bridgman. He decided to go to Cambridge. His studies there did not work out too well. He was not accepted to work under Rutherford, as he had hoped, but did some experimental research under J.J. Thomson, which did not make much progress. However, he had the chance at Cambridge of meeting many distinguished people, including Niels Bohr and other theoreticians, and it became clear to him then that he wanted to do theoretical work. During the Cambridge period he had times of very deep depression and unhappiness, but he was able to deal with his own disturbed state more effectively than any doctors he consulted.

After a year at Cambridge he moved to Göttingen, a congenial environment, to work with Max Born. This was the exciting time when quantum mechanics emerged, and the beginning of Oppenheimer's passionate devotion to theoretical physics, and also of his constructive contributions to the subject. He qualified in one year for a PhD, and returned to the United States in 1927. After a semester at Harvard and one at the California Institute of Technology, he spent another year in Europe, visiting Ehrenfest, Kramers and Pauli. Then he moved to California, holding appointments at Caltech and Berkeley, dividing his time between the two places. He liked this arrangement because at Caltech there were many theoreticians from whom he could learn, while at Berkeley he was practically the only modern theoretical physicist, and thus could contribute more to teaching and research. This unusual arrangement continued until he became involved with atomic energy in 1942. It was here that he started to gather a group of graduate students, who usually followed his annual migration — and that he developed his power as a teacher and leader in research. It was in the California years that he first became concerned with the world around him and with politics. It was in that period that he got married.

He was now an established and respected member of the physics community, as expressed in his election to the National Academy in 1941.

In 1942, when work on the atomic bomb was becoming a serious project, he was asked to take charge of work on fast-neutron fission, which was related to the problems of design and performance of a bomb. The period from this time until the end of the War is dealt with in Chapter 4. Here the task of the editors changes. It is no longer a question of searching out the few surviving letters and filling gaps, but rather to select, from amongst the voluminous files of official correspondence, the letters which are most informative of Oppenheimer's attitude and ways.

In coordinating the experimental and theoretical work carried out in different universities, he immediately showed his characteristic ability for summarizing, for stating the main issues clearly and for formulating questions. It soon became clear that efficiency demanded that this work be concentrated in a single centre, and he became involved in the planning of the new laboratory and the selection of a site. At some stage General Groves, head of the 'Manhattan District' (the code name for the atomic weapons project), decided to appoint Oppenheimer the director of the new laboratory. This was a daring decision, considering that Oppenheimer was a theoretician, not experienced in administration and had the reputation of being rather disorganized in practical matters. Yet the decision was amply justified by its success. Chapter 4 helps to understand why. In addition to his lucidity in recognizing and expressing the main issues, Oppenheimer managed to deal with people in a manner which made them feel that they were respected, and gave them the confidence that their views and their needs were taken into account. The letters give examples of the many large and small problems that the director had to handle, and the pressure under which he was working. One of the surprising facts is how much mutual respect, and indeed affection, developed between Oppenheimer and Groves, in spite of the enormous disparity between their personalities.

Chapter 5 covers the three months from the end of the War to Oppenheimer's departure from Los Alamos. The letters are now concerned with post-War plans for Oppenheimer, positions for the staff of Los Alamos and the organization of atomic-energy research, and reflect the burden of responsibility that scientists carried because of their work on the bomb. The last document by Oppenheimer is his speech at Los Alamos, in which he discusses the future of international relations and the idea of international control of atomic energy.

The editors decided, wisely, to terminate the collection of letters at this point, since from then on the glare of publicity which fell on him, the great volume of correspondence and his membership of numerous official committees, changed the style of his letters, which tended to become more official and more guarded. They do not give the kind of insight which makes the letters reproduced in the book such fascinating reading. The book therefore does not, except in a brief résumé, deal with the post-Los Alamos Oppenheimer, with his directorship of the Institute for Advanced Study in Princeton or with the security hearings usually called the "Oppenheimer Trials", but there are other sources to cover these matters. However, the period it does cover, the growth of an unusually gifted and sensitive person to maturity, and to his success in a gruelling job, is of absorbing interest. ☐

Sir Rudolf Peierls is Emeritus Wykeham Professor of Physics at the University of Oxford. He spent 18 months at Los Alamos working under Oppenheimer.

Pluto, the unique planet

J. Veverka

The Planet Pluto. By A. J. Whyte. Pp. 147. (Pergamon: 1980.) $17.50, £8.75.

FIFTY years have passed since the discovery of Pluto on February 18, 1930, but until recently the planet's physical properties were still subject to much debate. The discovery of a satellite by Christy and Harrington in 1978 made it possible to determine the mass of the planet, and recent speckle interferometry by Arnold, Boksenberg and Sargent produced the first good measurement of the radius. Finally we can say something about Pluto's mean density and composition.

Within half a century our conception of Pluto has changed from that of a rocky body, about the size of Earth, to an icy double-planet so tiny that it is dwarfed by such satellites as Ganymede and Titan. Latest data indicate that the planet is only some 1,500 km in radius (slightly smaller than our Moon, but three times bigger than the largest asteroid). Its companion, Charon, a relative giant, is almost half the size of the primary (our Moon is only a quarter as big as Earth). The average density of Pluto is probably less than 1.5 g cm^{-3}, indicating a predominantly icy constitution. It is still uncertain whether

Pluto does or does not have an atmosphere, but methane frost on its surface was discovered in 1976 by Cruikshank, Pilcher and Morrison.

Whyte's *The Planet Pluto* is one of two very timely recent books about this unique world. Both can be recommended highly. The second book is W. G. Hoyt's *Planets X and Pluto* (University of Arizona Press), a well-documented, readable account of the discovery and subsequent studies of the planet, based largely on Lowell Observatory records.

Whyte's book is a succinct, thorough summary of our growing knowledge of Pluto. Results are given more or less chronologically without critical comment. This type of presentation has its advantages, but there are occasions where one wishes the author had allowed himself to be more critical. Obvious examples involve Kiladze's numerology, Brady's planet, certain very noisy spectra over-interpreted in fantastic fashions and pedantic models of the planet's interior calculated before the mass or size of Pluto were known.

There are only occasional typos and the odd trivial error, and few important references are omitted. Most notably, no mention is made of such important papers as those of Seidlemann *et al.* (*Publs astr. Soc. Pacif.* **84**, 858) and Goldreich and Ward (*Publs astr. Soc. Pacif.* **84**, 737) which appeared in 1972 and demonstrated that Brady's huge trans-Neptunian planet is an impossibility. The references are up to date until July 1979, and thus do not include some important new results such as the speckle determination of the radius of Pluto by Arnold and his colleagues.

In spite of its high price, the book is recommended heartily to anyone interested in Pluto. It is hoped that it will make a contribution to a much-needed re-evaluation of Pluto's importance to our understanding of the Solar System. Perhaps more astronomers will see fit to observe the planet with the techniques now available while it is near perihelion during the next two decades. Pluto has emerged as a unique body in our Solar System and as such is worthy of closer study, and especially of direct exploration by spacecraft. Opportunities exist to fly-by Jupiter — and have another look at Io — and arrive at Pluto before the end of the century. ☐

J. Veverka is at the Laboratory for Planetary Studies, Cornell University, New York.

End of a chapter in population genetics

Alan Robertson

Mathematical Population Genetics. Biomathematics Vol. 9. By W.J. Ewens. Pp.322. (Springer-Verlag: 1980.) DM 59, $33.10.

SINCE the rediscovery of Mendelian segregation, the combinatorial properties of the phenomenon have been fascinating to the mathematician (as indeed they were to Mendel himself). What Ewens calls the "golden age" of mathematical population genetics was dominated by Fisher, Haldane and Wright, the first two with professional training and the latter an inspired amateur. For a time, the theory was far ahead of the relevant evidence but the emergence of new experimental techniques (gel electrophoresis, amino-acid sequencing of proteins and, more recently, DNA sequencing) has not only provided a large body of data, though mostly concerned with protein evolution, but has also stimulated new conceptual approaches, such as the misnamed 'non-Darwinian evolution', and a great deal of sophisticated mathematics. For instance, our view of the basis of mutation at individual loci is quite altered — we think no longer of 'forward' and 'back' mutation but of an infinite progression which almost never retraces its path and which has led to an 'infinite allele' theory of some elegance.

Many recent theoretical papers seem to have been written for mathematicians rather than biologists. Ewens does an excellent job of presenting the different contributions, many from himself or his students. Aimed at the graduate or research student, two threads are neatly interwoven throughout. Having first presented the theoretical approach to a topic, he ends with his own view of its present biological status. The book deals mainly with the statistics of genes in populations and less than 15 pages are concerned with quantitative genetics. Its value to the reader obviously depends on the latter's mathematical level. I have certainly found it useful and stimulating — an indication not only of my mathematics but that I share the author's prejudices.

Perhaps, too, this volume marks the end of a chapter — of a theory of evolution in terms of the substitution of single mutations. Papers dealing with the mathematical properties of systems of tandemly repeated loci have already appeared (though none are referred to here), and current issues of *Cell* and *PNAS* are full of discussions of transposable sequences, a new kind of genetic polymorphism, arising from a novel source of variation. ☐

Alan Robertson is Professor at the Institute of Genetics, University of Edinburgh.

The potential of peat

Hamish Anderson

Peat: Industrial Chemistry and Technology. By Charles H. Fuchsman. Pp.279. (Academic: 1980.) $28, £15.80.

AT A time when many countries, faced with ever-declining supplies and resources of basic raw materials, are currently re-assessing the potential of alternative sources of energy and of feedstocks for the chemical industry, the appearance of Dr Fuchsman's book is particularly welcome and opportune. Indeed, this publication constitutes the first real attempt in the English language to collect and collate information on the chemistry and technology of an industry which, until now, has centred largely in eastern and northern Europe. Based on data judiciously selected from over 450 references, including many from Soviet publications not readily accessible to Western scientists, the author presents a most readable and concise review of the nature of organic components in peat and of the alternative technologies available for converting these components into commercially useful and value-added products.

Following a general introduction on the nature and distribution of peat resources and the history of peat utilization for industrial purposes, Chapter 2 presents a somewhat superficial account of the classification and chemical characterization of different bog and peat types, as a result of which the complicated and often ambiguous terminology and nomenclature may trouble the non-specialist. It is also surprising that sapropel, a material now widely used in the USSR, is considered to be of little importance to chemical technology.

The extraction of peat with organic solvents is dealt with in considerable detail in Chapters 3–5, which help to clarify a murky area of the peat research effort. The chemistry and utilization of peat carbohydrates and hydrolysates of peat polysaccharides are comprehensively covered in Chapters 6–8, followed by an account of the hydrolytic production of furfural, lactic and glycolic acids and other sugar by-products. A further use of these hydrolysates is the indirect production of proteins and fats by the culture of yeasts — a process which has a long and honourable

The second edition of the *Glossary of Geology*, edited by Robert L. Bates and Julia A. Jackson, has been published by the American Geological Institute, Falls Church, Vermont. The updated *Glossary* includes 36,000 terms, compared to 33,000 in the 1972 edition, and is available from the AGI, price $60.

history in peat technology.

In a book which deals largely with the subject from an industrial viewpoint, it is surprising to find that the longest section (Chapter 12) is devoted to a review of the occurrence and structural chemistry of humic acids and lignin. By contrast, Chapters 13–15 provide a most valuable account of the theory and practice of peat carbonization, specifications for coke and related products, and the production and utilization of distillates and gases from peat pyrolysis.

Chapter 16 on chemical methods of peat analysis is perhaps the weakest in the entire book. In a work containing such an extensive and well-documented bibliography up to, and including, 1978, it is surprising to be presented with many analytical methods which are out of date. Thus much stress is placed on the use of paper chromatography for the estimation of components of hydrolysates, disregarding modern liquid and gas chromatographic techniques for the analysis of waxes, steroids, terpenes, phenols, sugars and amino acids. Automated flow analysis methods are not mentioned. The concluding three chapters deal with the scale of peat processing operations, economic and social implications, environmental impact and pollution control.

Overall, Charles Fuchsman's book fills an important gap in existing literature and will be widely welcomed not only by specialists in the field concerned but by all those engaged in peat research and development. □

Hamish Anderson is a Principal Scientific Officer at the Macaulay Institute for Soil Research, Aberdeen.

Art of the insoluble

R. H. Pain

Hydrophobic Interactions. By A. Ben-Naim. Pp.311. (Plenum: 1980.) $32.50, £20.48.

MEDAWAR has reminded us that the pursuit of science is the art of the soluble. This book is about the art of the insoluble.

To judge by the number of monographs recently published on the subject, interest in the hydrophobic effect and its involvement in the stabilization of biological structures is at a high point.

Kauzmann in 1959 (*Adv. Protein Chem.* **14**, 1) drew attention to the fact that the association of non-polar groups in an aqueous medium exhibits thermodynamic properties which can only be explained in terms of changes in the entropy of the solvent. Such groups, which are present on many biological molecules, come together not so much due to mutual attraction as to a mutual distaste for water. These concepts have been developed by several groups to provide a valuable tool with which biochemists can rationalize a wide range of interactions. What may be called the thermodynamic approach to hydrophobic interactions is widely accepted and remains useful because of the still limited understanding of the structure of water. The beauty of thermodynamics in such a situation lies in its ability to handle phenomena quantitatively without having to make any assumptions as to mechanism, and some of the workers in this field have vigorously eschewed any attempt to taint the purity of the approach by considering molecular mechanisms. The frustration which this kind of treatment apparently induces in biochemists is well illustrated by widespread references in the literature to 'water structures' and 'icebergs', and indeed there is much that we want and need to know about the details of the hydrophobic interaction.

DON'T MISS THE
Grand Tour!

Last year at Jupiter. They are already nearing Saturn. Then it's on to Uranus, and Neptune, and possibly Pluto. Voyager photos are amazing, data from onboard experiments revolutionary. And full coverage of the tour can now be yours, along with features on nearly every other body in this solar system. So keep up with science - by subscribing to Planetary Astronomy.

Published bi-monthly by the James-Mims Observatory, Inc., a non-profit corporation. Subscriptions are $5.00/yr., $9.50/2 yrs. (US), $7.00/yr., $13.50/2 yrs. (Canada, Mexico) $8.50/yr., $16.00/2 yrs Other countries).

PLANETARY ASTRONOMY
P.O. Box 15854 Dept. N
Baton Rouge,• LA 70895

Circle No. 04 on Reader Enquiry Card.

The monograph by Ben-Naim attempts to steer a course somewhere in between the thermodynamic and the molecular-structure approaches. It is not in any sense a review, as the limited and selective list of references indicates, but an account of the author's own attempts over a period of years to tackle the problem of hydrophobicity. The first impression is one of clarity in his treatment of the subject. He leads the reader patiently, if at times paternally, through the development of his argument in a way which is refreshing and helpful. The argument is clarified by a series of diagrams which enable the model-orientated reader to grasp the significance of the equations. Frequent "Comment" paragraphs provide summary, objective assessment of the previous sections. It is, surprisingly, these comments which first make for a sense of unease, for the general impression conveyed is that more experimental data are required to test the theory or that the theory being developed does not relate to real and highly complex macromolecular systems.

The author begins by drawing a useful distinction between the *direct* parts of the interaction between two particles in solution and the *indirect* part which comprises the hydrophobic interaction. His approach is based on that of statistical mechanics and he sets out to describe the interaction in terms of association rather than solubility. The contrasts with the thermodynamic approach are marked, in that the familiar description of the hydrophobic interaction in terms of characteristic changes in entropy and heat capacity is absent. In fact, consideration of these does not appear until three-quarters of the way through the book. The treatment progresses through discussion of the interaction between two simple particles to interaction between many solute particles, with particular emphasis on the non-additivity or cooperative aspects. The final chapter concerns the temperature and pressure dependence of hydrophobic interactions. Statistical mechanical derivations are assigned to appendices in order to make the text more readable. Various kinds of experiments are described, although some of these, such as those involving the association of carboxylic acids, are notoriously difficult to interpret in terms of the hydrophobic contribution.

This book is unlikely to be of value to the biochemist. Little light is shed on the four fundamental questions raised in the preface as to the nature and role of hydrophobic interactions — these are still best answered by intuitions and prejudices based largely on the thermodynamic approach. The book is a useful contribution for the hydrophobic buff, summarizing the application of the statistical mechanical approach. For my money, though, further understanding of the hydrophobic interaction will only come as we learn more about the behaviour of the solvent at the molecular level. □

R. H. Pain is Professor of Physical Biochemistry at the University of Newcastle upon Tyne.

Plagiarism, piracy and principles

How honest is the scientific community? Is it, as the story books would have us believe, that every single member of the scientific community is a knight in shining armour, dedicated only to the pursuit of truth and indifferent to where the pursuit will lead? Or may it be, as some would say, that the scientific community is by and large no more honest or dishonest than any other group of professional people in which personal rivalry and ambition cannot be ignored? Might it even be that scientists are if anything less honest, more venial, than the professional groups with which they invite comparison? There is a sense in which these questions and others like them are strictly meaningless. The scientific community is at best a loose aggregation of people with often very different interests, working in laboratories of very different character with techniques that differ profoundly from each other. In some circumstances, scientists work alone, perhaps even in isolation. In others they are members of large teams of people, united by a common interest yet constantly (and understandably) on the look-out to ensure that no one person derives an advantage from the collaboration that cannot be justified by his own contribution to it. There are some who argue that in such circumstances even the notion of a scientific community makes no sense. But there is also a sense in which, from time to time, such questions cannot be avoided. In the past few months, they have been made inescapable by the discovery of cases of widespread plagiarism in the scientific literature, by the latest well-publicized case in which experimental data were as much a product of people's imagination as of laboratory measurement and by the general fear that when times are hard and budgets being reduced in many areas, standards are bound in any case to be at risk.

What is the truth? It is prudent first of all to recognize that recent scandals, however spectacular, are neither as great a slur on the reputation of scientists as many outsiders would like to think nor as novel as many scientists would pretend. There is a tendency among professional scientists reading for the first time tales of large-scale plagiarism (see *Nature*, 12 June and 31 July) to huff and puff, turn red in the face and utter some solemn declaration that something, almost anything, must be done to defend the fair name of science. This tendency should be resisted. It is too often forgotten that the misdemeanours of the present are often mere shadows of the misdemeanours of the past. The seventeenth century, after all, was riven with controversies about whose idea belonged to whom, and people such as Robert Hooke found it sensible to conceal notions such as *ut tensio si vis* in anagrams.

In the days when the importance of data gathered from the real world as the foundation of all theory was not widely appreciated, the theft of ideas pure and simple was easier but also potentially more damaging than at present. In a small part, the conventions by which the scientific profession now regulates itself derive from from the bad experiences of these early days. The object of the convention is to give truth an overwhelming advantage over falsehood, originality a powerful edge on repetitiveness and to make it possible that people whose contributions to the stream of discovery are very different are nevertheless able to work easily alongside each other. The scientific community should count itself lucky that these conventions are now so deeply ingrained, so widely respected and so infrequently dishonoured.

It is always something of a tragedy when the conventions are broken, especially if for personal gain or for the sake of personal esteem, but it is also important that when they are found to be broken, the scientific community should not get on its high horse and over-righteously pursue the transgressors. Especially because the conventions of the profession are so widely known, and because it is so widely understood that the penalty of being found out may be the end of a career, it is only charitable to acknowledge that a deliberate breach of the conventions may be a sign of something pathological, or of insupportable stress. The profession should, in other words, be more compassionate than is often at present the case towards those who fall foul of the conventions and are expelled.

None of this implies that the conventions themselves should be made less strict. On the contrary, there are some respects in which they need to be made tighter. But it is crucial that the scientific community should clearly understand the purposes that the conventions are meant to service. In this connection, even the most primitive of the conventions — that which outlaws falsehood — is not, as some would have it, a matter of morality in some high-minded sense; rather, it has a practical purpose. The scientific community, like any other branch of scholarship, hangs together because of a common interest in a common pool of knowledge. A person who announces the results of experiments showing that water will run uphill, or that chewing-gum becomes superconducting at the temperature of liquid oxygen, or who merely decides to make his way in the world by synthesizing data that confirm some widely held theory, is potentially misleading all his colleagues, wasting their time and diminishing their chance of making a substantial contribution to understanding. Falsehood is thus an impediment to the progress of science as whole, and small falsehoods may have a disproportionately great effect. Whether those who utter falsehoods are immoral in some wider sense is hardly relevant.

But what is a falsehood? The word is not synonymous with the opposite of truth. There is no shame in publishing in the literature an observation which turns out to be incorrect, perhaps because of some instrumental defect or conceptual flaw. Similarly, an entirely wrong-headed theory, the "luminerferous aether", for example, is not an offence against the conventions of the community provided that it is argued on grounds which are explicit, and accessible to all. (From this derives the subconvention that original publications should contain the details needed to repeat an experiment or to reconstruct an argument.) Popper would say that the discovery of untruths of this kind is not merely a chore but the essence of science. Falsehood is different, for it requires of the perpetrator the wish to deceive. Falsehood cannot as easily be rooted out. Telling one from the other without the lapse of time would inevitably entail the impossible task of assessing individual honesty. By convention, it is supposed that everybody is honest — how else could it be? How true is that assumption?

The second primitive convention, common to the whole of scholarship, is that credit must be given where it is due. The objective is not merely that scientists should enjoy that faint glow of pride that follows from discovery or authorship (which is nevertheless a justifiable reward in a profession where other rewards are few and far between) but that it should be possible for others to reconstruct the origins of new ideas, putting them in a wider intellectual context and making them intelligible. But failure to acknowledge sources adequately and generously is also bound to cause personal offence — people are human, after all — which can seriously damage the free exchange of data and ideas.

These, as they must be, are high ideals. How well are they kept? The recent flurry of plagiarism is not a good guide to present

0028-0836/80/350831-02$01 00

standards, if only because plagiarism is so easily detected and demonstrated. Plagiarists are either fools or desperate people. Concocting false data, cooking the books, is a more private matter and therefore harder to detect. Many heads of busy laboratories will be alarmed to think what may be happening without their knowledge — and will no doubt come to the conclusion that their only safeguard is to be directly involved in their own research, not merely as leaders but as colleagues of those who do the work. Even so, clearcut transgressions are likely to be rare. Less flagrant misdemeanours, or complaints thereof, are much more common. A helpful referee may find that his constructive comments become the gist of somebody else's publication. A member of a coordinated research programme may find that the contributions he has made to the planning of an enterprise turn up in the literature without his knowledge. Or references to important contributions to some field may be skimped for the sake of a false impression of originality. There is a lot of this about.

Remedies are unfortunately not easily devised. In the old days (half a century ago) it was the common practice for the head of a laboratory to take responsibility for everything that happened in it or was published from it. Grand old men used to terrorize their juniors yet give their work the stamp of authenticity. To turn back the clock would be impossible and would solve nothing, for even grand old men are capable of falsehood. Yet there is something in the view that the standards of behaviour would be improved if only laboratories as units engaged more freely and openly in discussions of their collective work. Falsehood is necessarily a private matter; open discussion must help to show it up — or even show that falsehood is unnecessary. It is only proper to record that many of the best laboratories are among the most willing to talk domestically. It would also help if external pressures on individual scientists could be abated. The competition for grants, promotion and kudos is the driving force. The need to publish derives from that. There is at least a chance that these pressures would abate substantially if the methods of financing research were only subtly changed. Shifting the balance of decision from external agencies to laboratories themselves would be certain to help. Is this the constructive course to follow after the disclosures of the past few weeks?

Pesticides in developing countries

Many years have passed since the argument about the future of the environment in which people live was sharply polarized, dividing those who considered that the surface of the Earth is a robust place and those who argued that, on the contrary, quite small changes affecting the ecological balance might have catastrophic consequences. Mercifully, these discussions are now conducted more moderately. Both sides in the old argument seem to have decided that everybody's interest will be served if consensus rather can conflict can be built around environmental problems. Unfortunately, however, it seems that old habits die hard. From time to time, vestiges of the sharp divisions of the 1960s crop up in public statements and in the newspapers. One of the citadels of the extreme environmentalists appears to be the journal called *New Internationalist*, published by no less an organization than Oxfam, widely respected for the way in which it has tackled problems in developing countries with energy, compassion and imagination which are rare even for the most dedicated voluntary organizations.

New Internationalist is, however, over-imaginative in the way it tackles problems of the environment in developing countries. Thus, in the July 1980 issue of the journal, an article by the editorial staff of the journal which appears under the heading "Peddling pesticide" begins with the declaration that "until DDT was banned as a proven cancer-causing agent it was the penicillin of pesticides . . .". The article goes on to argue that the chemical companies, disconcerted to have been "caught pushing poisons", stopped manufacturing DDT in developed countries but set about selling their manufactured stocks in countries overseas. The objective of the article is to argue that the multinational chemical companies are using the developing world as an outlet for sales that would otherwise be frustrated and asks that Western governments should put a stop to their wicked ways. The argument thus brings together two important elements of the demonology of the extreme environmental movement of a decade ago — big business in general, and international business in particular, and pesticides in general, DDT in particular. Nobody quite understands where these demons have sprung from but no doubt they have their roots in a variety of improper practices in the past. For there is no doubt that at many periods in the past century developing countries have been exploited unfairly by business interests from overseas. Similarly, it is beyond dispute that DDT and the other organochlorine pesticides were used indiscriminately and perhaps irresponsibly soon after their introduction — although it appears that most of the damage that followed was in North America, where agriculture is intensive, and not in the developing countries. None of this, however, excuses what *New Internationalist* has to say about DDT, especially because what the developing countries need to know most urgently is more complicated.

The truth is that DDT is not a poison in any reasonable meaning of that word. Its acute toxicity to people is low, which is why it was widely used, a quarter of a century ago, for the control of mosquito populations in the areas of the world where malaria is endemic. Similarly, the evidence that DDT is "cancer-causing" is ambiguous in the ordinary meaning of those words. It is true that high doses of DDT fed to laboratory animals will induce cancer, as indeed they provoke disturbances of liver function. But there is no evidence that the use of DDT has in the past caused damage to people when used with suitable precautions and in circumstances that are appropriate. The more toxic organochlorine pesticides are more damaging to animal life, but even they have not been taken off the market in most industrialized countries because of the damage they might do to people — rather they have been controlled and sometimes banned for fear of what they might do to wildlife populations.

In developing countries, circumstances are different. It may be regrettable but it is true that many governments in developing countries are less squeamish about wildlife populations than are the governments (and the electorates) of industrialized countries. *New Internationalist* would be fighting a good cause if it sought to alert them to the importance of a balanced wildlife population and to the importance of refraining from needlessly disturbing the natural ecology. In due course, many such governments would no doubt follow industrialized states in controlling DDT for fear of unwanted effects on the wildlife population. But for many of these governments there is a more urgent reason why powerful pesticides such as DDT should be used with discrimination. The original enthusiasm for the use of DDT in controlling malaria has evaporated now that problems of insecticide resistance have become natural restraints on what can be accomplished. Similarly, in the industrialized countries which practise intensive agriculture, the United States and Western Europe in particular, there are growing dangers that the uncontrolled use of pesticides may serve chiefly to stimulate the emergence of resistant insects. The difficulty is that such problems cannot be solved simply by taking one, or even several, offending chemicals off the market — somehow, instead, their use has to be planned imaginatively. Is not this the point that *New Internationalist* and its parent organization should be seeking to establish?

0028-0836/80/350832-01$01.00

Uranium exposure limits in dispute

A new dispute has arisen between epidemiologists and health physicists over the interpretation of data on the health effects of low levels of ionizing radiation, the subject of a recent report from the National Academy of Sciences (*Nature* 7 August p. 550).

This time the disagreement centres on whether current exposure limits to the radioactive gas radon and its decay products may present an unnecessarily high risk of lung cancer to the 7,000 uranium miners currently employed in the United States.

And the precise shape of the low-level dose–response curve has been given a new significance by growing concern about the possible health risk to the general public from radon-emitting building materials, since radon's precursor, radium-226, is a trace element contained in most rocks and soil.

In the light of epidemiological evidence on occupational exposures that has been accumulated since the current standards were set in 1971, the National Institute of Occupational Safety and Health (NIOSH) has suggested to the Department of Labor that permitted exposure limits for uranium miners should be significantly reduced.

However, the International Council for Radiological Protection (ICRP) argues that no change is needed. In a set of new recommendations currently being circulated to its members, the ICRP says that on the basis of dosimetric techniques applied to models of the lung, the current exposure limits appear to be adequate.

Mining companies — already facing a tight economic squeeze because of a virtual collapse in the international market for uranium ore — are using the ICRP's arguments to press the department not to reduce the limits. A move to reduce the limits could mean that mining companies would have to install expensive ventilation equipment.

Research in the 1950s and 1960s confirmed an abnormally high incidence of lung cancer among uranium miners. The cause was identified as radon and its alpha-emitting decay products — known as radon daughters — which become attached to air particles and can lodge in miners' lungs. The Department of the Interior introduced in 1971 an exposure limit of 4 working level months (WLM) a year, with a ceiling airborne concentration not to exceed 1.0 WL. (One working level (WL) is defined as a radon daughter concentration in one litre of air resulting in the emission of 1.3×10^5 MeV of potential alpha energy).

Since then, evidence from epidemiological studies in Canada, Sweden, Czechoslovakia and the United States, suggests, according to a report put together by a NIOSH study group, that the full effects of radon exposure may have been underestimated, and that "there appears to be no margin of safety associated with the present standard".

The working group point out that triggering doses may be substantially lower than the cumulative doses associated with a particular incidence of lung cancer, since the radiation absorbed after the triggering dose may have been biologically redundant. In addition, the contribution of smoking to lung cancer among miners may have been overestimated in previous work. Some studies appear to show a higher rate of lung cancer among miners who do not smoke than among those who do — perhaps because cigarette smoking creates a thicker layer of mucus which may provide some protection against alpha emissions.

In submitting the report to the Department of Labor's Mine Safety and Health Administration (MSHA) Dr Anthony Robbins, Director of NIOSH, says that the apparent excess risk of lung cancer among those who might accumulate 120 WLM over a working lifetime — perhaps twice previous estimates — was a cause for major public health concern.

"On the basis of the study group's report, we feel that the present MSHA standard of 4 WLM per year does not provide an adequate degree of protection for underground miners exposed to radiation when it is evaluated over their exposure lifetime," Dr Robbins says.

NIOSH officials met with MSHA at the beginning of this month, and agreed that there is enough scientific evidence to support a possible revision of the regulation.

The department has already been petitioned to reduce permitted exposure levels by Ralph Nader's Health Resources Group and the Oil Chemical and Atomic Workers, a labour union to which many of the uranium miners belong. The two organizations are demanding that the maximum allowed radiation be reduced from 4 to 0.7 WLM per year.

However, the department is being urged by the industry to take into account the ICRP regulations suggesting little need for change. The ICRP proposals, agreed in draft form at a meeting of the commission in Brighton, UK earlier this year, describe two different ways of estimating what might be considerd a safe exposure level.

Using epidemiological techniques based essentially on the same data as those analysed by the NIOSH working group, ICRP suggest that a safe limit would be between 2 and 10 WLM per year.

However, the ICRP also makes estimates based on a dosimetric analysis of the expected effect on the lung of a given amount of radiation, and in particular to that region of the lung particularly susceptible to alpha emission.

The latter approach, according to the ICRP, leads to a recommended exposure limit of 5–8 WLM per year based on a regular lung dose, or 9–14 WLM per year based on a mean lung dose. And given the variability in the epidemiological data, ICRP suggests that a figure of 5 WLM should be used as the basis for regulation — adding that for uranium miners already exposed to additional gamma radiation, this limit would tend to be reduced by 20 per cent for radon daughters alone, bringing it in line with the current US standard.

Ironically this conculsion is somewhat in conflict with the judgement of the National Academy of Sciences' Committee on the Biological Effects of Ionizing Radiation (BEIR), which last month moved closer to ICRP's position that for a different type of low level radiation (that resulting from X rays and gamma rays) a linear dose–response model may overstate the dangers.

In its comments on the dangers from alpha emission and other sources of high-LET (linear energy transfer) radiation, however, the BEIR committee drew heavily on the epidemiological studies of uranium miners and others to conclude that "the application of the linear hypothesis is less likely to lead to overestimates of risk and may, in fact, lead to underestimates".

High-altitude research

Reflated hopes

A threat to halt the launching of large scientific balloons from two sites in Australia may yet be averted if a proposal to update equipment and share running costs is accepted by the five countries which regularly use them. The continuation of the facilities is particularly important for astronomers from Australia, the United States, Britain, Germany and Japan who want to send balloon-borne payloads to high altitudes to study X-ray and UV sources in the Southern Hemisphere near the Galactic Centre.

The Australian government has threatened to close the facilities at Mildura, Victoria and Alice Springs in the Northern Territory because it says that it is heavily subsidizing foreign astronomers whose governments do not pay an economic fee. The United States is the only country that currently contributes to running costs: it pays a third, Australia making up the remaining two thirds. Other users of the facility currently pay about £10,000–11,000 for a launch and nothing towards basic running costs.

0028-0836/80/350833-02$01.00

Britain, Germany and Japan have each been launching on average two to three balloons per year. Australia started searching for alternative funds four years ago when Britain was the main foreign user apart from the United States. An attempt then to get Britain to pay one third of the running costs, about £50,000, failed with Britain's Science Research Council pleading poverty.

The current threat to close the facilities unless outside funds are found quickly seems likely to produce results. Britain and the United States have agreed to accept a proposal, put by Professor Vic Hopper of Melbourne University during recent visits to both countries, to share running costs between the five principal users and to update some of the out-dated equipment.

The new proposal appeals to Britain in particular because the cost would be shared by more countries, Germany and Japan having become regular users of the facilities over the past four years. The plan would also allow user countries to up-date equipment by providing their own. Hence the United States and Germany might consider providing a better launch truck for heavier balloons and Britain would be willing to provide an improved kilobit telemetry link from its now abandoned Skylark rocket programme. Professor Hopper left for Germany and Japan last week to discuss his ideas there.

Britain seems to have come round to the view that it can hardly refuse Professor Hopper's proposal, especially if the United States, Germany and Japan also agree to cooperate. Compared to the cost of other collaborative projects with Australia, such as the Anglo-Australian telescope, the cost would be almost insignificant. In the interests of international collaboration, at least, it would probably be worth it.

Judy Redfearn

Nuclear reactors

Czech closure

In a sudden policy about-face, the Czechoslovak Nuclear Energy Commission has admitted that the country's first nuclear power station at Jaslovske Bohunice had to be closed down permanently after a major incident a few years ago. Speaking on Prague Radio, Milos Drahny, a senior official of the Commission admitted that a serious defect had damaged the 440-MW No. 1 generating set at the country's first VVER-440 light-water nuclear power station.

This admission follows almost two years of semi-official denials backed up by glowing accounts in the media of the benefits which the station was bringing to the Czechoslovak national economy (a claimed 2 million MW generated in 1979). As recently as 17 July 1980, Prague TV carried a news item reporting the completion of "summer maintenance work" on the No. 1 set.

The closure of the station was first reported in November 1978 in Document 22 of the Charter 77 movement. This document reported two accidents. The first, on 5 January 1976, was due to an obstruction in the safety valve of a fuel cell (probably due to human error), leading to an escape of radioactive coolant (CO_2) and the death of two workers who could not be evacuated in time, since one of the emergency exits had been locked as part of an anti-pilfering campaign. The second accident, on 24 February 1977, was due to human error in the loading of a fuel cell, producing a rupture in the primary circuit and extensive contamination in the primary and secondary circuits. Activated steam was voided into the atmosphere, and there was an escape of liquid into a nearby stream, which had to be fenced off temporarily.

The public discussion which the Chartists had hoped to evoke never materialized. The authorities took the stance that there was no accident. But the total absence of sound data (workers at the plant who had been at risk in the first accident were not even allowed to know the extra dosage they had absorbed) caused rumours to proliferate. By 1979, it was widely believed that the liquid spilled from the second accident had got as far as the Danube — an allegation which the Chartists themselves have never either supported or denied, and which on the face of it would be very difficult to substantiate since the Danube Commission deals only with pollution caused by ships and there is, to date, no overall monitoring system for the river.

Document 22 in its concluding paragraphs called for a moratorium in the Czechoslovak nuclear energy programme until the public had been informed of, and had had a chance to consider, the hazards involved. But with the authorities firmly committed, like all Comecon countries, to nuclear power, construction went on apace; the No. 2 set at Jaslovske Bohunice is now undergoing acceptance trials, the Dukovany station is under construction and work on the Mochovce station has been started.

Nevertheless, and without any reference to Document 22, the Czech and Slovak media have from time to time appeared to be answering the Chartists on specific issues. One of the main criticisms made in Document 22 was of the psychological and physical health of the staff at Jaslovske Bohunice. The majority of workers, said the Chartists, were willing to work dangerously long hours without proper safety precautions in return for high pay and consoling themselves with alcohol and petty pilfering. Official releases countered this with descriptions of health and safety regulations, and the careful psychological monitoring of prospective employees. Other articles stressed safety precautions and contingency plans for antipollution measures in the event of any serious radiation leaks.

Drahny's belated announcement that such an accident has, in fact, already occurred, will come as no great surprise to the Czechs and Slovaks, accustomed as they are to the rewriting of the past. They may be intrigued, however, by the timing of the announcement, which came a few days before the anniversary of the 1968 Soviet intervention.

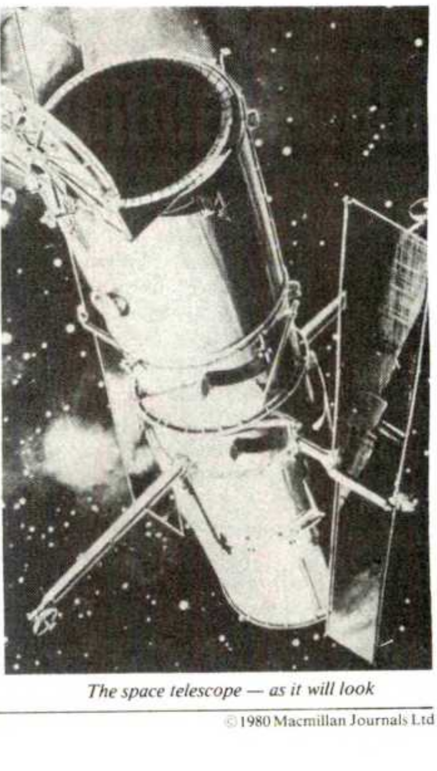
Vera Rich

Space telescope

Edinburgh's bid

Britain's Science Research Council (SRC) is to put in a bid to the European Space Agency (ESA) to house the European space telescope coordinating facility at the Royal Observatory, Edinburgh. Bids are also expected from the European Southern Observatory at Garching, West Germany, at least one astronomical institute in France and possibly one each in Spain and Italy. ESA plans to decide on a site early next year.

European scientists will receive at least 15 per cent of observing time on the space telescope — a joint ESA–US National Aeronautics and Space Administration (NASA) project — due for launch aboard the space shuttle in late 1983, roughly in proportion to ESA's contribution to its capital cost. The task of the European Coordinating Facility (ECF) will be to receive data from NASA's Space Telescope Science Institute, and to analyse and disseminate them to European users of the space telescope, within a matter of days of receipt of the data in the United States. But bigger plans are afoot for the ECF. It will be designed to handle all data produced by the space telescope; ESA is currently negotiating with NASA to receive data



The space telescope — as it will look

0028-0836/80/350834-02$01.00

which are not initially allocated to European astronomers when exclusive rights to it have expired after one year.

The SRC believes that its proposal stands a good chance of success because it would use Britain's Starlink facility which already employs highly sophisticated methods of image processing to analyse data from ground-based telescopes. The Royal Observatory in Edinburgh houses one of Starlink's six nodes. European astronomers would be able to access space telescope data quickly by travelling to Edinburgh or only slightly more slowly at one of the sites of the five other nodes, three of which are within easy reach of London, the other two being in Manchester and Cambridge. One of the main reasons for choosing Edinburgh rather than any of the five other institutes housing a node is that from next October, Dr Malcolm Longair will be director of the Edinburgh observatory. He has been closely involved in the space telescope programme since its inception.

To cope with the enormous increase in data, however, facilities at the Royal Observatory would need to be expanded, particularly by enhancing the existing image processing unit and building a special unit to cope with the data.

ESA plans to pay about £66,000 towards the capital cost of the facility, about £33,000 per year towards running costs and the salaries of seven staff. The host institution will be expected to find the rest of the cost from its own pocket.

The SRC estimates that to build the facility at Edinburgh, it would have to provide about £250,000 and pay for an extra five staff.

Judy Redfearn

German workforce

Ten years on

Microcircuits and other new technologies likely to be adopted in the 1980s in West Germany will result in the loss of 1.8 million jobs in some low-skill sectors, and a gain of 1.9 million in other higher-skill occupations, says a new forecast commissioned by three Federal German ministries.

This massive shift in employment will require government policy "specifically shaped to counteract what will be an increasing tendency towards conflict in the community" says the report, prepared by Mackintosh Consultants Ltd of the UK and Prognos AG of Basle.

The German government has described the report as a brilliant study and awarded the teams a prize for their efforts. Mackintosh Consultants reviewed probable technical developments by making studies in the UK, Japan, Germany and the USA; and Prognos AG looked at social and economic factors, including union and management attitudes affecting their introduction in the current decade. Both studies were detailed and sectional, dividing the economy into at least 50 sections and jobs into 26 categories, all of which were looked at individually (see table).

The study identified 15 sensitive sectors of the German economy where the pressure to innovate was great, but the ability to respond small. Prominent among them were the chemical industry and refineries, where the price of imported oil will require conversion to new feedstocks; but conversion will require massive investment in new capital equipment, new skills in the workforce and possibly new locations for industry to meet the distribution requirements of new raw materials.

Jobs directly connected with the introduction of the new technologies — such as installation, and the repair and maintenance of what may initially be unreliable (because untested) technologies — would increase during the 1980s by 471,000. But typically the qualifications required in the new jobs will be far in excess of the jobs being eliminated: spotting if a cherry is on a cake requires less education than spotting the fault in the device which detects cherries on cakes.

The area in which most jobs would be lost is in the operation of processing plants, largely through the introduction of microprocessors to handle decision-making on production lines. Here, the report estimates, there will be 396,000 fewer jobs in 1990 than there were in 1977. "Assembly", categorized separately in the study, would also lose 323,000 jobs, through reductions in numbers of components and the automatic assembly of, for example, television sets.

The Bundesministerium für Forschung und Technologie (BMFT) have estimated the range of unemployment which might follow from the Mackintosh-Prognos scenario, given different conditions of economic growth and government and industrial investment. At a pessimistic level of 2 per cent annual growth in gross national product (compared to the Mackintosh–Prognos estimate of 2.9 per cent), investment would be expected to be low, and unemployment would rise from 1.03 million this year to 2.23 million in 1985 and 2.4 million in 1990. It would fall again to 1.44 million in 1995, the BMFT estimate.

Mackintosh's project director for the study, Mr Tom Jacobs, said last week the likely speed of innovation would be great in the next decade but would need great social change. Hence, says the report, Germany must develop "a high level of social communication and willingness to support common objectives, which is only possible if based upon a high level of overall understanding of where the community's best interests lie. Thus, the management of social learning processes becomes a central task in politics."

Environmental carcinogens

Nitrite safe?

The US processed-meat industry received a welcome reprieve last week when the Food and Drug Administration (FDA) and the Department of Agriculture (USDA) announced that there was "insufficient evidence" to label sodium nitrite — a widely used meat preservative — a carcinogen.

Two years ago results of experiments contracted by the FDA to Dr Paul M. Newberne, Professor of Nutrition and Food Sciences at the Massachusetts

0028-0836/80/350835-02$01.00

Institute of Technology (MIT) suggested that nitrite produced cancer in the lymphatic system of laboratory rats.

Almost 13 per cent of 1,350 test animals in the study were said to have developed lymphomas, compared with only 5.75 per cent of the 573 not being fed nitrites.

The FDA had proposed a phased withdrawal of nitrites, but at the same time had announced that the MIT study was to be placed in the public record "so that the process of external scientific scrutiny can commence". As well as gathering comments from their own scientists, the FDA and the USDA commissioned a Washington-based contract research group, Universities Associated for Research and Education in Pathology, to review the 50,000 tissue slides taken by Dr Newberne of his 2,000 test animals.

Last week the two agencies announced that the review of the slides revealed insufficient evidence to support Dr Newberne's conclusions that nitrites increased the risk of cancer in the lymphatic system. The review group said that it found fewer of the slides indicated the presence of cancer than Dr Newberne had concluded, and the agency scientists agreed.

Some of the supposed lymphomas were noncancerous, the group said, and some were histiocytic sarcomas, which have no known human counterpart.

On the basis of this reassessment of Dr Newberne's data, the two agencies announced that they were dropping plans to phase out the use of nitrites.

However, the statement emphasized that steps are still being taken to reduce the level of nitrites in food because of concern that, through the effects of cooking or digestion with other chemicals, nitrites can form nitrosamines, known potent carcinogens.

Following last week's announcement, the FDA has also asked the National Academy of Sciences to review and evaluate all available scientific data about nitrites, and to analyse possible alternative preservatives for use in the meat and poultry industries.

The decision not to impose a ban on nitrites was widely welcomed by food industry officials, where nitrites are used not only to prevent the spread of botulism, but also to give meat the red colouring favoured by US consumers. The industry had complained that there was no alternative agent with equivalent taste, texture and handling characteristics, and had previously claimed that a ban might destroy the US pig industry, over 70 per cent of whose products are processed with the use of nitrites.

When his research results were reported two years ago, Dr Newberne urged that they should be confirmed by other research workers before any ban was introduced. Last week he was on vacation, unable to comment on the review group's critique of his research techniques.

David Dickson

Energy conservation

UK forecasts

The UK Atomic Energy Authority (UKAEA) has dismissed as "uneconomic and risky" proposals for an aggressive policy on energy conservation put forward by the International Institute for Environment and Development (IIED) 15 months ago.

That "low energy stategy" placed too much emphasis on conservation and too little on the expansion of indigenous fuel supplies say the UKAEA. Furthermore, the strategy leads to a shortfall in oil and gas supplies of up to 108 million tonnes of coal equivalent in the year 2025, say the authority, overestimates the savings possible in the domestic sector, and is inconsistent in its projections of sectional and overall economic growth.

What no doubt stuck in the authority's throat was the claim in the IIED report that electricity output can be met by building only 6 GW of nuclear capacity in the first quarter of next century, so that nuclear power would become "a peripheral issue", and that the fast breeder "could be shelved indefinitely". (In contrast, the UK government has since announced a 15-GW nuclear construction programme over the decade beginning 1982.) Thus the authority wish to argue that energy demand, and particularly electricity demand, will remain more buoyant than the IIED calculate.

Gerald Leach, principal author of the IIED report, last week admitted that the low energy strategy could lead to an oil and gas shortfall in 2025, in so far as it was possible to calculate that distance into the future, but said that it would be very easy to make good the shortfall by, for example, increased coal production for which his estimate for the year 2025 had been more conservative even than the 170 million tonne target set for the year 2000 by the National Coal Board.

In domestic conservation, the level of savings depended greatly on the assumed price ratio between gas and electricity as a function of time, said Leach. "Everyone is crashing out of electricity now", and electricity prices will increase further as coal and oil become more expensive. So if cheap nuclear electricity does come on line in the UK in the 1990s it may be too late.

On the other hand, argue the UKAEA, the assumption in the low energy strategy that real incomes in 2025 will be 3 times those of today, and that electricity prices relative to gas will be 2.4 times cheaper than today, are incompatible with the assumption that domestic electricity use will decline. The greater heat gains available from electric heat pumps and their quietness, compared with gas-driven heat pumps, will lead to their preferential adoption, say the authority; and the IIED have ignored a likely trend to greater size in domestic appliances. UK refrigerators average 5–6 cubic ft, whereas American ones average 12 cubic ft.

But potentially the most damning criticism in the UKAEA reply is that the IIED report is inconsistent. One of its most attractive conclusions was that high growth was possible alongside a reduction in energy use; but the assumed growth rate is not matched by the sectional estimates from which energy use is derived.

The IIED report, in its high growth case, assumes 2.94% annual growth in gross domestic product and the growth of non-energy manufacturing industry at only 2.19%. But that implies, the UKAEA point out, that the other sectors (which are mainly service industries) grow faster than 2.94%, whereas the IIED figures show much lower growth in the measures used (for example, floor area for the commercial and institutional sector).

Leach's reply to this is that he assumes, on the basis of many interviews and studies, that the monetary productivity of a given unit in the service sector will increase. For example, the £/m^2 generated in office work will increase through the introduction of microcircuitry.

Robert Walgate

Soviet space

Salyut women

Although Soviet planners decided in 1976 not to recruit any more women to follow Valentina Tereshkova into space as a pilot, they also announced that women would still be eligible to serve aboard space stations as doctors, astronomers or stewardesses. None has yet done so but it seems as if a welcome is now being prepared aboard Salyut.

Until now, the Salyut stations have been somewhat cramped, and, according to an unattributed talk on Moscow radio last month, "quite hard and difficult even for men". Now, however, Salyut-type stations have "more acceptable" conditions for joint work by both men and women. In the near future, stations will have separate cabins, rest rooms and showers.

Salyut 6 already has an experimental shower cabinet, in which the cosmonaut is sluiced by a stream of water drops borne by an airflow. In the future the beads of water which remain in the shower cabinet instead of passing on to the recycling system will be dealt with by the newest aid to space hygiene, a special towelling drying-bag.

One on-board luxury the would-be citizeness-cosmonaut still cannot expect is the traditional bunch of flowers on Women's Day (8 March). Soviet space biologists announced last month that they were abandoning attempts to grow flowers in space, for lack of positive results, and they were now concentrating their attention on radishes, cucumbers and carrots, which could form an important addition to the cosmonauts' diet.

NEWS AND VIEWS

Lamarckist revival in immunology

From R.B. Taylor

DARWIN'S concept of natural selection has gained almost universal acceptance. Along with it most biologists also tacitly accept Weissmann's doctrine of the inviolability of the germ-plasm, and so reject the possibility that acquired characteristics could be inherited. The old controversy on this last point has recently been re-opened by E. J. Steele. In his book (*Somatic selection and adaptive evolution*, Williams-Wallace, Toronto-London, 1979) he assembles evidence that acquired characteristics may be inherited, and suggests how this might occur. His proposal is based on Temin's protovirus and provirus hypotheses for the evolutionary origin and biological role of the C-type RNA viruses (*J. Nat. Cancer Inst.* **46**; *Science* **192**, 1975). These viruses can transduce genetic information from one somatic cell to another by capturing intracellular RNA sequences (e.g. messenger RNA) and infecting other cells where the RNA is copied by reverse transcriptase into DNA capable of being integrated into the genome. It would require only that such information be transduced into germ-cell DNA for inheritance of acquired characteristics to become conceivable — as indeed was suggested by Temin. If somatic mutations are capable of being selected by environmental pressures (as is widely accepted for the lymphocytes of the immune system) then this would increase the probability of their being transmitted to the germ-line and fixed as heritable characteristics.

This neo-Lamarckist hypothesis has recently received experimental support in a paper by Gorczynski and Steele, (*Proc. Nat. Acad. Sci. U.S.A.* **77**, 2871; 1980) who make the startling claim that neonatally induced immunological tolerance to MHC (major histocompatibility, or transplantation) antigens can be genetically transmitted to the offspring through at least two generations.

The experiment consisted first in the induction of tolerance in *male* mice of the CBA strain by the classical procedure of neonatal injection of lymphoid and bone marrow cells from a hybrid donor strain bearing foreign MHC antigens: (CBA × A)F_1 (Billingham *et al. Phil. Trans. R. Soc. B* **239**, 357; 1956). The neonatal injection was followed by regular further injections: a procedure known to induce a state of chimaerism. When they reached adulthood these tolerant males were mated with normal females. Some of the offspring from this first mating were killed and examined for tolerance by testing the ability of their spleen cells to mount a cytotoxic (CTL) response *in vitro* against target cells of the donor strain. Others were allowed to survive and were mated either with each other, or with normal CBA mice to give a second generation. These, and their first generation parents, were likewise examined for tolerance by CTL assay. Both generations, neither of which had been intentionally exposed to the tolerogen, showed a wide range of response, from normal down to undetectable. The important point is that a high proportion of them (50–60% of the 1st generation and 20–40% of the 2nd generation) gave responses significantly below those given by control CBA mice. Specificity was demonstrated by the fact that the mice responded normally to a 3rd party strain: C57B1/6J.

Such a remarkable result must be questioned very closely — both as to its technical adequacy, and as to the interpretation given to it. The CTL assay used in the experiment is a standard procedure and does not demand any major technical innovations. Although most of the results depend on one-point assays, the same degree of hyporesponsiveness was seen even at a fourfold higher concentration of attacker cells. One might ask for more controls to show that the inherited patterns of response were really dependent on the initial induction of tolerance, and not on a tendency of some CBA males to throw hyporesponsive liters. One might also ask that the tests *in vitro* should be supported by evidence of graft tolerance *in vivo*.

The further interpretation leaves even more room for questions. We must ask (a) *what*, in terms of phenotype, was transmitted; and (b) *how* was it transmitted? To answer the first question we need to define immunological tolerance in its various guises, and ask to which of these (if any) the Gorczynski-Steele phenomenon belongs.

In its broadest operational sense tolerance means a state of specific unresponsiveness, which includes states of significant hyporesponsiveness such as were found in many of the mice claimed to have inherited tolerance. It can exist in T cells or B cells or both. Underlying the condition of tolerance may be any of a variety of mechanisms which fall into two categories: those in which active suppression by suppressor lymphocytes has been demonstrated, and those in which it has not, and which are assumed therefore to be due to irreversible 'deletion' of competent cells. This distinction is important because although somatic selection could act to favour a mutant with positive function (suppression) it could not act on a loss mutant. The usual test for distingushing between deletion and suppression is to make a cell mixture in order to see if the tolerant cells will be able to prevent the normal cells from responding. However, this test could not necessarily be used to establish that suppressive mechanisms are operating in the mice with inherited tolerance. This is because it would not detect suppressor cells whose action was to *prevent the development* of competent cells from stem cells. It is this kind of cell which has recently been detected (by a different test) in mice which would otherwise be thought to have a deletion-type of tolerance (Gorczynski and MacRae *J. Immunol* **122**, 737 & 747; 1979).

The agents of active suppression have been identified both as suppressor T cells and as free antibodies. In both cases, there is now evidence that they may carry specificity for the variable regions (idiotypes) on the antigen receptors of the cells they suppress. The situation becomes even more complex when we consider artificially-induced tolerance to MHC antigens, because the tolerance-inducing inoculum usually contains cells capable of reacting against the host. This they can do either by the unexpected, but now well established ability of F_1 hybrid cells to recognise parental strain MHC antigens (Shearer, *et al., Cold Spring Harbour Symp*, **41**, 511; 1976); or by means of an anti-idiotypic response against the

0028-0836/80/350837-02$01 00

receptors by which the parent recognises the foreign antigens in the F_1 (Ramseier & Lindenmann *Pathol. Microbiol.* **34,** 379; 1969). This latter mechanism can suppress the parental cells so as to produce what amounts to a phenotypic state of tolerance (Binz *et al. Nature* **246,** 146; 1973). Thus a state of tolerance can involve any of a wide variety of different mechanisms, all of which may represent facets of the way self-tolerance is maintained. At least some of the positive suppressor mechanisms however seem to be specially stimulated after induction of tolerance by artificial means. This is important because it is clear that natural self-tolerance is not inherited; if it were one would expect to see it in the homozygous offspring of an $F_1 \times$ parent mating. In fact however such mice do not tolerate the foreign F_1 antigens any better than their homozygous, non-tolerant parent.

It is possible however that Gorczynski's and Steele's mice have inherited, not their fathers' suppressive mechanisms, but the antigen to which the fathers have been made tolerant. Very large numbers of donor cells were injected at regular intervals throughout the fathers' lives, so genes specifying donor antigens could as easily be imagined to have found their way into the germ-line as somatically mutated paternal genes. In that case such genes would be expressed in a proportion of the offspring and would be recognised and tolerated as 'self'. This possibility is mentioned by Gorczinski and Steele.

This brings us to the second of our two questions: was the information actually transmitted in the DNA of germ cells, or did it go by some less direct route? The fact that fewer of the second generation mice were tolerant than the first argues that the characteristic was not fixed in the germ line, and thus would require some special proviso for it to be accepted as inheritance in the DNA. In place of this, some other routes bear consideration. Could tolerance have been transmitted via a regulatory antibody or lymphocyte, or an antigen-bearing stem cell, in the seminal plasma? There is no precendent for such a route. In addition it would require the mothers to become tolerant, which seems highly unlikely in view of the known difficulty of inducing tolerance to MHC antigens in the adult animal.

Another possibility, by which one might escape frontal challenge to Weissmann's dogma, is that the information could be carried across the generations by viruses as such, without requiring violation of germ-line DNA. There are indeed a number of instances in which virus infection both *in vitro,* and *in vivo* has been associated with the appearance of unexpected (or 'alien') MHC specificities. But whether the virus actually transduces the MHC-specific information (as would be necessary if this were to explain the inheritance of tolerance) or whether it merely triggers some predetermined change in the structure of the MHC molecules is not known. In any case there is as yet no good evidence from this or any other source for viral transduction *in vivo.* Furthermore, for viral infection to serve as an explanation it would have to be strictly limited to the venereal route, otherwise tolerance would have been expected to appear in some control mice in the same animal house.

Yet another possibility (A. Müllbacher, personal communication) depends on the already-mentioned capacity of F_1 hybrids to make a response to the parent. Thus if the tolerogenic inoculum of F_1 lymphoid cells were making such a response to the CBA host, it might have the effect of selecting against the CBA-type among developing germ cells, and thus favour any mutations bearing A strain antigens. These mutations could then be perpetuated by normal inheritance, and there would be no need for a special viral transduction mechanism. Once again, however, there is no precedent for this type of selection.

In answer to our second question, then, it is not easy to offer an alternative mechanism for the transmission of tolerance which is any more credible than the Lamarckian one favoured by Gorczynski and Steele. Clearly, the basic result must be repeated in other laboratories. It will be important to establish mendelian inheritance through further generations, and to characterize the tolerant state. In addition one would expect from the point of view of survival value in evolution, that immune responsiveness as well as non-responsivenes would prove to be heritable. ☐

Solar luminosity variations

from Ronald L. Gilliland

THE solar luminosity is the primary force driving the earth's atmospheric circulation and it is probable that variations in the solar constant of as little as 0.3% would have a measurable effect on the climate. In a recent paper, Dearborn and Blake (*Astrophys. J.* **237,** 616; 1980) describe the effects on the solar luminosity of varying the efficiency of convection and they briefly discuss mechanisms which could produce such changes. One such mechanism is a fluctuation in the average properties of the convection cells seen near the solar surface. At the depth where the luminosity is quite sensitive to the convective efficiency the number of cells is $\sim 10^3$. If the properties of individual cells are allowed to vary by 10%, then stochastic variations of $\sim 0.3\%$ in the total flux could occur. An alternative mechanism for inducing changes of convective efficiency is interaction with the cyclic variation of magnetic field strength associated with the 11 year solar sunspot cycle.

To examine the significance of the Dearborn and Blake study it is necessary to briefly describe the solar convection zone. The sun has a convective region extending to a depth of some 200,000 km or $\sim 30\%$ by radius. As over most of this region convection is very efficient and capable of carrying a much larger flux than is actually present, changes in the convective efficiency will have little effect on the luminosity. In the outer 3,000 km the convective efficiency begins to drop. Here a significant part of the flux is carried by radiative transfer and changes in the convective flux are readily induced by small changes in the convective efficiency. Dearborn and Blake have adopted the standard approach of modeling the very complex phenomena of turbulent convection with a simple 'mixing length' theory in which the size of convective cells at any given level is given by the assumed mixing length. It is the assumed mixing length which Dearborn and Blake alter to bring about a change of convective efficiency. They find that quite small changes in the mixing length parameter on timescales of days to $\sim 10^3$ years can lead to significant luminosity variations. These results are interesting and provocative since they show that solar luminosity variations are theoretically plausible on these timescales. However, quantitative predictions cannot be made as there is no physical connection between the proposed mechanisms leading to convective efficiency variations and modeling of them.

The solar models which show luminosity changes in response to a forced variation of convective efficiency also show radius variation. Sofia *et al.* (*Science* **204,** 1306; 1979) argue that measurements of solar radius variations can be used as a proxy measure of luminosity changes. The use of radius variations as a proxy depends on the theoretical determination of the relative change of radius with respect to luminosity (defined as $W = \frac{\Delta R/R}{\Delta S/S}$, R = solar radius, S = solar constant) resulting from assumed changes in convective efficiency. This would be very useful since historical records of the solar radius (from transit timings of the sun crossing the meridian, eclipse observations, and timings of Mercury transits) extend back a few hundred years. Unfortunately, direct monitoring of the solar luminosity has been carried out only for parts of this century and there is insufficient data for long-term correlations with climate.

The early claim by Sofia *et al.* that radius

Devonian trilobites

from R. A. Fortey

In a recent publication*, Eldredge and Branisa describe a whole series of beautifully preserved trilobites from Devonian rocks in Bolivia, including a number of genera and species new to science.

The trilobites are an extinct group of arthropods that flourished from the Cambrian to Permian periods (about 600—250 Myr BP). Unlike many invertebrate fossils, they have a complex and varied morphology, and rapid changes have occurred in virtually all parts of the exo-skeleton. They are therefore an ideal group to use as tests of the different theories for reconstructing phylogeny. The visual system in particular is very sophisticated and there are complex shufflings in the arrangement and numbers of lenses. The specimens described by Eldredge and Branisa are remarkable for their well-preserved muscle impressions and they have been able to record speciation within a geographically and taxonomically limited group. Of particular interest is their demonstration of the number of specific variations that can be played on a relatively few morphological themes — a product of one of the rapid 'radiations' that happened from time to time during the long history of the trilobites. □

---

variations could be used as a means of determining luminosity changes has encountered several problems. First of all, similar calculations conducted by different groups have found widely discrepant values for W. (Dearborn and Blake found $W = 5 \times 10^{-3}$. Sofia *et al.* found $W = 7.5 \times 10^{-2}$. In my own studies I have found $W = 8.5 \times 10^{-4}$. This is a total spread of × 100!) The numerical discrepancies are related to a much more fundamental problem. The mixing length theory does not model the turbulent convective flow in a time-dependent deterministic sense (feedback with variations of individual cells or the magnetic field can not be included). The mixing length is a free parameter which is normally adjusted in order for the calculation to match time-averaged global observed conditions (for example, radius and luminosity). While the mixing length theories may adequately describe time-independent global structure, results of perturbations within the mixing length theory framework do not necessarily have any relation to actual physical processes. The mixing length theory does not adequately describe the detailed structure of the outer 3,000 km of the solar convection zone (where the changes in question arise). Indeed different versions of mixing length theory exist which give observationally indistinguishable solar models, but quite different structures in the outer 3,000 km which are so important for this problem. Using mixing length theory to determine more than rough qualitative estimates for the relative radius and luminosity variations is highly questionable.

In order to predict reliable quantitative results for solar radius and luminosity variations it will be necessary to directly incorporate the causal mechanisms. For the stochastic variation mechanism a deterministic hydrodynamic model of convection in multiple dimensions is required. To follow the effects of a variable magnetic field one must couple the full 3-dimensional hydrodynamic treatment of convection with an equation to determine the magnetic field. One must thus solve the non-linear astrophysical dynamo problem (see Moffat, H.K. *Nature* **285**, 16; 1980). This is a very difficult problem — reliable quantitative results are unlikely to be found in the near future.

While past measurements of solar luminosity and radius variations have not been highly significant, our ability to make precise measurements may be expected to improve in the near future. The Solar Maximum Mission launched February 14, 1980 should provide measurements of the solar luminosity with an absolute accuracy of 0.1% and a relative precision 0.02% over a planned period of 1-2 years. Preliminary results indicate that the quoted precision will be achieved and that statistically significant variations are occurring. Willson *et al.* (*Science* **207**, 179; 1980) have claimed direct detection of a 0.4% luminosity increase over a 2.4 year period with two rocket flights. A change of this magnitude occurring periodically over a few years or as part of a longer trend would have probable climatological significance. SMM and future satellite missions should allow us to know whether or not solar luminosity variations are taking place. The High Altitude Observatory is sponsoring a solar diameter measuring project based on transit timings which should be capable of detecting monotonic radius changes to < 0.01% over a baseline of a few years. Simultaneous radius and luminosity determinations are of importance in developing and checking theoretical models of solar variations. Thus, while current theoretical models of solar variations can be viewed as little more than suggestive, the day is near when direct observational determinations of such changes can be made, which in turn should help the development of realistic models. □

0028-0836/80/350839-02$01.00

Pseudogenes

from Nick Proudfoot

A new and unexpected discovery has now come from the molecular analysis of gene families that code for globin. Studies from a variety of mammalian species reveal that in each case more gene sequences are present in the genome than are necessary to encode the known globin polypeptides. Sequence analysis of these extra globin genes shows that they have a variety of nucleotide changes that would result in either aberrant or absent polypeptide formation. The term 'pseudogene' — defined as a region of DNA that displays significant homology to a functional gene but has mutations that prevent its expression — has been coined for these aberrant genes.

The first example of a eukaryotic pseudogene was described by Jacq, Miller and Brownlee (*Cell* **12**, 109; 1977) for the Xenopus 5S gene system. These and further studies (Miller *et al.* *Cell* **13**, 717; 1978) revealed that the 5S gene was directly adjacent to an almost but not quite faithful 5S gene copy. No pseudogene 5S RNA has ever been detected *in vivo*. More recently extra genes which may be pseudogenes have been found in the rabbit (Hardison *et al.* *Cell* **18**, 1285; 1979) and human β-globin gene clusters (Fritsch *et al.* *Cell* **19**, 959; 1980) and human α-globin gene cluster (Lauer *et al.* *Cell* **20**, 119, 1980).

During a recent meeting entitled "Haemoglobin Switching" at Airlie House, Virginia, US the β-like gene families of human, rabbit, mouse, sheep and goat and α-like gene families of human and mouse were described in some detail. In each case more genes were detected than expected and evidence was presented suggesting that most of these extra genes are, in fact, pseudogenes. As recently published from the laboratories of Phillip Leder and Oliver Smithies (Nishioka *et al.* *Proc. natn. Acad. Sci. U.S.A.* **77**, 2806; 1980; Vanin *et al.* *Nature* **286**, 222; 1980), Nishioka and Vanin described a mouse α-globin gene that has various frame shift mutations which are in turn followed by in-phase termination codons. As a result no α-globin-like polypeptides can be produced. The gene has a further remarkable feature — both introns are precisely excised so that it resembles a somewhat mutated α-globin messenger RNA.

Both speakers suggested possible mechanisms to explain how such an 'intronless' gene could have arisen. A favourite model is that messenger RNA or its reverse transcript somehow upsets the replicative process, even though the presence of globin mRNA or reverse transcriptase in germline cells has yet to be demonstrated. During replication of a globin gene, messenger RNA or complementary DNA might base pair with the gene sequence and loop out the two introns. Subsequent repair of such hybrids could result in intron excission. Another, perhaps more plausible, model is that the enzymes involved in splicing out introns from precursor RNA might also be capable of splicing DNA in an analogous manner. Presumably such DNA splicing would have to be a freak occurrence, or no intron would be safe. Nishioka described a second mouse α-like globin gene that appears to be a candidate for pseudogene status. Although both introns are present, several base changes in the gene would alter amino acids thought essential for globin function. Furthermore, the normal termination codon is mutated so that translation of the mRNA would continue into the 3′ noncoding region. Such a mutation has been found to be the cause of a rare genetic disorder in man — haemoglobin Constant Spring (Clegg *et al.* *Nature* **234**, 337; 1971).

Two pseudogenes of the goat were described by Lingrel in a β-globin gene family (Zingrel, Haynes, Schon, Clearly & Gallagher, unpublished).One gene has several terminator codons close to the start of the gene that would prevent the expression of globin. The other has a variety of base changes that would alter amino acids essential to globin function. There are also β-like globin pseudogenes in positions between embryonic and adult globin genes in mouse and rabbit. Hutchinson described the mouse β-pseudogene which appears to have completely lost its 5′ side so that the first β-like sequence detectable is at around amino acid position 75. Beyond this the sequence is clearly β-like and the second intron is in place. However, short deletions and additions of sequence together with terminator sequences indicate that this gene is inactive (Jahn, Hutchinson, Phillips, Weaver, Haigwood, Voliva & Edgell *Cell* in the press). In contrast to the mouse gene the rabbit β-pseudogene as described by Hardison has β-like sequence corresponding to all regions of the adult β gene except for its 3′ noncoding sequence which is barely identifiable. Again a deletion of one nucleotide close to the beginning of the gene coding sequence quickly puts any translation product from this gene out of phase (Lucy & Maniatis *Cell* in the press). Finally, a human α-globin pseudogene was described (Proudfoot & Maniatis *Cell* in the press), again between the embryonic and adult α-like genes. This gene is 70-80% homologous to the adult α-globin gene throughout its sequence but has a deletion of 20 nucleotides in the middle of the gene that puts the amino acid sequence out of phase.

An interesting feature of the last four pseudogenes is that they lack the putative intron splicing signals found at the beginning and end of all introns (Breathnach *et al.* *Proc. natn. Acad. Sci. U.S.A.* **75**, 4853; 1978; Lerner *et al.* *Nature* **283**, 220; 1980). It therefore seems unlikely that any transcripts produced by these genes could be spliced correctly. Two further features of the globin pseudogenes described should be mentioned. First, most of them, in addition to mutations that would directly affect translation into globin polypeptides, have potential transcription mutations. For instance, the intronless mouse α-globin and the second goat β-globin psuedogenes lack the putative promoter signal or 'Hogness Box' PyATApu (M. Goldberg, Doctoral Thesis, Stanford University), while the human α-globin and the same goat β-globin pseudogenes lack the putative polyadenylation signal AATAAA (Proudfoot & Brownlee *Nature* **263**, 211; 1976). Second, in each case where the complete linkage arrangement of the particular globin gene cluster has been established (human α and β, rabbit β, mouse β) a pseudogene is found between the embryonic or fetal and adult globin genes.

Can any function be ascribed to pseudogenes? Vanin *et al.* postulate that pseudogenes might restrict gene expression by using up the transcriptional apparatus of the cell in futile pseudogene transcription. Perhaps the presence of a pseudogene next to each adult globin gene is related to such a regulatory process. Alternatively, globin pseudogenes could be the source of new gene products if translated in one of the two other coding frames or if translation includes intron sequences which are unspliced. However, so far no new protein product has been suggested or identified for these pseudogenes.

It may be better to consider pseudogenes as relics of evolution. Globin genes probably evolved by duplication. After the initial duplication event each member of a pair could diverge and useful sequence variations would be selected. Presumably, first α and β and then embryonic and fetal globin genes were produced in this manner. Mutations that restrict expression of the genes could also occur. In an extreme case, such as a promoter mutation, it is possible that one gene might be completely switched off. There would be then no selective advantage in the switched-off gene remaining globin-like so the whole gene sequence might be expected to gradually drift from the original sequence. In another case a mutation might only partially inactive the gene resulting in low level expression. Human δ-globin and mouse β-minor globin genes might be living examples of such an evolutionary process. Finally, it is possible that certain gene mutations such as a frame shift might not

---

N.J. Proudfoot is a Senior Research Fellow in Biology at the California Institute of Technology, Pasadena, California, U.S.A.

0028-0836/80/350840-02$01.00

only incapacitate the gene but result in the expression of a new protein detrimental to the whole animal. Although such mutant genes might be expected to rapidly disappear from the population, further inactivating mutations might occur that could then allow these genes to become fixed in the population. There is, in any case, no reason to believe that pseudogenes *per se* have any function although, of course, new genes could evolve from them.

The molecular analysis of globin genes is probably more advanced than any other mammalian gene system at this time. It seems likely that when other gene families are equally well characterized new pseudogenes will be identified. Indeed, extrapolating from the situation in globin, one in four gene sequences may be pseudogenes. Put in simple terms this suggests that one quarter of our genes might be dead. □

Volcanic ash southern style

from Ian Smalley

WITH the eruptions of Mt. St Helens still making the headlines in the northern hemisphere this was a good time to have a conference* on volcanic ash deposits (alias tephras) in New Zealand. It might be noted that the St Helens eruption has produced about 1 km^3 of ash but the last eruption of the Taupo volcano in the mid North Island of New Zealand produced about 24 km^3, possibly all in about 15 minutes through a vent 100 m wide.

P. Froggatt (Victoria University, Wellington) reviewed the tephras from Taupo. There have been 8 major rhyolitic eruptions during the past 10,000 years. Their stratigraphy and distribution is well understood and provides useful marker beds over most of the North Island. A source vent for each eruption has now been established. The most useful and widespread marker bed is the Taupo pumice (1,820 yrs BP) which erupted from within Lake Taupo at Horomatangi Reefs. The stratigraphy and nature of the Taupo pumice have now been revised and show a variety of eruptive mechanisms. The last phase of the eruptions was the most voluminous and destructive, being a series of pyroclastic flows which swept radially outward over all topography for more than 60 km. Reconstruction of the eruptive history of this ignimbrite has important implications for older eruptions such as the Kawakawa tephra (20,000 yrs BP) and the older welded ignimbrites.

P. Kamp (Waikato University) discussed the Pleistocene tephras in Hawkes Bay and their implications for Quaternary events. The tephras provide an absolute time-scale for the Kidnappers Group sedimentary succession, the deposition of which was predominantly glacio-eustatically controlled and which matches the standard deep-sea chronostratigraphy (core V28–238). The correlation of Pleistocene tephras elsewhere in New Zealand with Kidnappers tephras may enable events on land to be tied into the sea-level chronology. Nine discrete rhyolitic tephras, which Kamp has named informally A to I, occur in the 350 m thick Kidnappers Group succession.

V. Neall (Massey University) offered some comparisons between the volcanoes in the Cascade Range in the Western United States (including Mt. St. Helens) and Mt Egmont in New Zealand. The geological setting of each volcano and its relationship to non-volcanic rocks provides useful comparisons, particularly with respect to control of pyroclastic flow and lahar mudflow distribution. Frequency of tephra eruptions in Holocene times varies from 1 per 100–200 years at St. Helens (based on the last 4,000 years record), to 1 per 250–350 years at Egmont, 1 per 500–1,000 years at Rainier and 1 per 800 years at Shasta. The Egmont tephra succession displays a remarkably uniform mineralogy in marked contrast to tephras within the last 500 years. Pyroclastic flows from Egmont have been as frequent as those produced from St Helens and Shasta, but are much less in volume.

A. Palmer (Victoria University, Wellington) considered the occurrence of airfall tephra in the loess of the Wairarapa, at the southern end of the North Island. The 20,000 yr BP Kawakawa tephra occurs as a pinkish white 5–10 cm band of coarse silt to fine sand-sized glass and pumice fragments and is consistently found at two thirds the depth of the top (Ohakean) loess unit. The tephra influences bulk density and water contents for at least 50 cm above the primary airfall material and similar bulk density and water content variations within the older loesses probably indicate volcanic ash. Some further observations on loess were provided by N. Kennedy (DSIR Soil Bureau, Rotorua) but he was concerned with what has come to be known as 'tephric' loess. Some problems are arising in the more northerly parts of the North Island with a redeposited tephra material which might be classed as a loess. According to Kennedy tephric loess is deposited during arid climatic periods and is always found sandwiched between tephras of 15,000–20,000 yrs BP. Thus the period 15–20,000 BP is regarded as cold and arid. In the Rotorua basin the average rate of accumulation during that critical period was 0.3 cm/yr.

D. Seward (N.Z. Inst. Nuclear Sci.) reported on progress in fission track dating of tephra deposits. Tephras represent time planes within both marine and continental sediments and are most suitable for stratigraphic chronology and correlation. Glass was the first material used for fission track dating of tephras but most glasses have undergone varying amounts of annealing and this has reduced the size and density of the spotaneous fission tracks, and produced a 'young' age. The most suitable mineral in the tephras is zircon. The Tertiary-Quaternary sequences in New Zealand contain sufficient tephras for a tight time scale to be realised throughout. However, because of error limits the fission track ages of individual tephras must be closely analysed before tephras from one sequence can be absolutely correlated with those from another. C. Vucetich (Victoria University, Wellington) offered some Quaternary tephra correlations, from c.40,000 yrs BP to c.300,000 yrs BP. The chronology was based on two fission track dates for zircons by B. Kohn: Puketirau tephra (Tirau) 0.22 ± 0.03 Myr and Omokoroa tephra (Tauranga) 0.36 ± 0.04 Myr and indirect dating per c.120,000 yr marine transgression.

D. Lowe (Waikato University) demonstrated the usefulness of tephra layers preserved in peats. The recent identification of more than twelve unweathered and unmixed thin discrete air-fall tephras in piston cores from shallow peaty lakes near Hamilton have provided a stratigraphic record of late Pleistocene (post-Kawakawa tephra) and Holocene tephra deposits in the Waikato region. Identification of the tephras was greatly aided by using X-radiography techniques and these are being actively developed by the Waikato group, with particular possibilities seen in the techniques of xeroradiography which utilises a reusable photo receptor plate instead of conventional X-ray film.

The situation may appear hazardous but like the farmers persistently cultivating the slopes of Etna the scientists find rich results are derived from volcanic ash. The scale of New Zealand vulcanism in the past has been colossal with the Taupo eruptions judged by G.P.L. Walker to have been perhaps among the largest ever. The enormous spread of volcanic material in New Zealand means that the datable volcanic events in the north can offer useful stratigraphic indicators even down into the glaciated south. □

Strategies of drug resistance in herpes simplex

from H. J. Field and G. K. Darby

ALTHOUGH effective anti-viral drugs are only just being developed it already seems likely that viruses have diverse strategies of drug resistance. Foremost among the anti-viral drugs is acyclovir (ACV)*, a nucleoside analogue which has shown great promise particularly against herpes simplex virus (HSV) infection. A wealth of encouraging results already exist for animal model systems [1-8], and clinical trials in man are now underway in Britain and the US.

Workers at Burroughs Wellcome first showed that two virus specified enzymes are involved in the mechanism of action of this compound[9-11]. Firstly ACV is 'activated' in infected cells by conversion to its triphosphate, the initial step in this process being carried out by the virus-coded enzyme, thymidine kinase (TK). For the drug to block the multiplication of the virus, the ACV-triphosphate must then interact with a second virus-coded enzyme, DNA polymerase[9,12].

Elion and her colleagues[9] showed that a virus unable to induce thymidine kinase was resistant to the drug. It also seemed that a second class of resistant virus — one with an altered DNA polymerase function — was theoretically possible. Investigations of resistant viruses generated by passage of HSV in the presence of the drug[13] suggested that resistance could indeed arise in this way, although initially it was only observed in TK$^-$ viruses. Evidence that mutations in the DNA polymerase gene of HSV could confer resistance to ACV was provided independently by Coen and Schaffer [14] and Schnipper and Crumpacker[15]. In both cases viruses were investigated in which exposure to phosphonoacetic acid (PAA) — a compound acting predominantly at the level of DNA polymerase[16] — had produced PAA resistance. The TK$^+$ viruses selected for resistance to PAA had also frequently acquired resistance to ACV, and it was concluded that the most likely location for this second ACV-resistance locus was the polymerase gene. Both groups also observed that selection of resistant strains in the presence of ACV generally yielded TK-deficient viruses although Coen and Schaffer[14] described one strain which appeared in addition, to have acquired resistance at the polymerase locus.

Is ACV resistance likely to become a clinical problem in man? To answer this we must look at the biological properties of resistant viruses. TK$^-$ viruses arise readily in tissue culture in actively dividing cells where TK is a non-essential virus function. Evidence is accumulating, however, that such viruses are attenuated in animal model systems, particularly in their interactions with the nervous systems[13, 17-21]. This may make their establishment *in vivo* unlikely and may also explain the lack of reports of such isolates from animals undergoing treatment with ACV.

In contrast with the frequent isolation of TK-deficient viruses, the change to resistance at the DNA polymerase locus occurs much less readily[13-15]. Since in this case the enzyme function is essential for virus replication, there must be considerable constraints on structural alterations. Nevertheless, studies on PAA-resistant viruses[22] and a TK$^+$, ACV-resistant virus[13] suggest that these viruses may not be attenuated as much as TK-deficient strains and may therefore be more of a problem. It is interesting in this context that a study by Hirano *et al.* last year[23] revealed that resistant strains of HSV isolated from patients treated with Idoxuridine were TK$^+$, leading the authors to speculate that these were DNA polymerase mutants. This contrasts with the TK$^-$ phenotype commonly associated with Idoxuridine resistance generated *in vitro*.

In the next few months information should become available on isolates obtained from humans treated with ACV. The *in vitro* work to date suggests that the analysis of such isolates will be complex and may well reveal unexpected strategies employed by HSV to outwit the nucleoside chemist. ☐

Primeval galaxies and the X-ray background

from Beatrice M. Tinsley

YOUNG galaxies must have been spectacular objects, with very high rates of star formation and associated bright stars, supernovae, optical nebulosities and X-ray sources. Some years ago, Partridge and Peebles noted that primeval galaxies might be detectable not only as individual objects (*Astrophys. J.* **147**, 868; 1967) but also as a source of diffuse background radiation at wavelengths from ultraviolet to infrared. (*Astrophys. J.* **148**; 1968). The search for primeval galaxies began with those papers and continuing into the present has branched into X-ray astronomy.

Most of the effort has focussed on individual primeval galaxies, with optical searches for them and theoretical models for their properties in all parts of the electromagnetic spectrum, (for a review see Sunyaev *et al. Comments Astrophys.* **7**, 183; 1978; Meier & Sunyaev *Scientific American* Nov. 1979 and Tinsley *Phil. Trans. R. Soc.* **296**, 303; 1980). Galaxies have been found in deep counts that have much bluer colors and probably higher rates of star formation than their nearby descendents (Bruzual & Kron *Astrophys. J.* in the press), but it is not know whether these are young or luminous enough to quality as *bona fide* primeval galaxies.

Searching for the integrated background light of young galaxies has proved to be an extremely difficult task at optical wavelengths because the diffuse extragalactic

Beatrice M. Tinsley is Professor of Astronomy at Yale University.

0028-0836/80/350842-02$01.00

light is fainter than the zodiacal light and probably fainter than scattered starlight in our own galaxy. Thus the latest observational efforts (Spinrad & Stone, *Astrophys. J.* **226**, 609; 1978; Dube *et al.* *Astrophys J.* **232**, 333, 1979) have succeeded only in setting readily understandable upper limits to the integrated light of primeval galaxies.

A new idea is that young galaxies might be detectable in the X-ray background — a well-established isotropic radiation that may or may not be simply a superposition of quasars and other known X-ray sources (see Rees in *Objects of High Redshift* IAU Symposium **92**, ed. Abell & Peebles, 1980). Some astronomers have been tempted to account for the X-ray background by thermal bremsstrahlung from a hot intergalactic medium, perhaps dense enough to close the universe, but this is unsatisfactory because the energy required to heat the gas would be excessively high (Field & Perrenod *Astrophys. J.* **215**, 717; 1977). However, thermal bremsstrahlung is a possibility if the emitting gas is very highly clumped, and this is where young galaxies enter the picture: two papers by Tanaka and Ikeuchi (*Prog. Theor. Phys.* **62**, 393; 1979) and Bookbinder *et al.* (*Astrophys. J.* **237**, 647; 1980) consider the radiation from gas heated by supernovae in primeval galaxies. The supernovae would heat the gas to a temperature of about 100 keV, implying that its thermal X-ray emission could explain the spectrum of the background (at energies of about 2 - 50 keV) if most of the active phase of star formation in galaxies occurred rather recently in cosmic time, at redshifts less than 2.

The difficult question is whether young galaxies can supply enough X-rays to account for a significant fraction of the background intensity. Bookbinder *et al.* conclude that they can, but the point is debatable. Their ingenious approach is to estimate the X-ray emission of each young galaxy by relating its supernova production to the mass of metals produced by exploding stars; the mass of metals can then be estimated in turn from the quantity of metal-rich stars now remaining in each galaxy. The present luminosities and colours of galaxies are the observable quantities used to indicate the mass of metal-rich stars, and an uncertain factor in the calculation is the ratio of this mass to total galactic luminosity. Bookbinder *et al.* find that the emitted X-rays are sufficient if the mass-to-luminosity ratio is 90 solar units. This number is uncomfortably high, since, as the authors note, observed mass-to-luminosity ratios of the metal-rich parts of galaxies are typically about 10. Nevertheless, Bookbinder *et al.* feel that, within the uncertainties, hot has being driven from young galaxies could contribute signficantly to the background near 50 keV.

This would be a very satisfying result, both accounting for the X-ray background and implying that primeval galaxies have been found. It should be noted, however, that the predicted X-ray intensity depends on the square of the mass-to-luminosity ratio of metal-rich stars, so with the plausible value of 10 for that ratio the young galaxies contribute only 1% of the X-ray background. A similar result was obtained by Tanaka and Ikeuchi (loc. cit.), who scaled their result to the mean density of galactic stars in the universe, and found with a plausible density that young galaxies contributed about 1% of the X-ray background at 10 keV. A significantly higher contribution would require more supernovae in young galaxies than estimated by either set of authors, which does not seem very likely since Bookbinder *et al.'s* supernovae even accounted for the known metals in intergalactic space. It therefore seems most plausible that gas heated in young galaxies makes a negligible contribution to the X-ray background.

Primeval galaxies may also be bright in X-rays from other sources. For example, Bookbinder *et al.* consider the possibility of large populations of stellar X-ray sources, analogous to the famous Cygnus X-1 (black hole) system in our own galaxy. However, stellar and other possible diffuse sources in primeval galaxies probably do not contribute a significant part of the background, since they could not account for its spectrum over a significant energy range.

We seem to be back to the question of whether primeval galaxies can ever be found. Individual sources may be a more promising avenue of discovery than any integrated background radiation, because they can always be studied further for predicted signatures of young galaxies. As noted above, some faint blue galaxies have been found that are viable candidates for very young objects, and it would be most exciting to study these in all possible detail, including high resolution imagery with the coming Space Telescope. □

Noisy chaos

from N. MacDonald

IN experiments in hydrodynamics the onset of turbulence (see *Nature* **283**, 431; 1980) is frequently preceded by a sequence of bifurcations from one periodic mode to another of doubled period. This has caused renewed interest in those mathematical models characterised by a similar series of solutions with period doubling, followed by the onset of non-periodic 'chaotic' behaviour as some parameter of the model is varied.

Perhaps the best known deterministic physical model with a chaotic solution is that of Lorenz (*Nature* **271**, 305; 1978) for flows in a horizontal layer of liquid across which a temperature gradient is maintained. In Lorenz' own calculations chaos comes about, as the Rayleigh number *R* is raised, by a sudden transition from a simple periodic flow. However, Robbins recently has shown (*S.I.A.M.J.App.Math.* **36**, 457; 1979) that as one lowers *R* to approach the chaotic region from the other direction, there is a sequence of bifurcations of this kind.

In a much simpler category of models employing one-dimensional maps (May *Nature* **261**, 459; 1976) such as

$$X_{n+1} = \lambda X_n(1 - X_n) \qquad (1)$$

the multiple bifurcations are through solutions of period 2, 4, . . 2^N, . . as one increases λ. The transition values λ_N accumulate in a regular manner towards a limiting value λ_C at which a non-periodic solution first occurs. Models of this type, are commonly used to study the population dynamics of insects which have one distinct generation each year, and one such model has recently been applied to populations of annual plants (Watkinson *J. theor. Biol*, **83**, 345; 1980). Difference equations such as (1) also have a somewhat subtle connection with differential equation models such as that of Lorenz.

There are difficulties in interpreting experimental data by means of any purely deterministic model with non-periodic, and apparently randomly fluctuating, solutions. This is perhaps most readily seen when a model such as (1) is used to describe population dynamics. The reproductive rate λ is liable to change from year to year because of random environmental influences. How can one expecte to unscramble these effects from those of deterministic chaos for a fixed λ? Again, in any physical model with such delicately poised dynamics it would be wise to allow for the perturbing effects of thermal fluctuations by including an additional random force term.

Rather little attention seems to have been paid to this difficulty, but in a recent paper Crutchfield and Hubermann (*Phys. Lett.* **A77**, 407, 1980) have studied the equation

$$X_{n+1} = X_n(1 - X_n) + N\sigma, \qquad (2)$$

in which $N\sigma$ is a Gaussian random number with zero mean and standard deviation σ. They have also studied the effect of a random force term added to a model of an anharmonic oscillator with a periodic forcing term. Several authors (*Nature* **274**, 847; 1978) have studied chaos in deterministic models of this type, and Crutchfield and Hubermann have previously shown (*Phys. Rev. Lett.* **43**, 1743; 1979) that multiple bifurcations occur in their particular version. They have characterised the chaotic solutions in

N. MacDonald is in the Department of Natural Philosophy, University of Glasgow.

0028-0836/80/350843-02$01.00

terms of a frequency spectrum containing a number of strong spikes on top of a broad distribution of frequencies. As one moves across the chaotic region, away from the critical parameter value that ends the period-doubling sequence, these spikes merge in pairs, simplifying the spectrum. Eventually only the broad band remains, the solution giving way to a simple periodic solution. The authors mention that Lorenz, in unpublished work, has established a similar structure of the solutions of model (1).

The strikingly simple qualitative result now obtained by Crutchfield and Hubermann is that, both in model (2) and in the noisily forced oscillator, the effect of the noise term is to remove the later stages of the bifurcation sequence of chaotic solutions. As the amplitude of the noise term is increased, this bifurcation gap widens.

The authors believe that this result should be capable of experimental test in situations in which the noise level can be controlled. Their anharmonic oscillator model was originally devised for application to solid state systems where anharmonic degrees of freedom can couple to a periodic field. Superionic conductors are an example of such a system. They are (Boyce & Hubermann *Phys. Rep.* **51**, 189; 1979) solids which display ionic conductivities many orders of magnitude greater than those of normal salts. They can be characterised by the presence of a rigid lattice of one type of ion in which another type of ion can move freely. The diffusion coefficients are very dependent on temperature, and for this reason Crutchfield and Hubermann suggest that superionic conductors may be particularly suitable for controlled variation of the noise term to test for the bifurcation gap. □

Cystic fibrosis

from Leighton Dann

UNTIL a few years ago, the genetic disease cystic fibrosis (CF) was considered to be a childhood disease as most patients succumbed at an early age. With the use of modern drugs the prognosis has been much improved and patients commonly reach adulthood. Thus CF has graduated from the paediatric clinic and entered general medicine.

This changing pattern provided the focus for much of the 8th International Congress on the disease held recently in Toronto*, with sessions on progression with age, and on genetics, diagnosis and screening.

The basic defect, as yet unidentified, primarily affects exocrine glands and so various bodily functions are impaired. Bronchopulmonary disease remains the greatest problem, and successful treatment and control of infection is a major goal of research. Several delegates discussed alternatives to antibiotic therapy, and H.V. Reynolds (Yale University New Haven) reported the use of immunoprophylaxis. Much of the work has concentrated on the bacterium *Pseudomonas aeroginosa* as it is so prevalent and so highly pathogenic in CF lung infection, particularly in the later stages of the disease. Although he showed that immunization with a multivalent lipopolysaccharide vaccine boosted existing titres of antibodies against the organism in the blood, no effect was noted in the lungs of patients. As with antibiotic therapies, serum values of drugs or antibodies bear little relation to local concentrations in the lungs. Reynolds felt that although this method of treatment was of no value to the patient who is already infected, early immunization, before infection with *P. aeroginosa,* might prove beneficial. He also suggested that other antigens should be studied, for example exotoxin A and several high molecular-weight cell wall polysaccharides.

A most promising therapeutic application of the chelating agent EDTA was proposed by R.E. Wood (Case Western Reserve University, Cleveland). He and his colleagues found that incorporation of EDTA into the culture medium retarded the growth of *P. aeroginosa* due to sequestration of divalent metal ions, particularly magnesium. There was also marked synergism shown between EDTA and many commonly used antibiotics. Preliminary experiments on animals show that EDTA does not affect mucociliary transport at the concentrations needed to arrest growth of bacteria and may therefore prove safe for use in the human lung.

Another major problem of CF is pancreatic insufficiency. Although it may be controlled by administration of pancreatic extracts, large and often increasing amounts must be given as the disease progresses. A new form of enzyme supplement, Pancrease, (manufactured by Johnson & Johnson, Slough, UK) was discussed by R. Dinwiddie (Hospital for Sick Children, London) A. M. Weber (Hospital Ste-Justine, Montreal) and D. J. Holsclaw and H. Keith (Hahnemann Hospital, Philadelphia).

Pancrease consists of enteric coated microspheres of pancreatic enzymes in a gelatin capsule, and passes intact through the stomach to the intestine. With this mode of administration fat absorption is greatly improved and patients have access to a more normal diet as well as being able to take fewer tablets each day (about 6 instead of about 30). Similarly, better food absorption was reported by D.J. Cameron (Hospital for Sick Children, London) and E. Rossi (Childrens Hospital, University of Berne) if cimetidine is used as an adjunct to pancreatic supplements. This drug lowers gastric acid output and so higher concentrations of enzymes reach the intestine intact.

Early diagnosis is of paramount importance for good prognosis, and much effort was focussed on newer methods of detection, especially those potentially amenable to mass screening or to antenatal diagnosis. R.B. Ellio (University of Auckland) described his test for immunoreactive trypsin in newborns. Because the pancreatic ducts are blocked, trypsin leaks into the blood and is present in high concentrations in affected babies. Great interest was shown in this test, as it is done on dried blood spots and could therefore be incorporated into existing screening programmes for phenylketonuria.

J. Lieberman (Veterans Administrations Medical Centre, Sepulveda, California) described an assay which detects a specific IgM-binding fructose-specific lectin in CF serum. He suggested that this test could prove useful in detecting heterozygote carriers of the CF gene, as the lectin is present in the blood of parents of affected children. The connection between this lectin and the CF factor (a highly basic small protein found in many body fluids) remains to be elucidated.

J.C. Manson (Western General Hospital, Edinburgh) reported the production of antiserum in mice using CF factor isolated from serum by isoelectric focusing. Preliminary results with the antiserum are highly succesful but its availability is limited. This method has potential as a screening test for homozygotes not only in newborns but also antenatally, for amniotic fluid from an affected fetus contains CF factor. In another approach to antenatal diagnosis, reported by L.G. Dann (Queen Charlotte's Hospital, London), an arginine esterase assay is used on cultured amniotic fluid cells. However lack of suitable samples is hampering validation of the method.

While delegates were optimistic that the outlook for patients with CF would continue to improve, it was clear that a better understanding of the disease and in particular, the basic defect, was needed before CF became truly a treatable disease. The work in progress presented at the congress encourage the hope that by the time of the next congress, in Britain in 1984, much of this will have been achieved. □

Leighton Dann is in Queen Charlotte's Maternity Hospital, London.

*The Conference was held on 26th-30th May 1980 in the Royal York Hotel, Toronto and was organized by the Canadian Cystic Fibrosis Foundation.

Free calcium in heart muscle at rest and during contraction measured with Ca^{2+}-sensitive microelectrodes

Eduardo Marban, Timothy J. Rink*, Richard W. Tsien & Roger Y. Tsien*

Department of Physiology, Yale University School of Medicine, New Haven, Connecticut 06510
* Physiological Laboratory, University of Cambridge, Cambridge CB2 3EG, UK

Direct measurements of free Ca^{2+} in heart cells are needed for an understanding of the regulation of contractility. We developed and used Ca^{2+}-sensitive microelectrodes with fine tips, stable properties and ample sensitivity to free Ca^{2+} in the sub-micromolar range. In quiescent ventricular muscle, measurements which passed tests for electrode sealing and cell viability gave a mean free Ca^{2+} concentration of 0.26 μM. During contractures, we recorded Ca^{2+} transients rising as high as 10 μM. In studying the effects of catecholamines on free Ca^{2+} and force, we found evidence that adrenaline can reduce myofibrillar Ca^{2+} sensitivity in intact heart muscle.

ALTHOUGH it is widely believed that a rise in intracellular calcium activates contraction in heart muscle, the level of free Ca^{2+} at rest or during activity remains quantitatively uncertain. The strength of contraction can be widely varied by ions, hormones or drugs. It is often not clear, however, whether such inotropic agents act by changing the amount of activator Ca^{2+} or by modifying the Ca^{2+}-responsiveness of the contractile machinery. Direct measurements of free Ca^{2+} in cardiac muscle are obviously desirable. Recently, the Ca^{2+}-sensitive photoprotein aequorin has been used to record Ca^{2+}-related signals from various cardiac preparations[1-3]. The technique is well suited for monitoring changes in Ca^{2+} during twitch contractions, and has already provided much useful information about inotropic effects. However, as the investigators are careful to point out, the method has certain limitations. The light signals do not easily give absolute values of free Ca^{2+} because of various uncertainties, including interference from intracellular Mg^{2+} or H^+. A large number of cells must be injected with aequorin, resting levels can apparently not be detected, and light signals during twitches must be signal-averaged to overcome noise. Ca^{2+}-sensitive microelectrodes[4-6] offer another approach with different advantages and limitations, which may complement optical techniques using aequorin or other Ca^{2+}-indicators. In the first attempts at applying Ca^{2+}-electrodes to cardiac tissue, investigators[7,8] used sheep Purkinje fibres because the cells in this preparation are large enough (40–50 μm diameter) to tolerate electrode tip diameters of ≥ 1 μm. To be useful in the smaller cells of working heart muscle itself (10–15 μm diameter), Ca^{2+}-electrodes must have tips of sub-micrometre size, while retaining stable properties and ample resolution down to 10^{-7} M free Ca^{2+} or lower. These requirements are fulfilled by the Ca^{2+}-sensitive microelectrodes which we have made with a new Ca^{2+}-sensor. The electrodes enabled us to measure intracellular free Ca^{2+} in ventricular muscle, both at rest and during contractures.

Unbranched papillary muscles, 0.4–0.8 mm in diameter and 2–4 mm long, were isolated from right ventricles of 8–12-week-old ferrets (*Mustela putorius furo*). Ferrets were chosen because their hearts usually contain two or more robust preparations with suitable geometry for force measurements[9]. Muscles were placed in a chamber for superfusion with oxygenated Tyrode solution containing (in mM): 150 NaCl, 4 KCl, 1.8 $CaCl_2$, 0.5 $MgCl_2$, 5 glucose and 10 Tris HCl buffer (pH 7.2–7.4). The preparation was mounted with one end fixed and the other end attached to a force transducer. To reduce movements which would tend to dislodge the electrodes, the muscle was carefully positioned on a pedestal, with resting length well below that giving peak developed twitch force. Suitable high input impedance electrometers (WP Instruments) recorded signals from the Ca^{2+}-sensitive microelectrode (V_{CaE}) and a conventional microelectrode filled with 3 M KCl (V_m). Bath potential was defined as zero for both electrodes; the bath was earthed by an agar bridge containing 3 M KCl. The preparation was first penetrated by the conventional microelectrode, usually during continuous stimulation of twitch contractions. After a stable V_m impalement had been obtained, stimulation was discontinued and the preparation was impaled by the Ca^{2+}-electrode at a second site several cell lengths away from the V_m impalement. V_{CaE}, V_m and their difference ($V_{CaE} - V_m = V_{diff}$) were recorded along with contractile force on a chart recorder and a magnetic tape recorder. V_{diff} is a measure of free Ca^{2+} inside the cell.

Electrode construction and characteristics

Micropipettes were pulled from thin-walled, borosilicate tubing to a size that gave resistances of 8–12 MΩ if filled with 3 M KCl. The pipettes were baked dry at 200 °C, siliconized with tributylchlorosilane vapour, and back-filled under pressure with the pCa 7 buffer solution described in Fig. 1 legend. The electrodes were then bevelled until the resistance dropped to about 40% of the original value, giving a sharp tip with an outer diameter of about 0.5 μm. Next, a 10–50-μm column of the Ca^{2+}-sensor, dissolved in tetrahydrofuran, was sucked into the tip of the electrode. This sensor, a modification of the polyvinylchloride (PVC) macroelectrode membrane of Ammann *et al.*[10], consisted of 10% (w/w) neutral Ca^{2+}-ligand, *N,N'* - di(11 - ethoxycarbonyl)undecyl - *N,N'*,4,5 - tetramethyl-3,6-dioxaoctane-1,8-diamide, 8% tetraphenylarsonium tetrakis (p-biphenylyl)borate, 10% PVC and 72% (o-nitrophenyl)octyl-ether. The tetrahydrofuran, used to reduce viscosity, evaporated away in a few minutes, leaving a PVC gel impregnated with the other sensor components in the tip of the electrode.

This new PVC-gelled sensor offers various advantages over previous Ca^{2+}-sensitive microelectrode compositions. (1) Mechanical stability is much improved over liquid sensors; the

0028–0836/80/350845—06$01.00

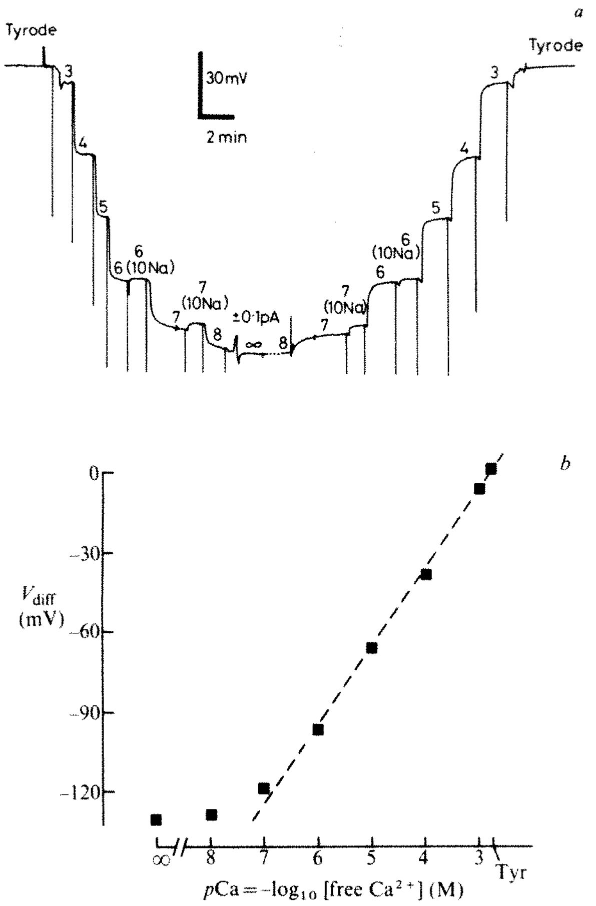

Fig. 1 Calibration plots for a Ca^{2+}-electrode with a bevelled tip of outer diameter ~0.5 μm. *a*, Calibration recording taken after a 5-h impalement of a ventricular cell. The e.m.f. of the Ca^{2+}-electrode was measured against a 3 M KCl reference electrode. The different test solutions are designated by their pCa values except for the initial solution which was the Tyrode solution containing 1.8 mM Ca^{2+}. The pCa 3 solution had 1 mM $CaCl_2$, 98 mM KCl and 10 mM K-MOPS, pH 7.3. The pCa 4, 5, 6, 7 and 8 solutions had 10 mM Ca-ligand (NTA, NTA, HEEDTA, EGTA, and EGTA, respectively), 5 mM $CaCl_2$, 90 mM KCl, 10 mM H^+ buffer (MOPS, Tris, HEPES, MOPS and HEPES) titrated with KOH to pH 7.39, 8.42, 7.70, 7.29 and 7.80. The 'pCa ∞' solution had 10 mM EGTA, no added Ca^{2+} and pH 7.6. The 'pCa 6 (10 Na)' and 'pCa 7 (10 Na)' solutions were the pCa 6 and 7 solutions to which 10 mM NaCl were added. '±0.1 pA' denotes current pulses to test the electrode resistance, $\sim 7\times10^{10}\,\Omega$. During the solution changes, the electrometer was switched into a standby mode for a few seconds. This was responsible for the electronic artefacts, a sharp downward spike followed by linear negative drift. *b*, Plot of the collected data from four calibration series including those shown in *a*, first descending, then ascending Ca^{2+} concentrations, before and after impalement. The potentials, V_{diff}, were read off the calibration recordings just before the next solution change. The zero of the scale was defined as the potential in 1.8 mM Ca^{2+} Tyrode in the first calibration run. The height of the symbols shows the full range (±1.5 mV) of potentials recorded in each buffer during the four calibrations. The dashed line indicates the theoretical (Nernst) slope, 29.5 mV per pCa unit at 24 °C.

PVC gel very seldom backs up or escapes from the tip. (2) Electrode response is increased at low Ca^{2+} levels, giving greater resolution between 10^{-6} M and 10^{-7} M free Ca^{2+} than previously achieved in fine microelectrodes suitable for use in small cells. (3) Electrode lifetime and stability are greatly increased. These electrodes retain their responsiveness over periods of 8–36 h. Use of the electrodes is often limited not by ageing, but rather by blunting of the tip with repeated penetrations.

The performance of the electrodes at low Ca^{2+} showed quantitative variations even when they were constructed in similar fashion from the same batch of sensor. Therefore, each electrode was individually tested by exposing it to a series of calibrating solutions (see Fig. 1 legend), following a procedure described elsewhere[11]. The calibrating solutions are designated by their free Ca^{2+} concentration, $[Ca^{2+}]$, given in units of pCa ($= -\log_{10}[Ca^{2+}]$). This convention was chosen instead of a Debye–Hückel activity scale so as to conform with (1) chemical measurements of Ca^{2+}-chelator dissociation constants[12], which are given in units of concentration, and (2) previous studies using aequorin or skinned fibres. The pCa scale can be readily converted into $-\log_{10}(Ca^{2+}$ activity) on a Debye–Hückel scale by adding a constant correction. This is possible because the KCl in the calibrating solutions keeps the Ca^{2+} activity coefficient nearly constant for $[Ca^{2+}] < 1$ mM. If, for example, one uses a Ca^{2+} activity coefficient of 0.36 (see refs 10, 13), our pCa 7 solution would be assigned a value of 7.44 for $-\log_{10}(Ca^{2+}$ activity).

Figure 1 shows the calibration of a fine, bevelled, PVC-sensor electrode. The response is nernstian down to 10^{-6} M, with some 24 mV between 10^{-6} and 10^{-7} M, and 10 mV below 10^{-7}, against a background of ~125 mM K^+. This is the best performance yet reported for a Ca^{2+} electrode with a sub-micrometre tip. At low Ca^{2+} levels, the electrodes have a small response to intracellular levels of Na^+ (refs 14–16). Figure 1*a* shows that 10 mM Na^+ increases the electrode potential by 1 mV at pCa 6 and 4 mV at pCa 7, so at intracellular resting Ca^{2+} levels, Na^+ interference needs to be taken into account. As with previous neutral ligand Ca^{2+} sensors[11,17], interference from Mg^{2+} and H^+ can be neglected. Even in Ca^{2+}-free solutions containing EGTA, increasing free Mg^{2+} from 0 to 5 mM (higher than estimated intracellular levels[18,19]) produces only 1–3 mV increase in electrode potential, and changing pH from 7.6 to 6.6 gives only 0–2 mV. At higher Ca^{2+} levels, ≥0.1 μM, interfering cations have even less effect. The influence of temperature must also be considered, as the calibrations were normally done at room temperature whereas the experiments were carried out at 35–37 °C. In separate experiments, calibrations were made at

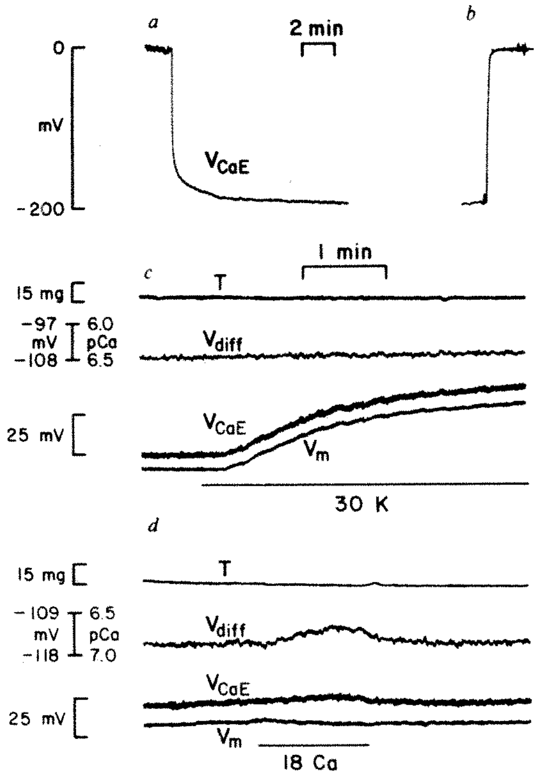

Fig. 2 Measurements of intracellular free Ca^{2+} and tests of their validity. *a*, Ca^{2+}-electrode signal (V_{CaE}) during impalement of a ferret papillary muscle. *b*, V_{CaE} during withdrawal of the same electrode after 3 h continuous intracellular recording. *c*, Common-mode rejection test in another preparation, using K^+-depolarization below the contractile threshold as a test signal. In this panel and subsequent ones, $V_{diff} (= V_{CaE} - V_m)$ is given on an absolute vertical scale, but the vertical positions of the V_{CaE} and V_m traces are arbitrary. At the beginning of *c*, $V_{CaE} = -200$ mV and $V_m = -92$ mV. *d*, Ca_0 elevation test in a third preparation. At beginning of record, $V_{CaE} = -196$ mV and $V_m = -81$ mV.

Table 1 Free Ca^{2+} concentration in unstimulated muscles

Preparation	Ca^{2+} electrode no.	Penetration no.	Test(s)	*p*Ca
Y22-2	26	3	18Ca, 30K	6.3

			Mean ± s.e.m.	6.59 ± 0.06

Intracellular *p*Ca values were determined by comparing V_{diff} levels, taken while muscles were bathed in 1.8 mM Ca^{2+}, 4 mM K^+ Tyrode solution, with electrode calibrations, carried out immediately after withdrawal from the muscle. Impalements satisfied quantitative criteria described in the text for electrode stability, sealing-in and cell viability. During tests of common-mode rejection using 16 or 30 mM K_o, $(\Delta V_{diff}/\Delta V_m)$ ranged between 0.98 and 1.07.

both 21 and 37 °C, using Ca^{2+} buffer compositions adjusted for temperature according to data from ref. 12. Raising the temperature merely scaled the response of the electromotive force (e.m.f.) by the ratio of absolute temperatures, in accord with the Nernst equation. For values of e.m.f. obtained in resting cells, the temperature correction amounts to about 3 mV, opposite and approximately equal to the magnitude of the sodium correction. The response time of the electrodes is many seconds at micromolar levels of Ca^{2+}, so they are not expected to follow transients during single twitches. Attention was therefore focused on 'resting' levels and slow changes during maintained contractures.

Intracellular measurements in resting muscles

Figure 2 illustrates electrode recordings during penetration and withdrawal, along with some tests of the validity of intracellular measurements. Figure 2*a* shows V_{CaE} during impalement of a cell with a Ca^{2+}-sensitive microelectrode. V_{CaE} undergoes a rapid negative deflection due in part to the membrane potential, and a slower negative-going change which can be attributed to sealing-in of the electrode and its sluggish response at low free Ca^{2+}. Figure 2*b* shows V_{CaE} during withdrawal of the Ca^{2+} electrode after a continuous 3-h impalement. The main point is the comparison between steady e.m.f.s measured at the beginning and end of the intracellular recording. The steady levels measured in the tissue agree extremely well, as do the levels in the external solution, indicating the absence of significant d.c. drift.

If $(V_{CaE} - V_m)$ is to be taken as a measure of intracellular free Ca^{2+}, it is necessary to consider the seal around the tip of the Ca^{2+} electrode and the viability of the impaled cell. Two types of test were applied to screen out defective impalements. One test uses changes in external potassium concentration (K_o) to vary the membrane potential over the range below contractile threshold. If the Ca^{2+}-electrode records from a cell which retains its normal resting potential, it should respond to a moderate elevation of K_o with a voltage change (ΔV_{CaE}) which closely matches the depolarization measured elsewhere in the preparation by the conventional microelectrode (ΔV_m). This is the case in Fig. 2*c* during a depolarization produced by 30 mM K_o. The quality of the common-mode rejection is also evident on the V_{diff} trace, which remains quite steady. Measurement of contractile force (*T*) confirmed that this level of depolarization was insufficient to activate tension.

In another test of impalement quality, the extracellular calcium concentration (Ca_o) was elevated, as shown in Fig. 2*d*. If the seal around the electrode tip was poor, or if the cell was otherwise damaged, one would expect a large V_{CaE} signal, as was sometimes seen. If, on the other hand, the tip was well sealed within a viable cell, one would expect only a modest change in V_{CaE}. In the experiment illustrated in Fig. 2*d*, a 10-fold increase of Ca_o produced little change in V_m and only a small positive-going deflection in V_{CaE}. The maximal change in V_{diff} was 4 mV, corresponding to $\Delta p\mathrm{Ca} = 0.22$, but there was no measurable development of force.

In these experiments and others, measurements of free Ca^{2+} in unstimulated muscles were examined according to various criteria to decide whether or not the impalements were acceptable. (1) Electrode stability was assessed in each case by comparing pre-impalement and post-impalement calibrations. The measurement was rejected unless the responses to *p*Ca 6 agreed to within 10 mV. (2) The quality of the seal around the Ca^{2+}-electrode tip and the viability of the impaled cell were checked by one or both of the following tests. First, exposure to 18 mM Ca_o (as in Fig. 2*c*): measurements were rejected if V_{diff} changed by more than 10 mV. Second, exposure to 16 or 30 mM

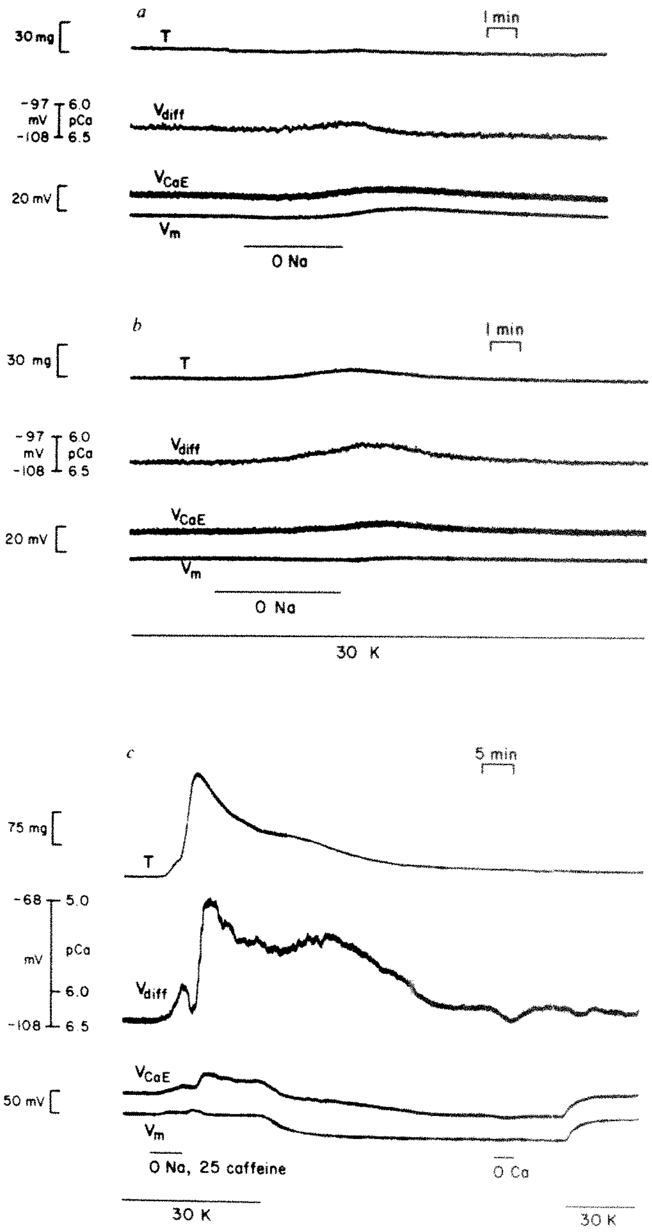

Fig. 3 Changes in free Ca^{2+} and force in response to a series of zero Na^+ challenges during continuous V_{CaE} and V_m impalements. *a*, Exposure to 0 Na(choline) in the presence of 4 mM K_o. V_m was −92 mV at beginning of record. *b*, 0 Na(choline) exposure in the presence of 30 mM K_o. V_m was −48 mV at beginning of record. *c*, Exposure to 0 Na(choline), 25 mM caffeine in the presence of 30 mM K_o. K_o was reduced from 30 to 4 mM and later restored to 30 mM as a test of whether both electrodes would respond equally to an imposed membrane potential change. Exposure to nominally Ca^{2+}-free solution was used to check continued responsiveness of V_{CaE}.

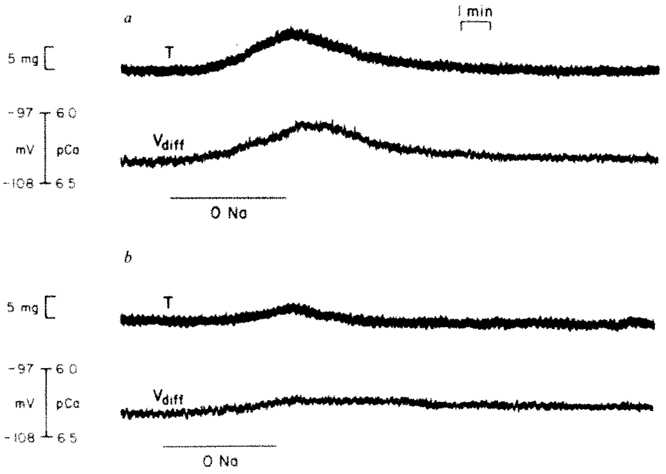

Fig. 4 Effect of isoprenaline (3 μM) on Ca^{2+} and force signals produced by Na^+ withdrawal in the presence of 30 mM K_o. Relative to control (*a*), Ca^{2+} and force transients were both attenuated by the catecholamine (*b*) and showed partial recovery towards their original amplitudes when a third 0 Na(choline) challenge was applied 25 min after removing the drug (records not shown). Records in *a* are taken from the same run as those in Fig. 3*b*.

K_o (see Fig. 2*d*): measurements were rejected if ΔV_{CaE} and ΔV_m differed by more than 10%. From a large number of attempts, 12 measurements were considered acceptable by these criteria (Table 1). The average resting level in *p*Ca units was 6.59 ± 0.06 (mean ± s.e.m.), or 0.26 μM. In the same series of measurements, the average resting potential in 4 mM K_o was −84.7 ± 1.7 mV.

Calcium transients during contractures

How does the free Ca^{2+} in unstimulated muscles compare with the level needed to activate the contractile proteins? One indication comes from the above-mentioned test of raising extracellular Ca^{2+} from 1.8 to 18 mM. Although any resulting large rises in intracellular Ca^{2+} were discarded due to the likelihood that gross penetration damage had occurred, small increases (as in Fig. 2*c*) were nevertheless observed even in five runs where independent tests with 16 or 30 mM K_o indicated good electrode sealing (Table 1). In those runs, raising extracellular Ca^{2+} 10-fold gave a peak increase of 1.2–2.6-fold in intracellular Ca^{2+}, but no measurable force ever developed. This suggests that resting levels were safely below the threshold for Ca^{2+}-activated force development in the conditions of our experiments. Such a conclusion may not hold at longer sarcomere lengths, corresponding to the peak of the length–tension relationship[20–22], where the myofibrils are known to be more sensitive to Ca^{2+} (refs 23, 24).

The relationship between free Ca^{2+} and force was studied further during sodium-removal contractures. Figure 3 shows records from a continuous Ca^{2+}-electrode impalement illustrating the responses to progressively stronger contracture challenges. Figure 3*a* shows the effect of replacing extracellular Na^+ with choline in the presence of 4 mM K_o. Here, Na^+ removal elicited an apparent 40% rise in free Ca^{2+}, but only a barely detectable increase in force. (Because the presumed fall in intracellular Na^+ would have depressed V_{diff} by 1 to 2 millivolts, the true rise in Ca^{2+} would have been slightly more than 40%). In Fig. 3*b* the stimulus for increasing intracellular Ca^{2+} was strengthened by partially depolarizing the preparation with 30 mM K_o before Na^+ removal, a procedure known to enhance Na^+-free contractures. In this case, the intracellular Ca^{2+} rose to a peak of almost 1 μM. (1 μM Ca^{2+} is high enough for changes in intracellular Na^+ to have a negligible effect on the electrodes.) Finally, in Fig. 3*c*, the contracture challenge was further augmented by including 25 mM caffeine in the Na^+-free solution. This produced a much larger force transient, and a Ca^{2+} signal which reached a peak of 10 μM. To demonstrate that the V_{CaE} signal was not due to dislodgment of the Ca^{2+} electrode, K_o was changed. Both V_{CaE} and V_m display similar hyperpolarizations during reduction of K_o from 30 to 4 mM, as well as the corresponding subsequent depolarization when 30 mM K_o was restored. The quality of the common-mode rejection, seen at higher amplification on V_{diff}, argues that the Ca^{2+}-electrode remained well sealed within a viable cell. The three parts of the experiment demonstrate the feasibility of recording both small and large calcium transients during varying degrees of contractile activation.

Relaxant effects of catecholamines

The advantages of the Ca^{2+}-electrode approach encouraged us to study the regulatory effects of catecholamines on excitation–contraction coupling. Stimulation of β-adrenoreceptors by adrenaline or isoprenaline not only increases developed force during a twitch (the positive inotropic effect) but also abbreviates the twitch and accelerates relaxation. These 'relaxant effects' (refs 25–29) are important in allowing adequate time for diastolic filling when the heart rate increases, as with exercise. A closely related relaxant phenomenon can be seen during contractures when exposure to adrenaline or isoprenaline reduces the force evoked by K^+-induced depolarization[25–27] or Na^+ withdrawal[26]. Two possible mechanisms involving cyclic AMP[28–30] have been suggested by studies of subcellular fractions or of skinned or hyperpermeable preparations. First, cyclic AMP may increase Ca^{2+} uptake by the sarcoplasmic reticulum[31,32] and, second, it may decrease the Ca^{2+} sensitivity of the myofibrils by promoting phosphorylation of a regulatory protein such as troponin-I[33–36]. Contracture experiments with Ca^{2+}-electrodes offer the possibility of seeing whether either or both

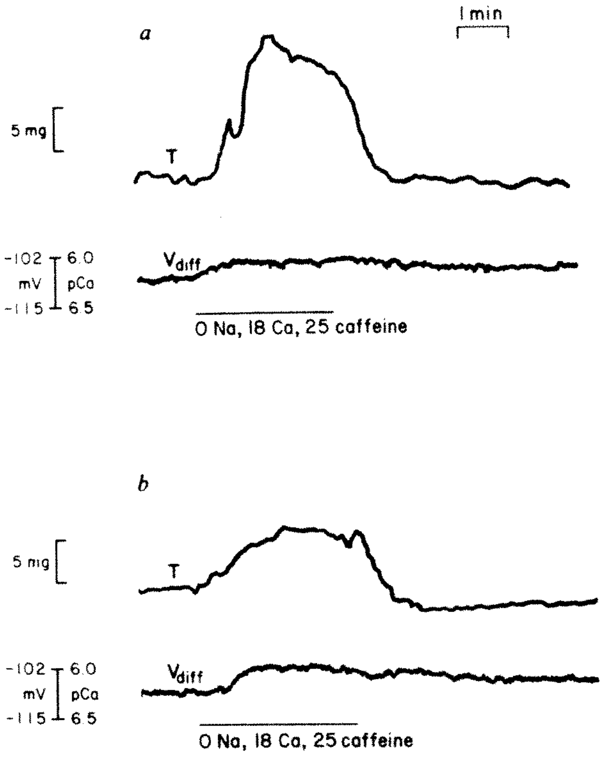

Fig. 5 Effect of adrenaline on Ca^{2+} and force signals evoked by caffeine-containing contracture solution. Horizontal bars indicate period of superfusion with 0 Na(choline), 18 mM Ca, 25 mM caffeine. 30 mM K_o present throughout. *a*, Control; *b*, 10 μM adrenaline (7 min). Contracture force returned to within 25% of control when the challenge was repeated after 20 min superfusion with adrenaline-free solution containing 1 μM propranolol but the Ca^{2+}-electrode was unfortunately dislodged by the contracture. The force records are unusually noisy in this figure because a force transducer with low sensitivity and low compliance was used in the hope of minimizing preparation movement.

mechanisms operate in intact cardiac muscle. Figure 4 shows Ca^{2+} and force signals during Na^+-withdrawal contractures: Fig. 4*a* is the response to Na^+-free solution before drug treatment, and Fig. 4*b* is the response in the presence of 3 μM isoprenaline. Both the force transient and the Ca^{2+} transient were reduced by the catecholamine (and showed partial recovery when the drug was removed). Similar results were obtained in an experiment using 10 μM isoprenaline. Because the Ca^{2+} transients, as well as force, were attentuated, these observations are consistent with enhancement of Ca^{2+} uptake by the sarcoplasmic reticulum as the predominant relaxing mechanism, although other possibilities are not excluded.

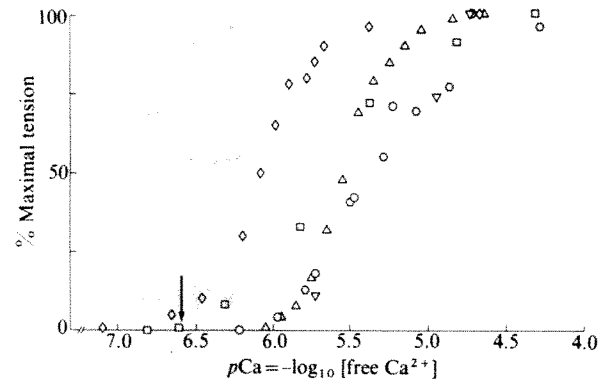

Fig. 6 Calcium requirements for cardiac myofibrillar activation, taken from published work on skinned or hyperpermeable preparations of mammalian cardiac muscle. All data have been adjusted along the horizontal axis so that recalculated *p*Ca values conform with Ca-EGTA binding constants given in ref. 12. The same binding constants were used in preparing calibration buffers for the Ca^{2+}-electrodes[11] and give log (effective stability constant for Ca-EGTA at *p*H 7.0) = 6.42. This value is in close agreement with the value (6.40) determined by Allen *et al.*[42]. ◇, Solaro *et al.*[43], Fig. 3, triangles. ○, Fabiato and Fabiato[44], Fig. 7, inverted triangles. ∘ , Kerrick and Donaldson[45], Fig. 1, filled triangles. □, Endo and Kitizawa[46], Fig. 7. ▽, McClellan and Winegrad[35], Fig. 9, open circles. △, Hibberd and Jewell[24], Fig. 1, filled circles. The arrow denotes the mean *p*Ca (6.59 ± 0.06) in quiescent myocardium as determined in this study.

Any reduction of myofibrillar Ca^{2+} sensitivity could best be seen if the Ca^{2+} transient were not reduced. To this end, caffeine was included in the contracture solution to inhibit Ca^{2+} uptake by the sarcoplasmic reticulum and promote net release[37]. As Fig. 5*a*, *b* illustrates, adrenaline treatment actually increased the Ca^{2+} transient during a 0 Na^+/18 Ca^{2+}/25 caffeine challenge. However, the contracture force was reduced, as expected if the contractile machinery were less responsive to a given level of Ca^{2+}. This result was confirmed in each of two additional experiments using 10 μM adrenaline. These observations provide evidence that adrenergic regulation of myofibrillar Ca^{2+} sensitivity, first proposed on the basis of biochemical studies, can indeed occur in intact cardiac muscle.

Discussion

Our experiments show that Ca^{2+}-sensitive microelectrodes can be made sharp enough and selective enough to measure free Ca^{2+} inside relatively small mammalian cells. The bevelled tips of these electrodes are sufficiently fine for impalements to be maintained with no greater difficulty than those of ordinary voltage-recording microelectrodes, despite the strong contractility of cardiac ventricular muscle. The nearly logarithmic response of the Ca^{2+}-electrode to free Ca^{2+} makes it possible to quantify intracellular Ca^{2+} levels both at rest and during contraction, with only slight interference from other ions. Limitations of this technique include the rather slow speed of response at the low intracellular Ca^{2+} levels, and the requirement for simultaneous measurement of membrane potential. Also, a Ca^{2+}-electrode takes a point sample which could be unrepresentative of Ca^{2+} concentrations elsewhere. Gradients inside one small ventricular cell are unlikely to persist over the time scale examined in the present work, but we have seen marked variations in the pattern of Ca^{2+} responses in different cells in the same papillary muscle. Thus it is not surprising that the tension recorded from the whole muscle often fails to track the Ca^{2+} transient, which was always measured in a single superficial cell. When studying modifications of contractile responses, we have assumed that physiological or pharmacological interventions have qualitatively similar effects on all the cells.

Our mean resting level of free Ca^{2+}, 0.26 μM (*p*Ca 6.59) in ferret ventricular muscle, is somewhat lower than that reported by Coray *et al.*[38], 0.36 μM in sheep myocardium, but higher than results of Uhm *et al.*[39], 0.12 μM in rabbit ventricular muscle. Over the critical range 0.1–1.0 μM free Ca^{2+}, the liquid sensor electrodes of those workers had a smaller response (5–9 mV)[8,38] than the PVC-gelled electrodes of the present study (18–24 mV), so that any small errors in estimates of the membrane potential or of interference from other ions would have less influence on our values for *p*Ca. Although the present measurements are not limited by electrode sensitivity to Ca^{2+}, all microelectrode recordings are susceptible to artefacts from impalement damage. We have accepted only those measurements which passed above-mentioned criteria for good electrode sealing and cell viability, but some residual perturbation by penetration damage cannot be excluded.

It is interesting to compare Ca^{2+} levels measured in intact fibres with levels which produce tension in 'skinned' or 'hyperpermeable' mammalian ventricular preparations, where Ca-EGTA buffers are applied directly to the contractile apparatus. Figure 6 shows *p*Ca-tension relationships from six published reports, adjusted for a standardized Ca-EGTA dissociation constant. Our resting value of *p*Ca 6.59 (vertical arrow) is at, or in most cases well below, the apparent threshold for Ca^{2+}-activated force. Moreover, the peak Ca^{2+} readings in the series of challenges shown in Fig. 3 are *p*Ca 6.3, 6.1 and 5.0. Reading off from the main cluster of *p*Ca-tension relationships for skinned fibres, we would expect barely detectable, small and near-maximal tensions, respectively, and indeed, the observed peak tensions were ~0, 9 and 240 mg. This agreement should be viewed with caution because of the microelectrode sampling problem discussed above and because skinned fibre *p*Ca-tension relationships can be markedly influenced by temperature[40,41], solution composition[35], sarcomere length[23,24] and perhaps, method of skinning and source of tissue. The effects of adrenergic compounds on Ca^{2+} transients and contractures were also in qualitative agreement with results from subcellular fractions[31–34,36] or hyperpermeable preparations[35]. Working with intact muscle, we found evidence that catecholamines may modify myofibrillar Ca^{2+} sensitivity and reduce peak Ca^{2+} elicited by sodium removal. These results illustrate how Ca^{2+} electrodes could be useful in future studies on the regulation of cardiac contractility.

This work was supported by the USPHS and the SRC. T.J.R. received travel grants from the Royal Society and Wellcome Trust. We thank Professor W. Simon for (*o*-nitrophenyl)octylether and Drs C. J. Cohen, W. K. Chandler and R. C. Thomas for helpful comments.

Note added in proof: Lee, Uhm and Dresdner[47] have just described Ca^{2+}-electrode measurements in rabbit ventricular muscle. Their Ca^{2+} values incorporate a calculated activity coefficient of 0.32 and are based on an effective stability constant for Ca-EGTA of $10^{6.76}\,M^{-1}$ at *p*H 7.0 rather than $10^{6.42}\,M^{-1}$ as in our work. Multiplication by 6.84 corrects their data to our units of free Ca^{2+} concentration and brings their value of 38 nM Ca^{2+} activity in resting cells to 260 nM free Ca^{2+} concentration, in fortuitously exact agreement with our results. O'Doherty *et al.*[48] have recently reported another sensor composition which appears to have comparable performance to the mixture used here.

Deletion of immunoglobulin heavy chain genes from expressed allelic chromosome

Yoshio Yaoita* & Tasuku Honjo*

Department of Physiological Chemistry and Nutrition, Faculty of Medicine, University of Tokyo, Tokyo 113, Japan

We have studied the organization of immunoglobulin heavy-chain genes in a γ2b-chain (BALB/c allotype)-producing myeloma BKC F_1 #15 induced in a F_1 mouse between C57BL and BALB/c. Southern blot hybridization studies using cloned μ, γ1 and γ2b-chain genes as probes demonstrate that the μ- and γ1-chain genes of the expressed chromosome are deleted while these genes of the unexpressed chromosome are retained. The γ2b-chain gene of the expressed allele is rearranged while that gene of the unexpressed allele seems unchanged, as do the γ2a-chain genes. These results support the allelic deletion mechanism in heavy-chain class switch and the order of H chain genes.

DREYER and Bennett[1] proposed a model that a variable region (V) and a constant region (C) of the immunoglobulin polypeptide chain are encoded by two separate genes in the germ-line, which are eventually brought together by somatic recombination. Recent isolation and characterization of immunoglobulin light (L)- and heavy (H)-chain genes have convincingly borne out the predictions of the Dreyer–Bennett hypothesis[2–11]. Analyses of L-chain genes have demonstrated that the V–C recombination takes place between a germ-line V_L gene and a J_L region that is a few thousand nucleotides away from the C_L gene[12,13]. It is believed that the intervening sequence separating the J and C genes is removed at the RNA level by splicing[14].

Possible mechanisms have been proposed to account for the V–C recombination, which can be classified into deletion, copy-insertion, excision–insertion and inversion models[15–19]. A model for the immunoglobulin gene organization and reorganization should explain such unique phenomena known in lymphocytes as allelic exclusion and class switch. In a given lymphocyte a C_H gene of one allele is expressed and that of the other allele is suppressed (allelic exclusion). A V_H-region sequence is successively joined with different C_H-region sequences during differentiation of a lymphocyte (class switch).

Previously we showed that the copy numbers of the specific C_H genes in myeloma DNA were reduced depending on the class or subclass of the C_H gene expressed in the myeloma[20]. Our data indicate that the DNA segment located between a V_H gene and the C_H gene expressed is excised out of the chromosome to recombine the two genes. Such recombination seemed to occur only on one of the two allelic chromosomes. We have also proposed that H-chain genes are aligned on one chromosome in the order: V_H genes, unknown spacer, μ, γ3, γ1, γ2b, γ2a and α (ref. 20). Such alignment, together with successive deletion, can explain the class-switch phenomenon. This model is called the allelic deletion model. The deletion of C_H genes, in accord with the above order of the C_H genes, was recently confirmed by Rabbitts *et al.*[21]. The deletion of the DNA segment located between two adjoining sequences was also confirmed in the κ-type L-chain gene by Sakano *et al.*[12].

Elsewhere we have reported cloning of the rearranged γ1-chain gene from a γ1 chain-producing myeloma MC 101 and compared its structure with H-chain genes cloned from newborn mouse DNA[22]. Such analyses indicate that the rearranged γ1-chain gene contains at its 5′ flanking region a newly introduced segment that was located originally at the 5′ flanking region of the μ-chain gene in newborn mouse DNA. The recombination site is not the putative J region but a novel region called *S* region. These results are in agreement with the prediction of the deletion model, although they do not necessarily prove the model.

In this report we describe direct evidence that the deletion of the specific H-chain genes takes place only on the expressed chromosome using a myeloma induced in a F_1 mouse between C57BL and BALB/c which have different allotypes in the H-chain C regions.

Probes and restriction maps of the μ-, γ1- and γ2b-chain genes

We have already cloned the *Eco*RI fragments containing the γ1-, γ2b and μ-chain genes from newborn mouse DNA and determined their nucleotide sequences[4,8,9,22–24]. We used the 1.2-kilobase pair *Hin*dIII fragment of the cloned μ-chain gene,

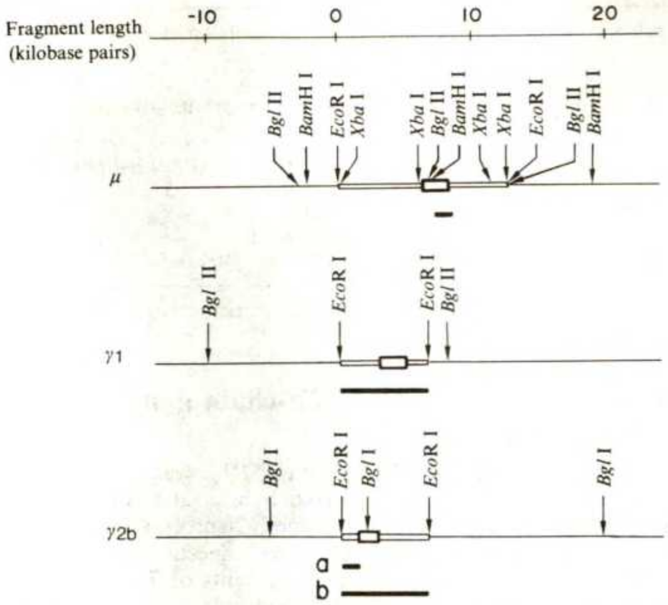

Fig. 1 Restriction enzyme cleavage sites around the μ-, $\gamma 1$- and $\gamma 2b$-chain genes. DNA is displayed from left to right with the direction of transcription. Narrower rectangles show the cloned DNA fragments. Wider rectangles show locations of structural genes. DNA fragments used for probes are indicated by horizontal bars below the restriction maps. μ-chain gene probe, 1.2-kilobase pair *Hin*dIII fragment that contains the CH3 and CH4 domains of the μ-chain gene clone[21]; $\gamma 1$-chain probe, 6.6-kilobase pair *Eco*RI fragment containing the $\gamma 1$-chain gene[8]; $\gamma 2b$-chain gene probe a, 1.35-kilobase pair, *Bam*HI fragment (5′ fragment) of the $\gamma 2b$-chain gene clone[22]; $\gamma 2b$-chain gene probe b, 6.6-kilobase pair *Eco*RI fragment containing the $\gamma 2b$-chain gene[22].

the cloned *Eco*RI fragment (6.6 kilobase pairs) of the $\gamma 1$-chain gene, the cloned $\gamma 2b$-chain gene and the 1.35-kilobase pair *Bam*HI fragment of the cloned $\gamma 2b$-chain gene as probes for hybridization (Fig. 1). Although the whole $\gamma 2b$-chain gene clone ($\gamma 2b$ probe b) has extensive homology with the $\gamma 2a$-chain gene[23,25], the 1.35-kilobase pair *Bam*HI fragment ($\gamma 2b$ probe a), which corresponds to the 5′ fragment of the cloned $\gamma 2b$-chain gene, does not cross-hybridize with the $\gamma 2a$-chain gene under the stringent washing conditions used in the present study. Detailed maps of restriction endonuclease cleavage sites within these clones have been determined[8,22–24]. We have determined the restriction sites of *Bgl*II adjacent to the cloned $\gamma 1$-chain gene fragment by digestion of mouse DNA with several combinations of two restriction enzymes, followed by Southern blot hybridization of the restriction DNA fragments. Similarly, we have determined the restriction sites of *Bgl* I adjacent to the cloned $\gamma 2b$-chain gene fragment and the sites of *Bam*HI and *Bgl* II adjacent to the cloned μ-chain gene fragment. These restriction sites were confirmed by Southern blot hybridization using the 5′ or 3′ fragment of the cloned DNA as a probe. Figure 1 summarizes the results of these analyses and the known sites of restriction endonucleases used in the present study. The fragments used for probes are also shown.

Allelic deletion of the μ- and $\gamma 1$-chain genes

To prove the deletion of the C_H gene from one chromosome, it is essential to distinguish the C_H genes on different chromosomes. BALB/c and C57BL mice have different allotypes in H-chain C regions[26], suggesting that their C_H genes may have different nucleotide sequences. We searched for restriction endonucleases that produce the C_H-gene fragments of different lengths between BALB/c and C57BL alleles. Among restriction endonucleases tested (*Pvu*II, *Bam*HI, *Eco*RI, *Hin*dIII, *Sma*I, *Pst*I, *Kpn*I, *Xba*I *Bgl*II) we found that *Bgl*II can distinguish the $\gamma 1$-chain genes of BALB/c and C57BL alleles. As for the $\gamma 2b$-chain gene, we have tested *Xho*I, *Ava*I, *Sal*I, *Xba*I, *Bgl*II, *Bam*HI, *Bst*EII and *Bgl*I, and found that *Xho*I or *Bgl*I digestion produces different $\gamma 2b$-chain gene fragments between BALB/c and C57BL DNAs. The μ-chain genes of C57BL and BALB/c alleles were distinguished by digestion with *Xba*I, *Eco*RI or *Kpn*I, while digestion with *Bam*HI or *Bgl* II did not distinguish the two alleles.

Only a few myelomas are available, which were induced in the F_1 mouse between BALB/c and C57BL (ref. 27). BKC F_1 #15, that produces the $\gamma 2b$-chain protein with the BALB/c allotype, is suitable for our purpose since the allelic deletion model predicts the deletion of the $\gamma 1$- and μ-chain genes from the BALB/c chromosome of this myeloma.

When BALB/c and C57BL DNAs were digested with *Xba*I, blotted and hybridized with the μ-chain probe, they produced the 4.8 and 2.8-kilobase pair bands, respectively (Fig. 2*a*, lanes 1

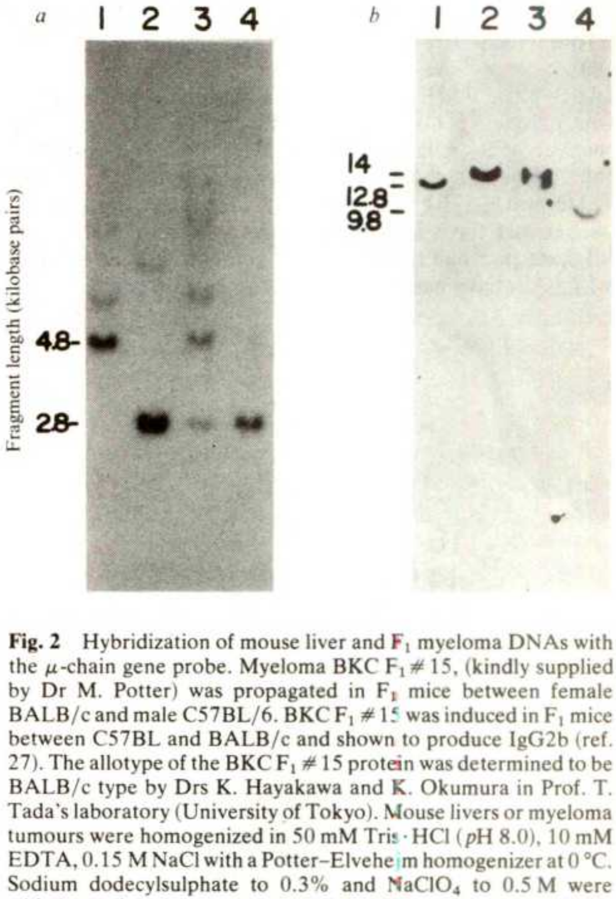

Fig. 2 Hybridization of mouse liver and F_1 myeloma DNAs with the μ-chain gene probe. Myeloma BKC F_1 #15, (kindly supplied by Dr M. Potter) was propagated in F_1 mice between female BALB/c and male C57BL/6. BKC F_1 #15 was induced in F_1 mice between C57BL and BALB/c and shown to produce IgG2b (ref. 27). The allotype of the BKC F_1 #15 protein was determined to be BALB/c type by Drs K. Hayakawa and K. Okumura in Prof. T. Tada's laboratory (University of Tokyo). Mouse livers or myeloma tumours were homogenized in 50 mM Tris · HCl (*p*H 8.0), 10 mM EDTA, 0.15 M NaCl with a Potter–Elvehjem homogenizer at 0 °C. Sodium dodecylsulphate to 0.3% and $NaClO_4$ to 0.5 M were added to a whole homogenate. The homogenate was extracted with 0.5 vol. each of water-saturated phenol and a chloroform–isoamyl alcohol mixture (24 : 1). The water phase was separated by centrifugation, dialysed against 0.1 × SSC (0.015 M NaCl, 0.0015 M Na citrate) for 24 h digested with RNase (100 $\mu g\ ml^{-1}$) in a dialysis bag for 24 h at room temperature and then extracted with phenol. After dialysis against 0.1 × SSC for 48 h, 1.27 g of CsCl was added to 1 ml of the water phase. After centrifugation at 30,000 r.p.m. for 48 h, fractions with high viscosity were collected and dialysed against 0.1 × SSC for 48 h. DNAs (5 μg each) were digested with *a*, *Xba*I or *b*, *Eco*RI, electrophoresed in 0.5% agarose gels (Sigma type I) and transferred to nitrocellulose filters (Schleicher and Schuell) according to the method of Southern[32]. DNA fixed on filters was hybridized with the μ-chain gene probe as described previously[8]. The probe DNA was labelled with [α-^{32}P]TTP (Amersham) by nick translation[33]. The specific activity of the probe was 200 c.p.m. pg^{-1}. After hybridization, filters were rinsed with 2 × SSC and then washed in 0.1 × SSC plus 0.1% SDS (four times) for 40 min each at 67 °C. Filters were finally rinsed with 2 × SSC, dried and exposed to X-ray film using a DuPont Cronex lightening plus intensifier screen at −80 °C. Origins of DNA used are: lanes 1, BALB/c liver; lanes 2, C57BL/6 liver; lanes 3, F_1 mouse liver; lanes 4, BKC F_1 #15 myeloma.

and 2). BKC F_1 #15 DNA, when digested with *Xba*I, yielded only the μ-chain gene fragment of the C57BL allele while F_1 mouse DNA contained the μ-chain gene fragments of both BALB/c and C57BL alleles (Fig. 2*a*, lanes 3 and 4). Faint bands larger than 6 kilobase pairs are due to contamination of other *Hin*dIII fragments of the μ-chain gene clone to the 1.2-kilobase pair *Hin*dIII fragment used as a probe (see Fig. 1) because these faint bands disappeared when the recloned 1.2-kilobase pair *Hin*dIII fragment was used as a probe. It is worth noting that a faint band (at 6.1 kilobase pairs) of the BALB/c chromosome is also absent from the F_1 myeloma DNA. The μ-chain gene of the C57BL allele in BKC F_1 #15 appeared to be unchanged at its 3′ distal region since DNAs of C57BL and BKC F_1 #15 produced identical μ-chain gene fragments of 12- and 8.5-kilobase pairs when digested with *Bam*HI and *Bgl* II, respectively (ref. 28 and see Fig. 1). However, the 5′ region flanking the μ-chain gene of the C57BL allele in BKC F_1 #15 is rearranged because the μ-chain gene fragment (9.8-kilobase pairs) in *Eco*RI-digested BKC F_1 #15 DNA was smaller than the band (14-kilobase pairs) observed in *Eco*RI-digested C57BL DNA (Fig. 2*b*, lanes 2 and 4).

BALB/c and C57BL DNAs, when digested with *Bgl*II, yielded the γ1-chain gene fragments of 18- and 14.5-kilobase pairs, respectively (Fig. 3, lanes 1 and 2). Naturally, F_1-mouse DNA contained the γ1-chain gene fragments derived from both BALB/c and C57BL alleles. It is evident that BKC F_1 #15 DNA has lost the γ1-chain gene of the BALB/c allele (the 18-kilobase pair band), whereas the gene on the C57BL allele (the 14.5-kilobase pair band) seems to remain intact (Fig. 3, lane 4).

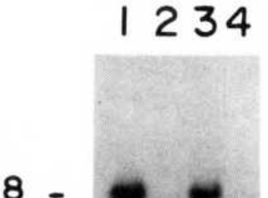

Fig. 3 Hybridization of mouse liver and F_1 myeloma DNAs with the γ1-chain gene probe. DNAs (30 μg each) were digested with *Bgl*II and hybridized as described in the legend to Fig. 2 with the [α-^{32}P]-labelled γ1-chain gene probe. Origins of DNA used are: lane 1, BALB/c liver; lane 2, C57BL/6 liver; lane 3, F_1 mouse liver; lane 4, BKC F_1 #15 myeloma.

Table 1 Restriction fragments of immunoglobulin H-chain genes in mouse liver and myeloma

Origin of DNA	Size of restriction DNA fragments (kilobase pairs)			
	μ (*Xba*I)	γ1 (*Bgl*II)	γ2b (*Bgl*I)	γ2a (*Eco*RI)
BALB/c liver	4.8	18.0	7.5	23.0
C57BL liver	2.8	14.5	9.5	23.0
F_1 liver	4.8+2.8	18+14.5	–	–
BKC F_1 #15	2.8	14.5	9.5 and 6.5	23.0

The results of Figs 2–4 are summarized. Restriction enzymes used are shown in parentheses.

Rearrangement of the γ2b-chain gene of the expressed allele

The γ2b-chain gene in BKC F_1 #15 DNA was analysed by digestion with *Bgl* I and Southern blot hybridization using the 5′ fragment of the cloned γ2b-chain gene (γ2b probe a) as a probe. As shown in Fig. 4 (lanes 1 and 2), *Bgl* I digestion of BALB/c and C57BL DNAs produced the fragments of 7.5- and 9.5-kilobase pairs respectively, which hybridized with the γ2b chain probe a. BKC F_1 #15 DNA, when digested with *Bgl* I, yielded the γ2b-chain gene fragments of 6.5- and 9.5-kilobase pairs (Fig. 4*a*, lane 4). The results indicate that the 5′ region of the γ2b-chain gene on the BALB/c allele was rearranged, while that gene on the C57BL allele seems to remain unchanged in BKC F_1 #15 DNA. However, we do not exclude the possibility that the γ2b-chain gene on the C57BL allele may have undergone some rearrangements which we did not detect. We also found that the 3′ region flanking to the γ2b-chain gene of the BALB/c allele is rearranged in BKC F_1 #15 DNA when the 3′-portion probe of the γ2b-chain gene was used[28].

Presence of the γ2a-chain genes

Both BALB/c and C57BL DNAs, when digested with *Eco*RI, produced the 6.6- and 23-kilobase pair fragments hybridizing to the γ2b-gene probe b which cross-hybridizes with the γ2a-chain gene (Fig. 4*b*, lanes 1 and 2). The 6.6-kilobase pair fragment corresponds to the cloned γ2b-chain gene and the 23-kilobase pair fragment was identified as the γ2a-chain gene fragment[21]. F_1-mouse and BKC F_1 #15 DNA contained the γ2a-chain gene fragment (23-kilobase pairs) (Fig. 4*b*, lanes 3 and 4). The γ2a-chain gene seems to be intact in BKC F_1 #15 although we cannot exclude the possibility that the γ2a-chain gene contains an undetected rearrangement.

Organization of immunoglobulin H-chain genes in BKC F_1 #15 myeloma

Restriction DNA fragments of the μ-, γ1-, γ2b- and γ2a-chain genes in BALB/c mice, C57BL mice, F_1 mice and BKC F_1 #15 myeloma are listed in Table 1. It is evident that BKC F_1 #15 has lost the μ- and γ1-chain genes of the BALB/c chromosome and contains the rearranged γ2b-chain gene of the BALB/c chromosome. This myeloma contains the μ-, γ1- and γ2b-chain genes of the C57BL chromosome. BKC F_1 #15 contains the γ2a-chain gene although we did not distinguish two alleles. These results are in agreement with the prediction of the allelic deletion model. Nevertheless, we found an unexpected rearrangement at the 5′ region flanking the μ-chain gene of the C57BL chromosome that is unexpressed in BKC F_1 #15. The two chromosomes of BKC F_1 #15 are schematically represented in Fig. 5.

Unexpected rearrangements in BKC F_1 #15

Although the deletion profile of C_H genes in BKC F_1 #15 DNA is as predicted by the allelic deletion model, we found two unexpected rearrangements in BKC F_1 #DNA; one in the 5′

region flanking the μ-chain gene of the unexpressed chromosome (Fig. 2*b*, lane 4) and the other in the 3′ region flanking to the γ2b-chain gene of the expressed chromosome[28].

It is possible that rearrangement in the 5′ region flanking the μ-chain gene of the C57BL allele is related to the mechanism to suppress the H chain genes on the C57BL chromosome. It may be relevant to this assumption that the 5′ region flanking the μ-chain gene is proposed to contain the putative J region and the *S* region that is important to class-switch recombination[22].

It is difficult to understand why the rearrangement in the 3′ region flanking the γ2b-chain gene of the expressed chromosome is necessary to express the γ2b-chain gene. It may be possible that the 3′ rearrangement of the C_H gene takes place so that the class switch stops at this particular gene. Otherwise, a V_H gene together with a J region moves farther down to a C_H gene remaining at the 3′ side of the expressed gene.

Deletion of C_H genes in other myelomas

Rabbitts *et al.*[21] reported that C_H genes, which are located 5′ to the expressed C_H gene, are absent from both chromosomes in several myelomas induced in BALB/c mice. We also observed similar deletion from both chromosomes and found that the expressed C_H genes are rearranged in different manners between homologous chromosomes in these myelomas[28]. The results may suggest that C_H gene deletion, which accompanies the rearrangement of the expressed C_H genes, takes place successively, but not simultaneously, in the allelic chromosomes. Several forms of rearranged κ-type L-chain genes were isolated from κ-chain-producing myelomas[29,30].

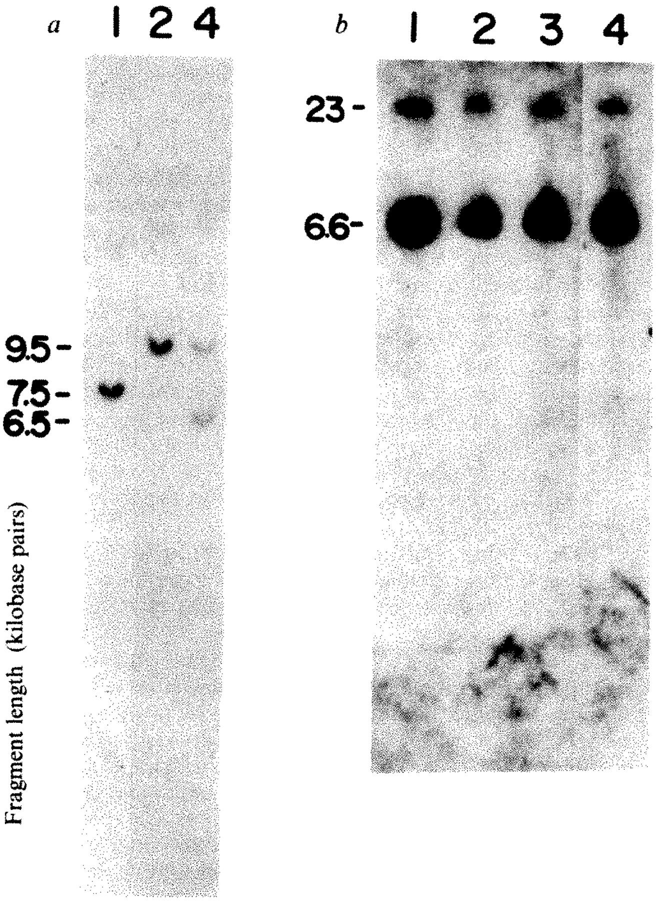

Fig. 4 Hybridization of mouse liver and F_1 myeloma DNAs with the γ2b-chain gene probes. DNAs were digested with *a*, *Bgl*I or *b*, *Eco*RI, and hybridized as described in the legend to Fig. 2 with [α-^{32}P]-labelled probes indicated. The γ2b probes a and b were used in *a* and *b* respectively. Origins of DNA used are: lanes 1, BALB/c liver; lanes 2, C57BL/6 liver; lanes 3, F_1 mouse liver; lanes 4, BKC F_1 #15 myeloma.

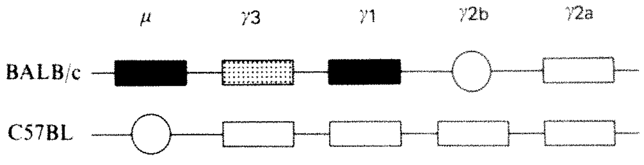

Fig. 5 Schematic representation of C_H genes in BKC F_1 #15. Each line shows one chromosome derived from each parent. The order of C_H genes is as proposed before[20]. Open and closed rectangles indicate 'intact' and deleted genes, respectively. (The word 'intact' simply means that the change is not detected in the present study.) Circles indicate rearranged genes. The γ3-chain gene, which was not determined in the present study, is assumed to be deleted from the BALB/c chromosome and indicated by a dotted rectangle.

However, we cannot exclude the possibility that such rearrangements could be secondary mutations in myelomas. We are quite aware of the fact that chromosomal anomalies are rather frequent in myeloma cells[29]. Nonetheless, the perfect agreement of the C_H-gene deletion profile (the order and allelic chromosome) with the prediction of the allelic deletion model is something more than accidental coincidence. Seidman and Leder[5] reported that only one member of an allelic pair of L-chain genes is rearranged in κ-chain-producing myelomas, MOPC 149 and MOPC 41. Studies on differentiated B lymphocytes are necessary to determine whether or not the case of BKC F_1 #15 is universal and directly applicable to normal lymphocytes.

We are grateful to Dr Y. Mano for continuous encouragement, Drs T. Tada, K. Okumura and K. Hayakawa for stimulating discussions and determination of the allotype of the BKC F_1 #15 protein and Drs Y. Suzuki and M. Obinata for critical reading of the manuscript, also to our colleagues for helping us to maintain tumour-bearing animals. This investigation was supported in part by grants from the Ministry of Education, Science and Culture.

The 5′ ends of *Drosophila* heat shock genes in chromatin are hypersensitive to DNase I

Carl Wu

Society of Fellows, Harvard University, and The Biological Laboratories, Harvard University, 16 Divinity Avenue, Cambridge, Massachusetts 02138

Many specific sites in Drosophila *chromatin are hypersensitive to DNase I. The positions of such sites were mapped along the regions of the genome coding for two heat shock proteins. Such sites lie at the 5′ ends of heat shock genes and may function as elements for recognition by molecules which regulate gene activity.*

EUKARYOTIC DNA is packaged as chromatin, a complex of protein and DNA within the cell nucleus (see ref. 1 for review). How might this compaction affect the expression of genetic information? Recently, in a study of the chromatin structure at specific regions in the *Drosophila* genome, we reported that certain localized sites were exquisitely sensitive to the nucleolytic enzyme DNase I (ref. 2). By digesting native chromatin gently with DNase I, electrophoresing the DNA on agarose gels and visualizing specific regions by hybridization with a cloned probe[3], we could show that each of five *Drosophila* loci displayed a unique set of preferred cleavages[2]. This preference did not appear on naked DNA, nor in the cleavage pattern of the entire genome[2]. Here, I map such DNase I-sensitive sites near the genes for two heat-inducible polypeptides in *Drosophila melanogaster.*

Mapping DNase I-sensitive sites

I mapped the positions of DNase I-sensitive sites by a novel indirect end-labelling technique that displays the partial digestion products. After gentle treatment of chromatin in nuclei with DNase I, the purified DNA is cleaved completely with a rarely cutting restriction enzyme, electrophoresed and blotted on to nitrocellulose in a typical Southern transfer[3]. The blot is then probed with a short cloned ^{32}P-labelled DNA segment that abuts a chosen restriction cut; the lengths of the labelled subfragments greater than the probe length define the distance between the restriction cut and the partial DNase I cuts.

This technique was applied to the genes for two heat shock proteins in *D. melanogaster* (Oregon R) embryos and in cultured cells [Schneider line 2 (ref. 4)] derived from such embryos. In *Drosophila*, an elevation in temperature from 25 °C to near 37 °C rapidly activates a small number of specific genes, and sharply reduces pre-existing gene activity (see ref. 5 for review). Cytologically, new puff sites appear in the salivary gland polytene chromosomes[6,7]. The heat-induced messenger RNAs direct the synthesis of new polypeptides, the heat shock proteins[8–14], present in all tissues tested as well as in some cell lines.

The most abundant heat-induced product is a 70,000 molecular weight heat shock protein, hsp 70. There are five copies of the uninterrupted 2.2-kilobase pair hsp 70 coding sequence, two at the cytogenetic locus *87A* and three at *87C* (refs 15–25). The five copies of the coding region and an adjoining 0·3-kilobase pair 5′-noncoding region are closely conserved; however, the sequences near the 5′ terminus diverge somewhat between the genes at the two loci, reflected in characteristic restriction site differences[20,24]. At *87A*, the two genes lie head to head, an inverted repeat around a central spacer[25]. At *87C*, a single hsp 70 gene lies at a distance, not yet determined, from an array of two (or three, in a variant) tandem copies organized in a direct repeat[19–23].

Figure 1*a* shows the partial DNase I cuts in Schneider cell chromatin upstream from the internal *Bam* site common to all five hsp 70 gene copies; the fragmentation pattern is aligned following the left to right, 5′ to 3′ convention. The *Bam* digest alone, on purified DNA, is shown in Fig. 1*a*, lane 2. Fragments obtained in low yield in this and subsequent similar digests are due either to cross-reaction with partially homologous sequences[24] or to polymorphism in the organization of the sequences adjacent to the hsp 70 coding region. (Populational polymorphism in these cultured cells is not surprising. Schneider initiated the line with explants from several hundred embryos[4]; the subcultures used here have to my knowledge never been cloned.) Increasing extents of partial DNase I cleavage on chromatin (Fig. 1*a*, lanes 3–5) reveal preferred cuts at two adjacent sites which span about 150 and 90 base pairs, flanking and extending through the 5′ end of the hsp 70 coding region. The control DNase I cleavage on naked DNA reveals a fairly uniform fragmentation pattern (Fig. 1*a*, lanes 7, 8). Although some sequence specificity[26] can be seen, this effect is minor (see also Fig. 4 of ref. 2). Hypersensitivity to DNase I must, therefore, primarily be a function of chromatin structure.

To show that no sensitive regions lie near the internal *Bam* site, I mapped the cuts upstream from an internal *Sal* site close to the hsp 70 3′ end (Fig. 1*b*, lane 2). Consistent with the previous *Bam* map, preferred cuts are localized at the 5′ end of the hsp 70 coding region, overlapping the *Sal* restriction cut characteristic of the two genes at locus *87A*. A number of preferred cuts are also observed upstream from the 5′ regions for the gene copies at locus *87C*. Some of these sites may map to the region at *87C* containing repeated sequences responsible for the heat-induced, nontranslated RNA of unknown function[17,27]. The locations of the 5′ ends of these RNAs have not been determined.

Downstream from the internal *Bam* site (Fig. 2), no sensitivity in the hsp 70 coding sequence can be detected near the common 3′ *Sal* site, but other sensitive sites are found past the hsp 70 messenger sequence (Fig. 2, lane 4). As two (or in a variant, three) of the hsp 70 gene copies at *87C* are organized in a direct repeat[19–23], the 5′ sensitivity in a distal gene copy would map downstream from its preceding partner (2.0–2.1 kilobase pairs from the internal *Bam* site, expected from the tandem hsp 70 map in ref. 21). No known genes occur near the two other sensitive sites. Only three out of five *Bam* fragments are selectively lost on DNase I digestion (Fig. 2, lane 5), so two hsp 70 gene copies must lack preferred cleavages downstream from their 3′ ends for at least 1 and 3 kilobase pairs, respectively. The minor DNase I cleavages which characteristically occur very close to the 5′ sensitive regions (Figs 1–3) coincide with positions of micrococcal nuclease cleavage (data not shown), and might reflect sensitivity of the linker regions between specifically

0028–0836/80/350854—07$01.00

placed nucleosomes[1] adjacent to the hypersensitive sites (see below).

5′ Sensitivity for individual hsp 70 genes

Are the 5′ sensitive regions common to all gene copies of hsp 70? I exploited the restriction site differences between the genes at *87A* and *87C* to display selectively locus-specific DNase I cuts. By digesting with both *Sal* and *Bgl*I in the experiment shown in Fig. 3*a*, all fragments from *87A* can be of no greater length than the 1.7-kilobase pair *Sal–Bgl*I segment. Thus, any longer partial fragments must be from *87C*. Figure 3*a*, lanes 2–4, show that the 5′ sensitive sites are present for the three gene copies at *87C*. It is likely that this sensitivity is a sum of three individual contributions; otherwise, some of the *87C* restriction fragments should be disproportionately retained on DNase I cleavage (Fig. 3, lane 4).

Similarly, digesting with *Pst* (Fig. 3*b*) ensures that all hsp 70 fragments from *87C* can be of no greater length than the 1.1-kilobase pair *Pst* fragment. Thus, any longer partial fragments must be from *87A*. The preferred cuts about 1.3 kilobase pairs upstream from the reference *Pst* site (Fig. 3*b*, lane 3) indicate 5′ sensitivity for the two hsp 70 gene copies at *87A*. Both must possess a 5′ sensitive site, from the identical rates at which the two smallest *Bam* fragments disappear on DNase I digestion in Fig. 1*a* (these two fragments are specifically reduced by a *Bam* plus *Bgl*I digest not shown, to the 0.8-kilobase pair

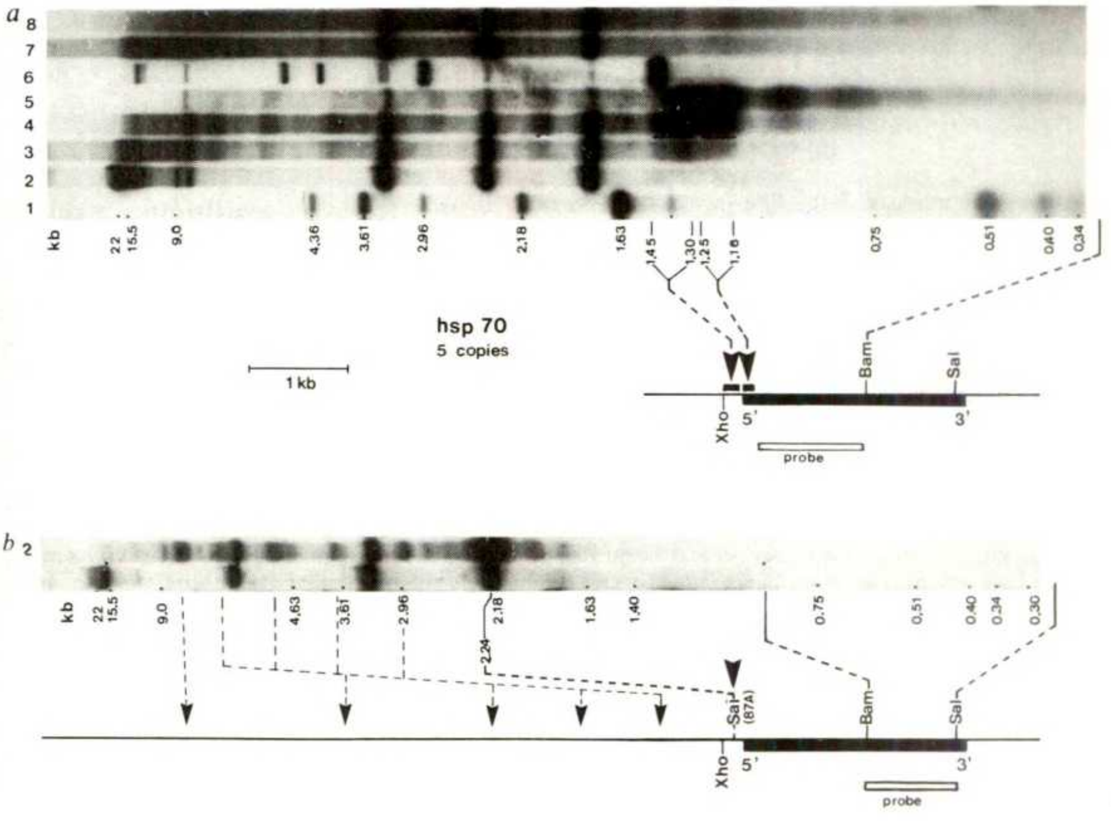

Fig. 1 Autoradiograms showing the partial DNase I cuts in Schneider cell chromatin upstream from the internal *Bam* site (*a*) and the 3′ *Sal* site (*b*) common to all hsp 70 gene copies. ***a***, Nuclei were purified from *Drosophila* Schneider line 2 tissue culture cells as described elsewhere[2], except that the final centrifugal spin was through 1.5 M sucrose. The nuclear pellet was rinsed once before resuspension at about 3×10^8 nuclei per ml in digestion buffer[2] (60 mM KCl, 15 mM NaCl, 15 mM Tris-HCl, *p*H 7.4, 0.5 mM dithiothreitol, 0.25 M sucrose, 3 mM $MgCl_2$, 0.05 mM $CaCl_2$). Various amounts of DNase I (Worthington) were added to aliquots of nuclei and digestion proceeded for 3 min at 25 °C. The reaction was terminated by the addition of EDTA and SDS to 12.5 mM and 0.5%, respectively, and the DNA was purified by immediate organic extractions. RNA was removed by RNase A and T1 digestion, the RNases by proteinase K digestion and the protease by repeated organic extractions as described in ref. 2. The DNA was precipitated in ethanol and redissolved at a concentration of 1 or 2 mg ml^{-1} in 10 mM Tris-HCl *p*H 7.4, 5 mM NaCl and 1 mM EDTA. Secondary *Bam*HI restriction digestions were carried out according to manufacturer's directions (New England Biolabs). The digestions were terminated as above, and the DNA samples in 10% glycerol, 5% Ficoll and marker dyes were electrophoresed on a 1.3% agarose gel, 30 cm long, in a Tris-acetate buffer system[41]. The upper half of the gel containing the large DNA fragments was immersed in 0.1 M HCl for 15 min to facilitate transfer of the DNA out of the agarose gel[42]. The DNA was denatured, neutralized and blotted on to nitrocellulose essentially according to Southern[3]. The nitrocellulose filter was rinsed in 9×SSC (1×SSC is 0.15 M NaCl, 0.015 M Na citrate, *p*H 7.0), 0.9 M NH_4 acetate, dried and baked under vacuum for 3 h at 75 °C. The filter was presoaked in 5× Denhardt's solution[43] (1× Denhardt's solution is 0.02% Ficoll, 0.02% bovine serum albumin, 0.02% polyvinylpyrollidone), 5× SSC, 50 mM Na phosphate, *p*H 7.0, and 0.25 mg ml^{-1} denatured salmon sperm DNA for 8 h at 67 °C and hybridized for 8 h at 67 °C in a slit chamber to plasmid pPW232.1 (ref. 17), labelled with ^{32}P by nick translation as described elsewhere[2] to a specific activity of about 1×10^8 d.p.m. per μg DNA. The hybridization mixture contained 5× Denhardt's solution, 5×SSC, 20 mM Na phosphate *p*H 7.0, 0.5 mg ml^{-1} denatured salmon sperm DNA, 0.1% SDS and 10% dextran sulphate to accelerate the hybridization reaction[42], and about 0.3 μg labelled plasmid DNA per 40 ml hybridization solution. After hybridization, the filter was washed twice in 5× Denhardt's solution, 3×SSC, 25 mM Na phosphate *p*H 7.0, 0.25% SDS and at least thrice in 0.1×SSC, 0.1% SDS, each round for 20–30 min at 67 °C. Autoradiography was on Kodak XR5 film. For later blots, the background noise could be reduced by doubling the concentration of Denhardt's solution at all stages and similarly for SDS in the primary wash. pPW232.1 (ref. 17), the cloned probe segment, is homologous to the 1.1-kilobase pair (kb) *Pst* fragment in Fig. 3 representing approximately the 5′ half of the hsp 70 coding region, indicated on the restriction map by the open bar. The lanes indicate: 1, marker DNA fragments from pBR322 (ref. 44), cut with *Pst*I; *Hin*fI; *Pst*I/*Sal*I; *Pst*I/*Eco*RI; *Pst*I/*Ava*I, and other recombinant plasmid fragments homologous to pBR322 sized at 9.0, 15.5 and 22 kilobase pairs. On a gel of this agarose content (1.3%), a linear relationship between log fragment length and mobility is obtained in the region bounded by the 0.75- and 3.61-kilobase pair markers; the resolution is about 30 base pairs for fragments not overexposed. 2, *Bam* digest on Schneider cell DNA, purified directly from whole cells. An identical pattern is observed with purified DNA from isolated nuclei incubated in digestion buffer without DNase I. 3–5, Partial DNase I digests on chromatin at a final DNase I concentration of 1, 2 and 4 units ml^{-1}, respectively. Only the major regions of preferential DNase I cleavage are indicated by the arrows on the hsp 70 restriction map, aligned beneath the autoradiogram. The filled bars directly under the arrows indicate the measured span of hypersensitivity, taken from the lines drawn on the autoradiogram adjacent to lane 4. 6, *Bam* plus *Xho* digest on Schneider cell DNA. The reaction did not go to completion. 7, 8, Partial DNase I digests on naked DNA. DNA at 0.4 mg ml^{-1} was digested with DNase I at 0.1 and 0.3 units ml^{-1}, respectively, for 1 min at 25 °C before secondary *Bam* cleavage. These two digestion points were picked from a series for purposes of comparison against the chromatin digests in lanes 4 and 5 because of their approximately equivalent overall extents of DNase I cleavage, monitored by gel electrophoresis and ethidium bromide staining after DNase I cleavage (data not shown). ***b***, See legend to *a* for a description of materials and methods. *Sal* was used for the secondary cleavage; the DNA fragments were sized on a 1.2% agarose gel; pPW229.1 (ref. 17), the cloned probe, is homologous to the *Bam–Sal* fragment representing approximately the 3′ half of the hsp 70 coding region. The lanes indicate: 1, *Sal* digest on Schneider cell DNA. The 2.24-kilobase pair *Sal* fragment is due to the hsp 70 gene copies at *87A*. 2, Partial DNase I digest on chromatin, as in *a*, lane 4. The hsp 70 gene copies at *87A* are reduced to the 2.24-kilobase pair *Sal* fragment or shorter fragments, so all longer fragments must be due to DNase I cleavage upstream from the hsp 70 coding regions at *87C*. The more prominently cleaved sites are indicated by the arrows over the restriction map at about 3.0, 3.8, 4.7, 6.1 and 8.0 kilobase pairs from the 3′ *sal* site. Interestingly, the preferred cuts about 3 kilobase pairs upstream from the 3′ *Sal* reference site map to a common region of homology upstream from the hsp 70 coding region; what Moran *et al.*[20] refer to as the x element. See text for discussion of the other sensitive sites.

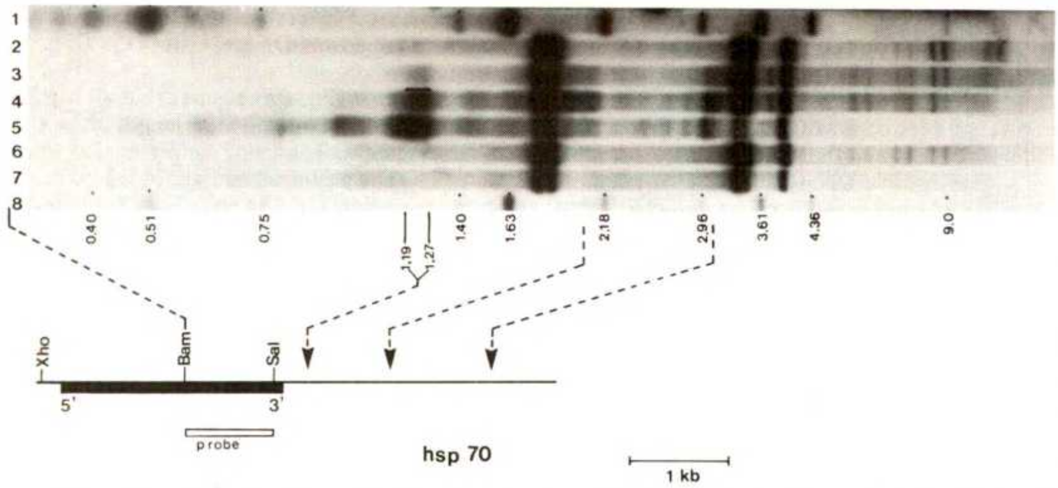

Fig. 2 Autoradiogram showing the partial DNase I cuts in Schneider cell chromatin downstream from the central *Bam* site common to all hsp 70 gene copies. *Bam*HI was used for the secondary cleavage; the DNA fragments were sized on a 1.3% agarose gel; pPW229.1 (ref. 17) was the labelled probe. The lanes indicate: 1, 8, Marker DNA fragments. 2, *Bam* digest on Schneider cell DNA. 3–5, Partial DNase I digests on chromatin at a final DNase I concentration of 1, 2 and 4 units ml^{-1}, respectively. The hypersensitive sites in lane 4 are indicated by arrows over their mapped positions on the hsp 70 restriction map at about 1.2, 2.1 and 3.1 kilobase pairs from the central *Bam* site. The second and fifth largest *Bam* fragments seen in lane 5 are not selectively lost on DNase I digestion. From densitometry of these fragments in lanes 2 and 5, they are about half as sensitive to DNase I as the other three *Bam* fragments (data not shown). See text for discussion. 6, 7, Partial DNase I digests on naked DNA, as in Fig. 1*a*, lanes 7, 8.

fragment characteristic of the *87A* hsp 70 sequences). In summary, the data indicate that a 5′ sensitive structure is present for most or all of the hsp 70 gene copies.

The other set of preferred DNase I cuts in Fig. 3*b*, lane 3, is likely to be wholly a result of the inversely repeated arrangement[25] of the hsp 70 genes at *87A*. Its interpretation is complicated by the variable length of the spacer region between these two genes[25], reflected in the *Pst* restriction pattern. Assuming that the 2.6–2.9-kilobase pair fragments are derived from the most abundant variant *Pst* segment, their display would be accounted for by the probe reacting with partial DNase I fragments from both ends of this 4.0-kilobase pair *Pst* segment. The two slightly longer and more sharply defined minor daughter fragments remain mysterious; they may be due partly to local DNase I sequence preference, shown in the control naked DNA digest (Fig. 3*b*, lane 5).

DNase I sensitivity of the active hsp 70 sequences

The 5′ sensitivity described so far is present before induction. Figure 4*a* shows the state of hsp 70 chromatin before and after 15 min of heat shock at 35 °C. Essentially the whole of the active hsp 70 coding sequence becomes sensitive to DNase I[28], but with a magnitude less than the 5′ sensitivity, which is still partially retained (Fig. 4*c*, lanes 4, 6). Curiously, some of the normally sensitive sites upstream from the hsp 70 5′ ends seem to lose definition with heat shock.

As a control, the DNA blot shown in Fig. 4*a* was immediately reprobed with another cloned segment not related to the heat shock genes, pDm4 (ref. 29), locus *62F*; the previous label was not removed. Densitometry (Fig. 4*c*), of the resulting blot in Fig. 4*b* shows that all hsp 70 restriction fragments are selectively

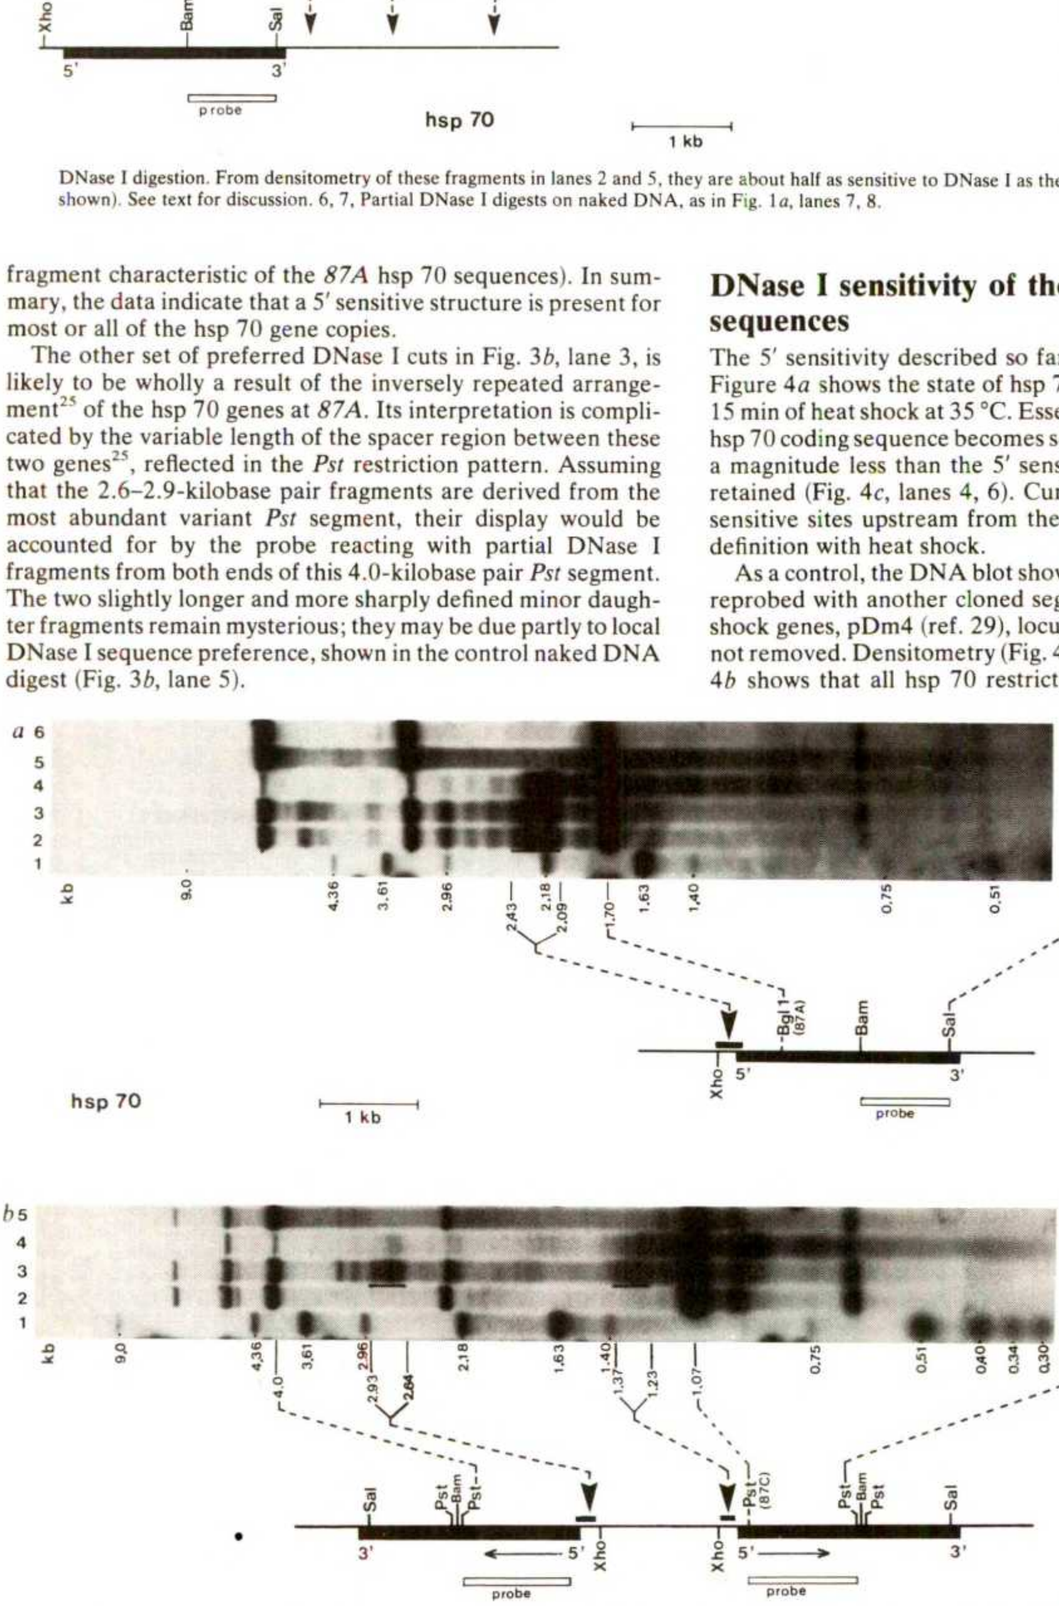

Fig. 3 *a*, Autoradiogram showing *87C* locus-specific DNase I cuts in Schneider cell chromatin upstream from the hsp 70 3′ *Sal* site. *Sal*I and *Bgl*I were used for the secondary cleavage; the DNA fragments were sized on a 1.2% agarose gel; pPW229.1 (ref. 17) was the labelled probe. The lanes indicate: 1, Marker DNA fragments. 6, *Sal* plus *Bgl*I digest on Schneider cell DNA. 2–4, Partial DNase I digests on chromatin from two separate experiments, using a final DNase I concentration of 8 units ml^{-1}, and 2 and 4 units ml^{-1}, respectively. 5, Partial DNase I digest on naked DNA, as in Fig. 1*a*, lane 7. *b*, Autoradiogram showing 87*A* locus-specific DNase I cuts in Schneider cell chromating upstream from a central *Pst* site in the hsp 70 coding region. *Pst*I was used for secondary cleavage; the DNA fragments were sized on a 1.3% agarose gel, and pPW232.1 (ref. 17) was the labelled probe. Only the restriction map for the 4.0-kilobase pair *Pst* fragment is shown, redrawn from the map of clone 122, from ref. 25. See text for discussion. The lanes indicate: 1, Marker DNA fragments. 2, *Pst* digest on Schneider cell DNA. 3, 4, Partial DNase I digests on chromatin at a final DNase I concentration of 2 and 4 units ml^{-1}, respectively. 5, Partial DNase I digest on naked DNA, as in Fig. 1*a*, lane 7.

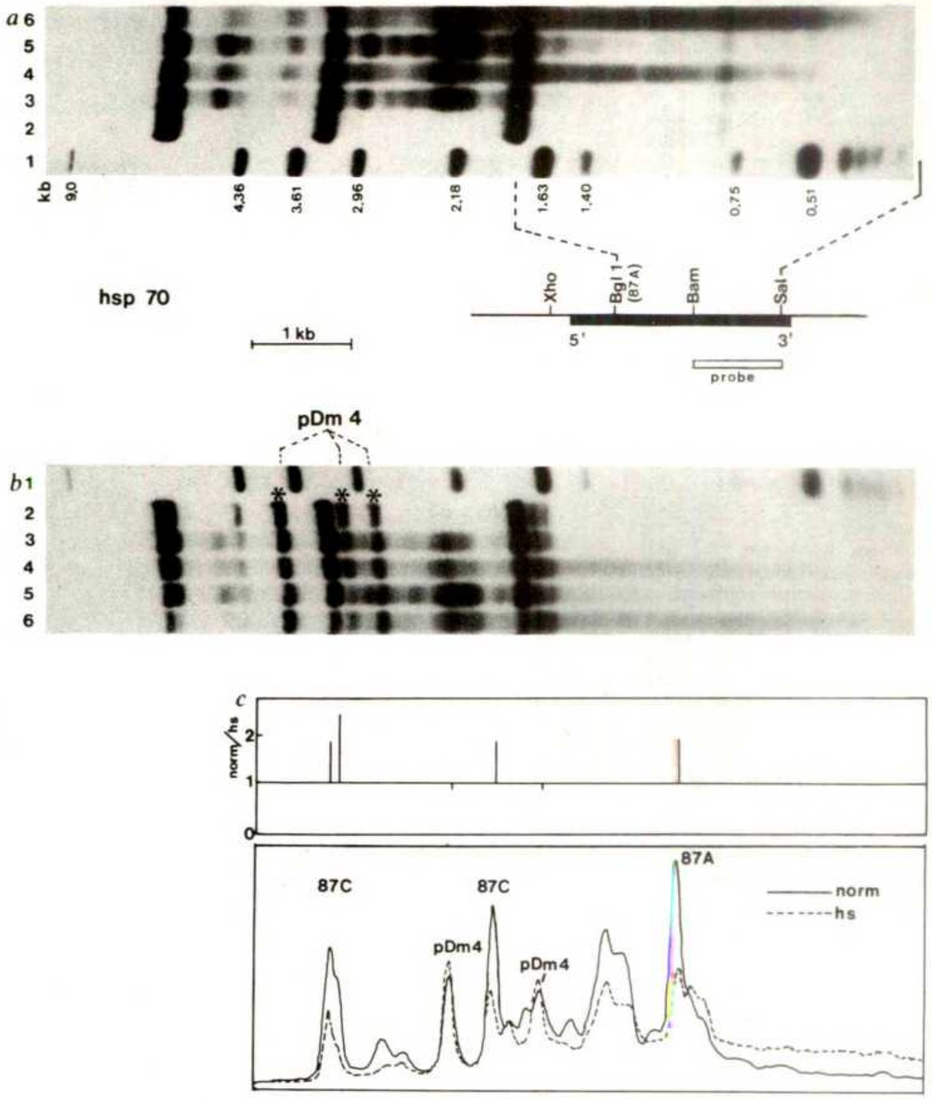

Fig. 4 *a*, Autoradiogram showing the state of hsp 70 chromatin before and after heat shock induction. *Sal*I and *Bgl*I were used for secondary cleavage; the DNA fragments were sized in a 0.8% agarose gel, and pPW229.1 (ref. 17) was the labelled probe. The lanes indicate: 1, Marker DNA fragments. 2, *Sal* plus *Bgl*I digest on Schneider cell DNA. DNA from heat-induced cells gave an identical pattern (data not shown). 3, 5, Partial DNase I digests on uninduced Schneider cell chromatin at a final DNase I concentration of 6 and 8 units ml^{-1}, respectively. 4, 6, Partial DNase I digests on chromatin in Schneider cells heat shocked at 35 °C for 15 min, as described elsewhere[28]. The two digestion points (final DNase I concentrations of 2 and 4 units ml^{-1}, respectively) were chosen out of a series for comparison against those in lanes 3 and 5 because of their close equivalence to the latter in overall extents of DNase I cleavage. They were monitored by gel electrophoresis and ethidium bromide staining (data not shown) and by reprobing this DNA blot with a cloned *Drosophila* DNA segment not involved in the heat shock response (see *b*). *b*, Autoradiogram showing the state of the chromatin at sequences homologous to pDm4 (ref. 29) before and after heat shock induction. The DNA blot in *a* was immediately reprobed with labelled pDm4 without removal of the previous label. See legend to *a* for key to the lanes. Both pDm4- and pPW299.1-specific fragments are displayed. The most prominent fragments labelled by pDm4 are indicated by asterisks. *c*, A densitometric scan of lanes 5 and 6 in *b*. The ratios of the peak heights between normal (norm) and heat shocked (hs) conditions for the pPW229.1- and two pDm4-specific fragments are schematically displayed over the scan.

digested after heat shock, whereas the pDm4 fragments are not. This indicates that most or all of the five gene copies of hsp 70 are in the active chromatin conformation, consistent with the finding that transcription occurs at both *87A* and 87*C* loci after heat shock[17,24].

Hsp 83 chromatin

The sequences for the 83,000 dalton heat shock protein, hsp 83, reside at the cytogenetic locus *63BC* (ref. 24). From a *Sal* restriction site within the single-copy coding sequence[24], partial DNase I cleavages upstream and downstream in a region extending about 40 kilobase pairs were mapped (Fig. 5*a*, *b*). A cluster of preferred cuts lie about 2.3–3.2 kilobase pairs upstream from the internal *Sal* site, and two clusters are observed starting from about 1.8 kilobase pairs downstream. No preferred cuts lie near the internal *Sal* site (data not shown). Holmgren and Meselson (manuscript in preparation) have recently mapped the 5′ terminus of a precursor to the hsp 83 mRNA to about 160 base pairs downstream from the *Eco*RI site indicated in Fig. 5. Thus, a DNase I-hypersensitive region overlaps or is very near the sequences complementary to the 5′ end of this RNA. No known genes occur at the clusters of preferred cuts downstream from the hsp 83 sequence. A low level of hsp 83 RNA is produced in normal conditions in Schneider cells (R. Holmgren and M. Meselson, in preparation). This would account for the slight sensitivity to DNase I shown by sequences homologous to RNA in Fig. 5. Previous single DNase I digests at this locus show that at 35 °C these sequences become more DNase I sensitive[30].

Nucleosome arrangement near DNase I-sensitive regions

The basic structural unit of eukaryotic chromatin is the nucleosome, composed of about 200 base pairs of DNA, of which 140 base pairs is wrapped around a core of histones (see ref. 1 for review). Analysis of the nucleosome organization of the hsp 70 genes has been complicated by the multiplicity of the gene copies. In Fig. 6, I map the partial micrococcal nuclease cuts upstream from the *Sal* site in the single-copy hsp 83 coding region; this nuclease preferentially cleaves the linker or spacer DNA between nucleosome cores.

The specific cuts made by micrococcal nuclease in chromatin (Fig. 6, lanes 2–5) reveal a striking degree of order in nucleosomal arrangement, in spite of the sequence specificity shown by the enzyme on naked DNA[31] (Fig. 6, lanes 7–9). Each of the three DNase I-hypersensitive sites near the 5′ end of the gene for hsp 83 is flanked by distinctive micrococcal nuclease cuts. The relative intensity and 100–110-base pair interval between the flanking cuts suggest a deviant structure at these regions. Further upstream, eight specific cuts are evident, beyond which nonlinear mobility of the DNA fragments and special sensitivity of some sequences make interpretation of the pattern difficult. However, the data show sufficiently that those eight nucleosomes are positioned specifically on the DNA[32–35] (but see ref. 36), and furthermore, that the spacing between adjacent nucleosome cores is irregular (suggested from previous general studies; see ref. 1), determined probably by the local DNA sequence[34]. Downstream from the region of DNase I

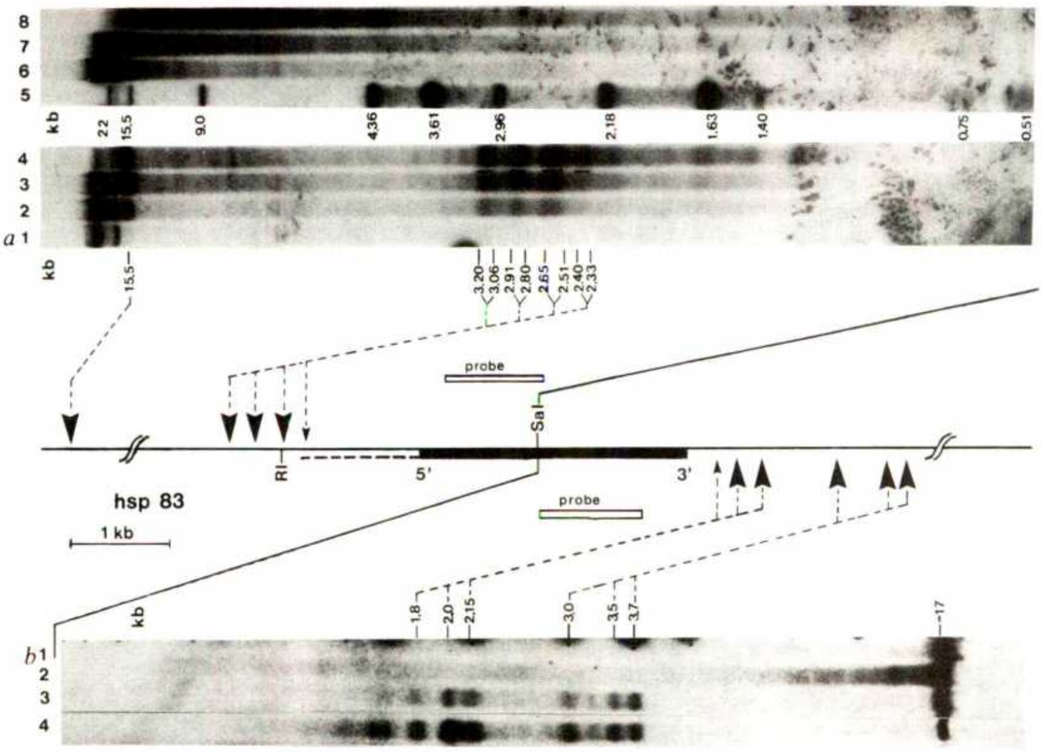

Fig. 5 *a*, Autoradiogram showing the partial DNase I cuts in Schneider cell chromatin upstream from the *Sal* site in the hsp 83 coding region (redrawn from Holmgren *et al.*[24]). The position of the *Eco*RI site was determined on a DNA blot not shown here. The filled bar depicts the location of the coding region downstream from the single intervening sequence in this split gene (R. Holmgren and M. Meselson, in preparation). *Sal*I was used for secondary cleavage; the DNA fragments (10 μg per track) were sized on a 1% agarose gel, and the labelled probe was a subclone from pPW244 (ref. 24) containing the *Pst* segment representing approximately the 5′ half of the hsp 83 coding region. This probe extends through the internal *Sal* site by about 50 base pairs (see restriction map) but the small extra segment barely, if at all, labels the cleavages downstream. The lanes indicate: 1, *Sal*I digest on Schneider cell DNA. A minor polymorphism at the external *Sal* site, or cross-reaction with a partially homologous fragment is observed. 2–4, Partial DNase I digests on chromatin at a final DNase I concentration of 0.5, 1 and 2 units ml^{-1}, respectively. Only the more prominent cleavages are noted by the arrows on the restriction map. 5, Marker DNA fragments. 6–8, Partial DNase I digests on naked DNA. DNase I at a concentration of 0.025, 0.05 and 0.1 unit ml^{-1}, respectively, was reacted with the DNA at 0.4 mg ml^{-1} in digestion buffer for 1 min at 25 °C. *b*, Autoradiogram showing the partial DNase I cuts in Schneider cell chromatin downstream from the *Sal* site in the hsp 83 coding region[24]. *Sal*I was used for secondary cleavage; the DNA fragments were sized on a 0.8% agarose gel; the cloned probe was a *Sal–Hae*II fragment gel-purified after cleavage from pPW244, representing approximately the 3′ half of the hsp 83 coding region[24]. A Du Pont Lightning Plus intensifying screen was used for this film exposure. The lanes indicate: 1, *Sal*I digest of Schneider cell DNA. 2, Partial DNase I digest of naked DNA, as in *a*, lane 6. 3, 4, Partial DNase I digests on chromatin, at a final DNase I concentration of 6 and 8 units ml^{-1}, respectively. This experiment was separate from that in *a*, lanes 3, 4, but the overall extents of cleavage are comparable. Only the more prominent cleavages are indicated by arrows on the restriction map.

hypersensitivity, the micrococcal nuclease cuts are less discrete, except for a cut 1.2 kilobase pairs from the *Sal* reference site. Such disperse cuts[28,30] would be expected for the slightly active hsp 83 gene at 25 °C. On further activation at 35 °C, the fragment pattern in Fig. 6 remains essentially similar (data not shown).

Comparison of hypersensitivity in cultured cells and embryos

Figure 7 shows a comparison of hypersensitive sites in chromatin from Schneider line 2 cells and from 6–18-h *D. melanogaster* (Oregon R) embryos. The 5′ sensitivity in the hsp 70 and hsp 83 genes (denoted by asterisks in Fig. 7*a*, *b*) is essentially the same for both materials, in spite of the populational polymorphism in external restriction sites shown largely by the Oregon R DNA. Intriguingly, several randomly selected regions not involved in the heat shock response [pDm4 (ref. 29), locus *62F*, and pPW100 (ref. 2), loci *57BC*, *83C*] reveal sensitive sites (denoted by asterisks in Fig. 7*c*, *d*) in the cell line, but not in Oregon R embryos. This result suggests that some hypersensitive sites in chromatin are not omnipresent, but perhaps limited to certain cell types or to particular stages in development.

An element for recognition?

The two *Drosophila* genes examined at three chromosomal loci exhibit a DNase I-sensitive chromatin structure at the 5′

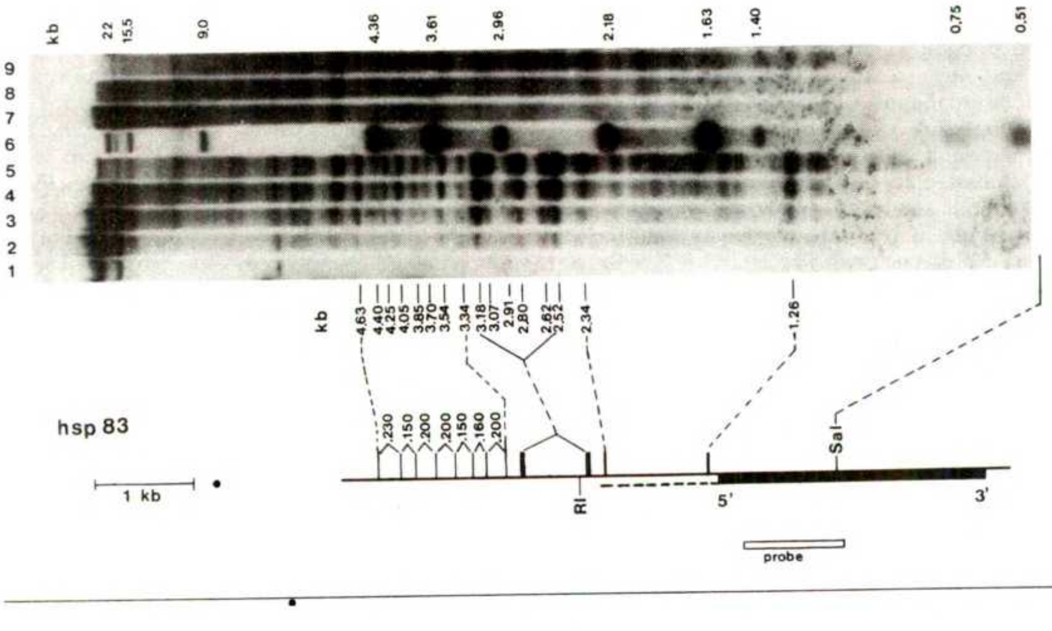

Fig. 6 Autoradiogram showing the partial micrococcal nuclease cuts in Schneider cell chromatin upstream from the *Sal* site in the hsp 83 coding region; produced as in Fig. 5*a*. The lanes indicate: 1, *Sal*I digest on Schneider cell DNA. 2–5, Partial micrococcal nuclease (Worthington) digests on chromatin at a final nuclease concentration of 0.75, 1.5, 3.0, 6.0 units ml^{-1}, respectively, at 25 °C for 3 min. 6, Marker DNA fragments. 7–9, Partial micrococcal nuclease digests on naked DNA at a final nuclease concentration of 1.25, 2.5 and 5 units ml^{-1}, respectively, at 25 °C for 1 min.

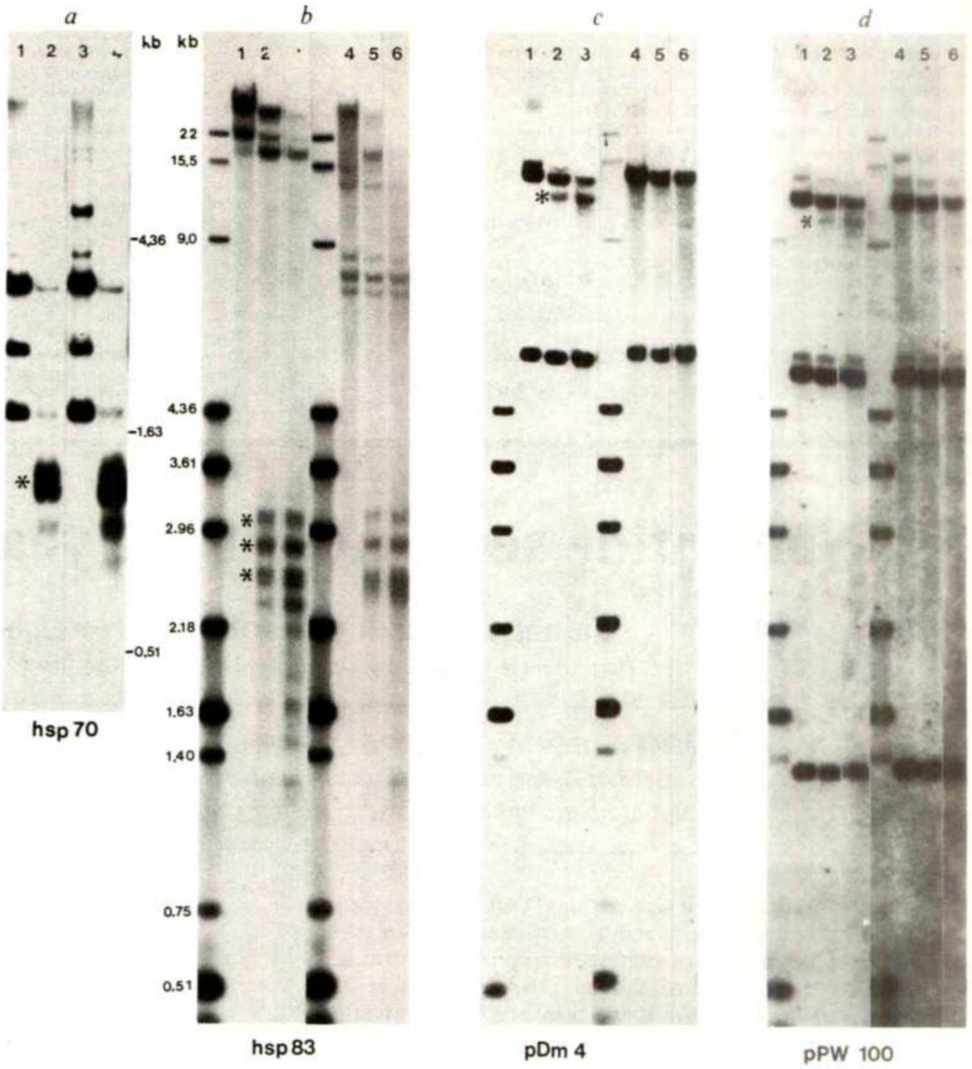

Fig. 7 Autoradiographic comparison of DNase I-hypersensitive sites at chromosomal regions homologous to four cloned segments, between Oregon R embryos and Schneider line 2 cells. Nuclei from 6–18-h embryos were isolated as described elsewhere[2]. The rest of the experiment was essentially as described in Fig. 1 legend. *a*, The hsp 70 region. DNA fragments were sized on a 1.1% agarose gel; *Bam*HI was used for secondary cleavage and the blot was probed with pPW232.1 (ref. 17). The lanes indicate: 1, 3, *Bam*HI digest of Schneider cell and Oregon R DNA, respectively. 2, 4, Partial DNase I digests of Schneider cell (8 units ml^{-1}) and Oregon R (6 units ml^{-1}) chromatin, respectively. ***b***, The hsp 83 region. DNA fragments were sized on a 0.8% agarose gel; *Sal*I was used for secondary cleavage; the blot was probed as in Fig. 5*a*. The lanes indicate: 1, 4, *Sal*I digest of Schneider cell and Oregon R DNA respectively. 2, 3, Partial DNase I digests (6 and 8 units ml^{-1}, respectively) of Schneider cell chromatin. 5, 6, Partial DNase I digests (2 units ml^{-1} in two separate experiments) of Oregon R chromatin. ***c***, ***b*** was reprobed with labelled pDm4 (ref. 34), without removal of the previous label. ***d***, ***c*** was reprobed with labelled pPW100 (ref. 2), without removal of the previous labels.

terminus of the coding sequence before activation. This 5′ sensitivity may reflect a specially exposed or structurally modified stretch of eukaryotic DNA for recognition by regulatory molecules. The other sites adjacent to the hsp coding regions may be indicative of the 5′ termini of unknown or yet unmapped transcription units, as in the repeated sequence elements at locus *87C* (refs 17, 27), or they may reflect other chromosomal functions. The findings documented here, although unique to eukaryotic gene structure, have a precedent in the structure of viral chromatin; the origin of replication (and transcription) of SV40 and polyoma virus has been shown to be in a preferentially nuclease-susceptible conformation[37–39].

What might be the basis of this unique sensitivity? A special DNA sequence at these regions could bind other macromolecules such as specific proteins that cause the sensitivity and align neighbouring nucleosomes specifically on the DNA, or the sequence may possess a peculiar base order that renders it sensitive when the DNA in the region is coiled and supercoiled in nucleosomes and higher order structures. The molecular basis notwithstanding, a new regulatory feature in relation to prokaryotic models of gene control appears: an element for recognition at the 5′ end of a gene based on an exposed chromatin structure that defines its potential for activation, this potential being realized on induction, perhaps according to the bacterial paradigm of specific activators and repressors. Such a two-stage model of eukaryotic gene regulation has some implications for developmental biology. Specifically, the hypersensitive sites observed in tissue culture cell chromatin but not in embryonic chromatin might suggest that a developmentally regulated gene (as opposed to the heat shock genes) possess a 5′ exposed structure only in the appropriate cell type or developmental stage. Sites of DNase I hypersensitivity have recently been observed in the chicken[40], and Weintraub and colleagues (personal communication) have detected tissue-specific hypersensitive sites for the chick globin gene. Will the various developmental systems currently amenable to molecular analysis yield data consistent with this view of gene regulation?

I thank Walter Gilbert for a crucial discussion on mapping hypersensitive sites and for suggesting the particular form of end-labelling used here. I also thank Robert Holmgren, Rick Morimoto and Matthew Meselson for continual communication, discussion and permission to quote research data before publication, Sarah Elgin, in whose laboratory part of the work with *Drosophila* embryos was performed, R. Holmgren, R. Morimoto, P. Bingham, J. Jack and M. Meselson for gifts of cloned DNA, many colleagues for discussions, Harold Weintraub for a prepublication manuscript, the Harvard Society of Fellows for a Junior Fellowship and W. Gilbert for critical comments on this manuscript, research facilities and support. This work was funded by NIH grant GM21514-06 to W. Gilbert.

Nucleotide sequence of the yeast plasmid

James L. Hartley & John E. Donelson
Department of Biochemistry, University of Iowa, Iowa City, Iowa 52242

The nucleotide sequence of the yeast DNA plasmid (2μ circle) from Saccharomyces cerevisiae *strain A364A D5 has been determined. The plasmid contains 6,318 base pairs, including two identical inverted repeats of 599 base pairs. Possible functions are suggested, and attributes of an improved vector for cloning foreign DNAs in yeast are discussed.*

THE yeast plasmid (2μ circle) is a circular DNA molecule with a contour length of about 2 μm (about 6 kilobases) that is present in about 70 copies per cell of most yeast strains and constitutes about 3% of the total yeast cellular DNA[1-3]. Its most distinguishing structural feature is the presence of two inverted repeat (IR) sequences of about 600 base pairs that are separated by a large unique region (about 2.7 kilobases) and a small unique region (about 2.3 kilobases)[3-8]. In yeast cells reciprocal recombination between the inverted repeats produces a mixture of two sequence forms (A and B) of the yeast plasmid that differ in the orientation of one unique region relative to the other[3-9]. When the yeast plasmid is cloned in *Escherichia coli* using recombinant DNA techniques this reciprocal recombination does not occur.

Two observations suggest that the yeast plasmid is located, at least some of the time, in the yeast nucleus. First, the plasmid can be isolated in a condensed nucleosome form with which histones are associated, similar to yeast nuclear chromatin[10,11]. Second, its replication occurs only during the S phase, each molecule is replicated only once, and replication is regulated by the same genes that control the initiation and completion of nuclear DNA replication[12,13]. There is no evidence that the yeast plasmid is capable of integrating into chromosomal DNA.

The biological function of the yeast plasmid is not known. However, portions of the plasmid are transcribed *in vivo* into polyadenylated mRNAs which have been mapped relative to restriction enzyme fragments of the DNA[14]. The poly(A)-containing RNAs direct the synthesis of protein in *in vitro* translation experiments. Plasmid-specific proteins have been detected when the plasmid has been introduced into *E. coli* minicell-producing strains[3,15,16]. Yeast strains have been isolated which do not have any plasmid sequences present, but possess normal growth properties in laboratory conditions[17,18].

Recently the yeast plasmid has acquired increased significance as an efficient vector for yeast transformation[19-24]. Experiments with chimaeric DNAs containing all or part of the yeast plasmid indicate that maximum transformation stability is obtained when one of the two inverted repeats is present[25], suggesting that the replication origin of the plasmid may be within this sequence. Thus the yeast plasmid is an attractive system for the study of eukaryotic gene control and chromosomal replication.

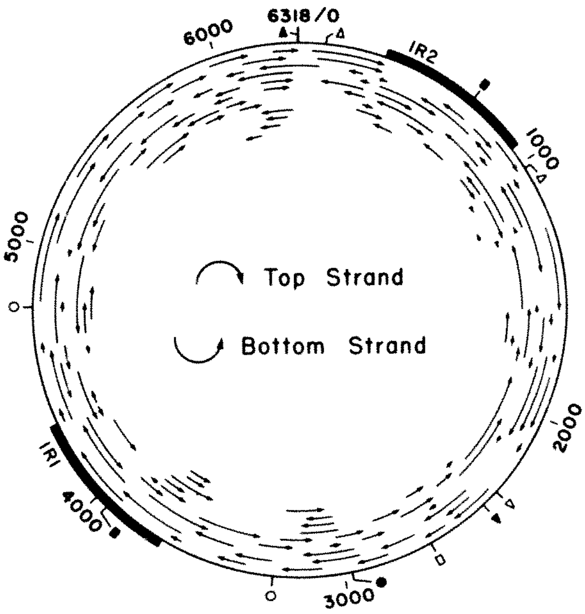

Fig. 1 Map of the yeast plasmid (form A) and the sub-sequences used to derive the sequence. Arrows indicate the location and extent of each subsequence, clockwise for the top strand, counter-clockwise for the bottom strand. Thick lines represent the inverted repeats IR1 and IR2. Restriction enzyme cleavage sites shown are *Eco*RI (▲), *Hin*dIII (△), *Xba*I (■), *Pst*I (□), *Hpa*I (●) and *Ava*I (○).

We report here the sequence of the yeast plasmid. The boundaries of the inverted repeats are defined and potential protein coding regions are identified. The location of the origin of replication and the function of one of the protein coding regions are discussed. Improvements in the cloning of foreign DNAs in yeast are suggested.

0028–0836/80/350860—06$01.00

Source of the sequence

For the sequence determinations, the yeast plasmid was recovered from the recombinant plasmid p82-6B. This is a plasmid which was found in a library of random yeast strain A364A D5 DNA fragments cloned in the *E. coli* plasmid pMB9 (ref. 26) by the poly(dA)·poly(T) tailing technique[27]. It was initially identified by screening individual colonies in the library for the presence of yeast plasmid sequences by the Grunstein and Hogness procedure[28] and subsequently shown to contain about 1.5 copies of the yeast plasmid (E. Gubbins, K. Chen and J.E.D., unpublished data). The 1.5 copies probably arose from a yeast plasmid dimer that was tailed with poly(dA) at random internal single-strand nicks or double-strand scissions during the poly(dA) addition such that part of the dimeric sequence was removed during the cloning procedure.

The circular yeast plasmid (form A) contains two *Eco*RI sites, one in each of the two unique regions, such that *Eco*RI digestion generates two fragments of 3.9 and 2.4 kilobases (ref. 5). The initial sequencing strategy was to determine the sequence of these two fragments individually and then identify and sequence restriction fragments which would overlap the two *Eco*RI sites. As the sequencing progressed, it became convenient to subclone a 4.1 kilobase *Hin*dIII fragment that contained the entire 3.9-kilobase *Eco*RI fragment and hence possessed an *Eco*RI site near each end. Thus the sequence of the 2.4-kilobase *Eco*RI fragment was obtained using the fragment recovered directly from p82-6B, and the rest of the sequence was largely obtained from the cloned 4.1-kilobase *Hin*dIII fragment subcloned in pBR322. Both plasmids were completely stable when maintained in the *recA E. coli* strain HB101.

The sequence of the plasmid was obtained by collecting sequence data from as many 3′-terminally labelled *Hpa*II-, *Sau*3AI-, *Taq*I-, and *Hin*fI-fragments as could be strand separated[29] or digested with a second restriction enzyme to separate the labelled ends. In practice, about three-quarters of the fragments could be separated into two distinct strands on a strand separation gel. Overlapping sub-sequences were identified by computer analysis[30] or by inspection. Restriction sites found during this process were used for subsequent sequencing runs to fill gaps or to increase coverage of both strands. The individual sequences (about 140 in all) were each read at least three times. All changes and corrections were made on a computer file to minimize clerical error.

Features of the sequence

Figure 1 shows a map of the restriction fragments used to obtain the sequence data and Fig. 2 shows the complete sequence. The inverted repeats are designated IR1 and IR2 according to the nomenclature of Hollenberg[16]. Of the 6,318 base pairs, 61% are dA+dT, close to the dA+dT content of yeast chromosomal DNA (about 64%) and much lower than the value for mitochondrial DNA of 79% (ref. 3). The sequence is numbered taking nucleotide 1 as the G of the *Eco*RI site nearest IR2. The inverted repeats are 599 base pairs long, extending from 341 through to 939 (IR2) and from 3,714 to 4,312 (IR1). The unique regions are therefore 2,774 and 2,346 base pairs long. The sequence contains previously mapped sites for the restriction enzymes *Eco*RI (1; 2,407), *Pst*I (2,652), *Hin*dIII (105; 1,017; 2,331), *Hin*cII (217; 2,964), *Hpa*I (2,964; subset of *Hin*cII sites), *Ava*I (3,258; 4,764) and *Xba*I (703; 3,945). In addition, sites for *Pvu*I (1,755; 2,729), *Pvu*II (2,029; 2,133), *Bal*I (264), *Bcl*I (304) and *Cla*I (6,284) are predicted. Sites for the enzymes *Bam*HI, *Kpn*I, *Sal*I, *Sst*I, *Sst*II, *Xho*I, *Bgl*I and *Bgl*II do not appear in the sequence. A total of 87% of the plasmid was sequenced on both strands and at least one overlap was obtained for all restriction sites used in sequencing. The sequence of the region 1–1,022 has been reported previously by another laboratory[32] and differs from that presented here at eight positions.

The inverted repeats are the most prominent feature of the plasmid. Their sequences were determined separately and found to be completely homologous. The IR boundaries are not marked by any striking symmetry features. However, a remarkable concentration of symmetry elements occurs near the centres of the IRs, at 640–761 and 3,892–4,013. In these 122-base pair regions are found a 13-base pair direct repeat and a dyad symmetry (abc—c′b′a′) of 16 base pairs, both contained within an imperfect dyad symmetry of 49 base pairs. These regions can be drawn as two alternative stem and loop structures (Fig. 3) which would have thermodynamic stabilities of the order of −50 kcal mol^{-1} when calculated by rules derived from oligoribonucleotide studies[33]. The longest run of alternating purines/pyrimidines found in the plasmid is located at 564–581 and 4,072–4,089. It has been proposed that these might form left-handed helical structures *in vivo*[34]. Possible implications for these features are discussed below.

A second concentration of symmetry elements is found in the large unique region. About 5.5 copies of a sequence of 62–63 base pairs arranged as direct tandem repeats are found between positions 2,960 and 3,302 (Fig. 2). Five repeats, 2,987–3,048, 3,049–3,111, 3,112–3,173, 3,174–3,235 and 3,236–3,297, share 78–97% (average 90%) homology with a consensus sequence

5′-TTTTTPuPyAGAACAAAAATGCAACGCGAGAGCG

CTAATTTT$\frac{\text{A}}{\text{T}}$CAAACAAAGAATCTGAGCTTCA-3′.

Two sets of two of these repeats, 2,975–3,098 and 3,099–3,223, can be aligned to give tandem copies of 124 base pairs which share 97% homology. In addition, this area is rich in dyad symmetries, including a perfect dyad at 2,987–3,002 and 3,236–3,251. The significance of these symmetries is not known. They appear to be dispensible to the plasmid, however, since deletions in this area are seen in natural isolates[5]. No large alphabetic palindromes (abc—cba) were found in the yeast plasmid.

The sequence was examined for potential protein-coding regions, that is, regions starting with an ATG codon and terminating with any of the stop codons. Three such long open translation reading frames were found, ‘Able’ (423 codons, molecular weight (MW) 48,625; 5,570–520; top strand; reading frame 2), ‘Baker’ (373 codons, 43,235 MW; 2,008–890; bottom strand; reading frame 3) and ‘Charlie’ (296 codons, MW 33,199; 5,198–4,311; bottom strand; reading frame 2) as shown in Fig. 4. All three coding regions terminate within inverted repeats, although ‘Baker’ ends just inside the IR1 boundary. ‘Able’ terminates with TAA, ‘Baker’ with TAG and ‘Charlie’ with TGA. Proteins of MW 20,000 and less could be encoded by other regions. Overlapping coding regions such as are seen in several circular viral genomes[35–37] are not found in the yeast plasmid.

Homology between the yeast plasmid and the bacterial cloning vector pBR322 has been reported[38] on the basis of hybridization experiments. Computer comparisons of the two DNAs under various homology requirements did not reveal any extensive identities. The longest perfect homology is 13 base pairs.

Discussion

The sequence of the yeast plasmid can be inspected from the standpoint of (1) its utilization as a vector for cloning foreign DNA fragments, and (2) its existence as a eukaryotic ‘minichromosome’ organized by histones into nucleosomes, and containing an origin of replication and one or more genes with attendant regulatory elements. Two conclusions regarding the plasmid's *in vivo* functions can be drawn from the sequence and from the work of other investigators: the location of the origin of replication and the identification of the gene product which mediates the interconversion of forms A and B. Both conclusions concern the use of the yeast plasmid as a cloning vehicle.

Several lines of evidence support the suggestion that the origin of replication of the yeast plasmid is near the *Xba*I site in IR1 (position 3,945). First, the regions surrounding the *Xba*I

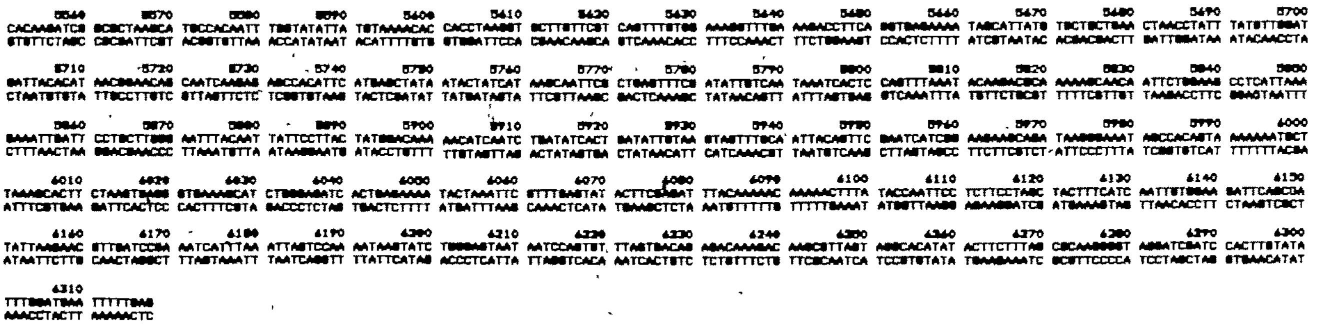

Fig. 2 Sequence of the yeast plasmid. Boundaries of IR1 (3,714–4,312) and IR2 (341–939) are shown. Symmetry elements are identified by number: 1, regions which can be drawn as stem and loop structures (Fig. 3); 2, longest dyad symmetries (abc–c'b'a') in the sequence; 3, perfect direct repeats; 4, direct tandem repeats of 62–63 bp, or portions thereof; 5, dyad symmetries associated with these repeats. Sequences were determined by the method of Maxam and Gilbert[29]. Restriction fragments were labelled using repair synthesis of DNA polymerase I (10 units of enzyme in 100 μl of 70 mM Tris–HCl, *p*H 8.0, 70 mM NaCl, 10 mM $MgCl_2$, incubated at 4 °C for 10 min with [α-^{32}P]dNTP and 5–15 pmol of each restriction fragment). Sequencing gels were 0.4 mm thick, 6% (90×30 cm) or 20% (43×43 cm) polyacrylamide/urea gels run warm[42].

sites in both IR1 and IR2 contain extensive elements of symmetry which can be drawn as large secondary structures (Fig. 3). Such structures are highly significant statistically (data not shown) and have been found near the origins of replication of many genomes[39–41]. Second, J. Broach and J. Hicks (J. Broach, personal communication) have cloned various pieces of the yeast plasmid and shown that vectors which contain IR1 can successfully transform [cir°] yeast (strains which lack endogenous 2μ circles), whereas vectors containing only IR2 cannot. Third, deletion mapping by Broach and Hicks indicates that about 100 base pairs of the large unique region adjacent to IR1 is an essential part of the origin. Since IR1 and IR2 are precisely identical, the involvement of this unique segment presumably determines which inverted repeat will be used for the origin. Examination of translation reading frames of the plasmid (Fig. 4) shows that this is the only segment next to an inverted repeat that is not part of a potential protein coding region. It is possible that this segment (from around position 3,600 to within IR1) is transcribed to yield the RNA primer for initiation of replication. Since electron microscopic examination of replicating yeast plasmid molecules suggests that a second origin, presumably within IR2, is used at least some of the time (C. Newlon, personal communication), this primer may contain some inverted repeat component.

The yeast plasmid sequence contains three regions which could code for proteins of MWs 33,000, 43,000 and 48,000 (Fig. 4). The location of these are in general agreement with the results of previous studies[14–16]. Observations of Guerineau and co-workers[22,23] suggest a function for one of these regions. They constructed vectors containing the entire yeast plasmid in which the coding region 'Able' was interrupted by the insertion of a piece of bacterial DNA. Such vectors successfully transformed [cir°] yeast, but no recombination between the inverted repeats was seen, that is, cells transformed with form A vectors maintained the chimaeric DNAs as form A for long periods[23]. In contrast, [cir⁺] strains (which contain endogenous yeast plasmid) rapidly interconverted forms A and B, such that only a mixture of the two forms was detected[22]. Broach and Hicks have made similar observations (J. Broach, personal communication). A diffusible product of coding region 'Able' is thus implicated as mediating the form interconversion process. This gene product and its substrate, the inverted repeats of the 2μ circle, represent

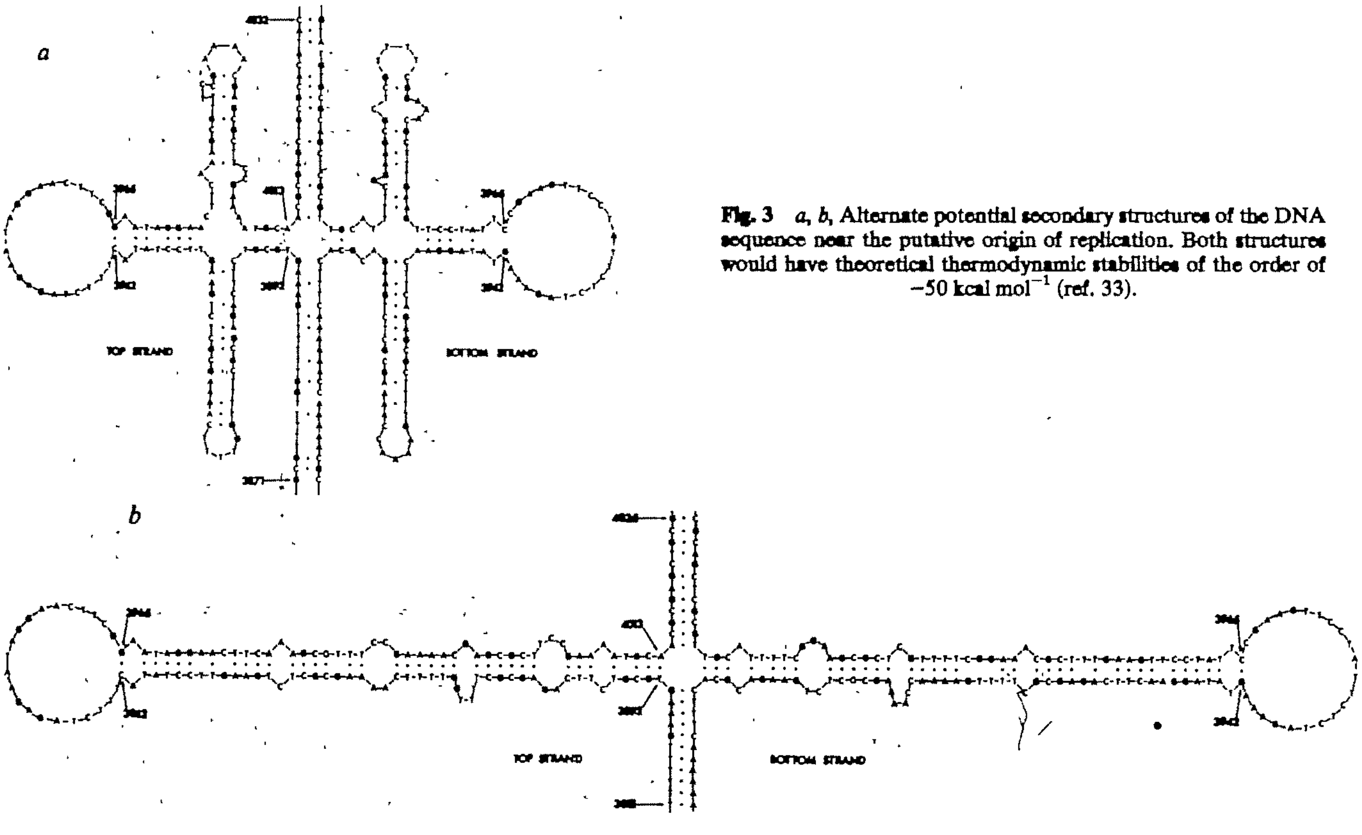

Fig. 3 *a*, *b*, Alternate potential secondary structures of the DNA sequence near the putative origin of replication. Both structures would have theoretical thermodynamic stabilities of the order of −50 kcal mol^{-1} (ref. 33).

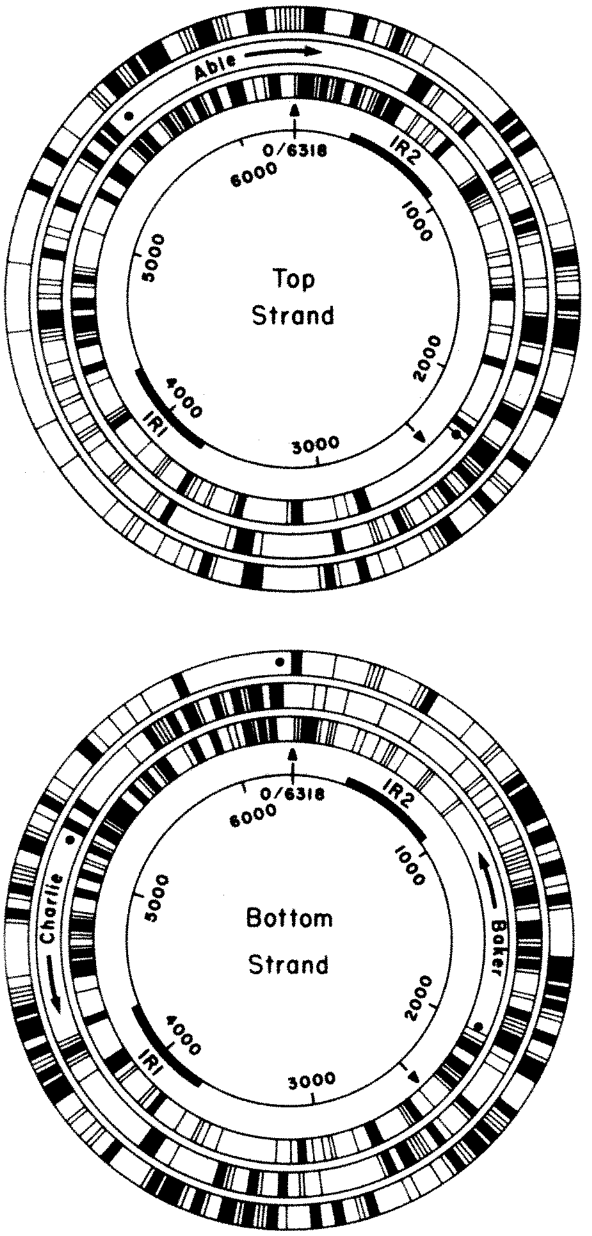

Fig. 4 Approximate positions of stop codons in the different reading frames of the yeast plasmid. TAA codons are represented by blocks (■), while TAG and TGA codons are shown as lines. Start codon positions for 'Able' and 'Baker', and 'Charlie' and two other large open reading frames are indicated by dots (●). The outer, middle and inner rings correspond to reading frames 1, 2 and 3, respectively. For the top strand reading frames 1, 2 and 3 begin with the codons GAA (positions 1–3), AAT (2–4) and ATT (3–5), while for the bottom strand reading frames 1, 2 and 3 begin with codons CTC (6,318–6,316), TCA (6,317–6,315) and CAA (6,316–6,314). Triangles indicate *Eco*RI cleavage sites.

a unique opportunity to study eukaryotic recombination at the molecular level.

A second observation of Gerbaud *et al.*[22] has implications for the construction of yeast transformation vectors. They determined the levels of expression of a yeast gene (*ura3*) inserted at two different points in their vector. It was found that the *ura3* activity per transformed cell was three times higher when the gene was inserted at the *Eco*RI site within coding region 'Able' than when it was carried within the bacterial plasmid segment of the vector. Since the 'Able' product is apparently actively expressed in yeast (above) it is reasonable to suppose that the higher expression was due to efficient transcription utilizing the 'Able' promoter or other transcriptional signals.

In view of these considerations, some attributes of a vector–host system for the transformation of yeast may be suggested. The host should be [cir^{+}] since high transformation frequency and reasonable stability are obtained[19,22]. The vector should contain the origin of replication but should not contain the entire yeast plasmid, since Toh-e *et al.* have shown that increased stability results from this arrangement when the host is [cir^{+}] (ref. 25). The vector should also contain coding region 'Able' for the insertion of foreign DNA to be expressed in the yeast host. The sequence indicates that the small *Ava*I fragment of the form B plasmid would have all these properties. This 2,945 base pair fragment would contain the origin of replication and the entire 'Able' coding region, as well as segments flanking both ends of 'Able'. Within the 'Able' sector there are single sites for the restriction enzymes *Eco*RI, *Hin*dIII, *Bal*I, *Bcl*I and *Cla*I which might be suitable for expression of foreign genes. In combination with a suitable selection marker(s) the resultant plasmid should possess improved properties for cloning foreign DNAs in yeast.

The sequence of the yeast plasmid may improve the usefulness of yeast for DNA cloning experiments. In addition, the sequence provides a starting point for further investigations of such functions as replication, recombination and gene control in a well characterized eukaryotic genetic system.

Copies of the sequence with a complete listing of all restriction sites are available on request.

We thank B. Nichols and P. Moynihan for help in sequencing experiments, T. Gregori for technical assistance, P. Gyllstrom for computer help, L. Korn for his computer program, J. Broach for communicating results before publication, and C. Newlon for critical readings of the manuscript. This work was supported by grant GM21696. Recombinant DNA experiments adhered to NIH guidelines (P2+EK1).

Addendum from J. Hindley, T. C. Elleman & G. A. Phear

Department of Biochemistry, University of Bristol,
Bristol BS8 1TD, UK

The accompanying article by Hartley and Donelson presents the sequence of the type A yeast plasmid recovered from *Saccharomyces cerevisiae* strain A364A D5 by cloning into pMB9. We have independently determined about 63% of the type A plasmid sequence from pJDB 71 (ref. 1; a hybrid constructed by inserting the 2μ plasmid from *S. cerevisiae* strain DR19/8T into the *Eco*RI site of pMB9), using a different approach and have compared the two sets of data. This is of interest for two reasons. First, Hartley and Donelson used the Maxam–Gilbert procedure whereas we have relied entirely on the dideoxynucleotide chain termination procedure using single-stranded templates generated by cloning restriction fragments into linearized phage M13mp2 RF-DNA and subsequently isolating the single-stranded recombinant phages[2]. The sequence comparison was made over a total of 4,004 nucleotides comprising sequences totalling 3,053 nucleotides from the larger and 951 nucleotides from the smaller unique regions of the plasmid. Both sets of data were in complete agreement. This result therefore completely validates the reliability of the newer sequencing procedures used in this work. Neither during propagation of the hybrid plasmid nor in the subsequent M13 cloning and primed syntheses is there any evidence of rearrangements or deletions of sequences.

Second, the data imply that the unique regions in the plasmid, bounded by the inverted repeats, are fully conserved in two unrelated strains of yeast. This identity includes a sequence of 863 nucleotides extending from the *Eco*RI site at position 2,407 to position 3,270. This region contains a set of 6.5 direct tandem repeats of 62–63 residues and in two other plasmid isolates (Scp 2 and Scp 3)[3], which contain deletions of about 130 and 220 base pairs respectively, the mapping data puts both these deletions within the region of tandemly repeated sequences. The available data therefore suggests that, apart from this deletable region, the unique regions of the plasmid are strongly conserved. Differences are found however when the inverted repeat regions are compared. All these seem to be single base changes and occur in regions outside the possible reading frames suggested by Hartley and Donelson (see ref. 4).

The twin quasars 0957+561 A,B, separated by only 6 arc s on the sky, have been shown to have nearly identical redshifts ($z_e \simeq 1.41$, $z_a \simeq 1.39$) by Walsh *et al.*[1], who suggested that they were the double image of a single object, split by the gravitational refraction of an unseen massive intervening object. Further optical spectroscopy[2] has confirmed the remarkable similarities of the emission and absorption spectra of the two quasars, and strengthened the case for a gravitational lens model. Radio maps at 6 cm made with the Cambridge 5-km telescope[3] and with the VLA[4] showed that, in addition to two unresolved sources coincident with the optical quasars, there were extended regions of radio emission, apparently associated with the north (A) quasar which greatly complicated the gravitational lens hypothesis. We now report a full 12-h synthesis made at the VLA at 6-cm wavelength[5] which confirmed the earlier maps and showed additional features at lower flux levels. In particular, this map revealed two small radio 'jets', one close to each of the quasars. The absence of corresponding second images of either of these jets near the other quasar was used to rule out models in which the gravitator was located near the midpoint of the line between A and B (ref. 5).

The lens hypothesis was boosted by the discovery[6,7] that the field of 0957+561 was overlaid by a rich cluster of galaxies at $z \simeq 0.39$. Furthermore, the nucleus of the brightest member of the cluster (designated G1) lay ~1 arc s north of the B quasar, very near the position of the B radio jet. Young *et al.*[7] presented models for gravitational imaging of the underlying object quasar, invoking both the properties of an extended gravitator (G1) and the existence of an additional source of bending (the cluster as a whole) and were able to account for most of the observed features. The B jet, however, remained difficult to understand as part of the gravitational image of the quasar and its extended radio emission. The present results clarify the nature of the B radio jet, and further strengthen the gravitational lens interpretation of the double quasar.

The observations consist of a full 12-h synthesis made at 6 cm on the Very Large Array of the National Radio Astronomy Observatory during 22–23 February 1980. A total of 22 antennas were functioning, with baselines ranging between 45 m and 22.4 km. Observing conditions were ideal, and the data were of significantly higher quality than those obtained in October 1979[5]. The performance of the array was monitored by frequent observations of the nearby point source 1031+567 and the flux scale was set by assuming the 4,885 MHz flux density of 3C286 to be 7.41 Jy. Editing, gridding, and Fourier transformation of the data were carried out using the standard VLA data reduction procedures. The resulting 'dirty' map was processed with the modified CLEAN algorithm of Clark[8]. The clean map, shown in Fig. 1, has a resolution of 0.66 by 0.41 arc s FWHM, and a dynamic range (map peak/r.m.s. noise) of ~200 : 1.

The significant feature of Fig. 1 is the resolution of the B jet into a point source (which we now denote G) of 2.3 ± 0.2 mJy flux, located 1.06 ± 0.02 arc s N and 0.15 ± 0.02 arc s E of the B quasar. The position and flux of G are consistent with our previous observations[5]. An optical photograph of the field, made on the University of Hawaii 2.2-m telescope by Stockton[9], puts the optical nucleus of G1 0.99 ± 0.03 arc s N and 0.19 ± 0.03 arc s E of the B quasar, or 0.08 ± 0.05 arc s SE of the radio position. Thus, the optical nucleus of G1 and the radio source G are coincident within the small uncertainties. The simplest interpretation is that G is a compact radio source in the nucleus of G1 and is not part of the gravitational image. If this is so, the 5 GHz power of G is $P_{5000} = 1.1 \times 10^{-23}$ WHz^{-1} sr^{-1} ($q_0 = 1/2$, $H_0 = 50$ km s^{-1} Mpc^{-1}, spectral index assumed to be 0.25). Although little is known about the compact radio structure of cD galaxies selected without regard for their low-frequency properties, G is comparable to the central components of 3CR radio galaxies[10]. Although there is at least one other interpretation (see below), the fact that G is not significantly north of the nucleus of G1 removes the last strong objection to the gravitational lens explanation of 0957+561.

0028–0836/80/350865—02$01.00

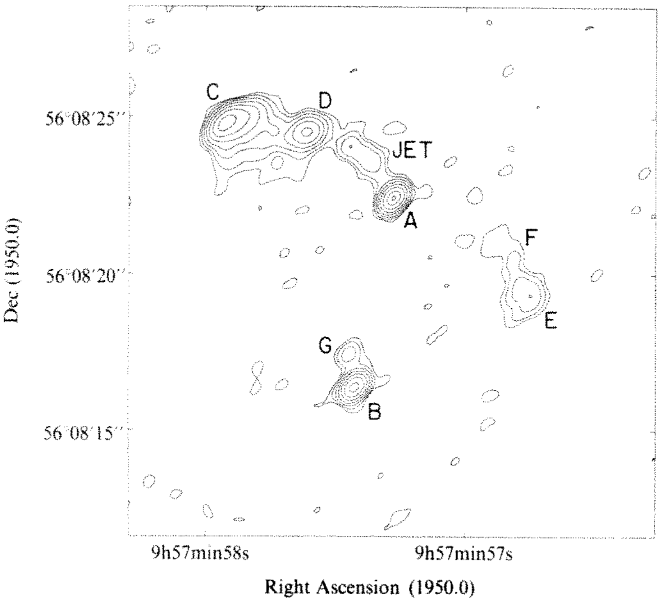

Fig. 1 The double quasar 0957+561 A,B, mapped at λ6 cm by the VLA on 22–23 February 1980. The point sources A and B are coincident with the optical quasars, and the small source G lies very close to the nucleus of the intervening galaxy G1 which is apparently forming the double image. The contour levels are 1, 2, 4, 8, 16, 32, 64 and 95% of the peak flux of 35.9 mJy.

We now consider how well the details of the gravitational imaging are understood, what further data may be needed, and what more can be learned from the double quasar. The important features to be accounted for are: (1) the near-equality of the fluxes of A and B despite their very different separations from G1; (2) the absence of second images of any of the extended radio emission; (3) the lack of resolution of the B image by the VLA or by existing VLBI observations; and (4) the fact that the nucleus of G1 lies slightly (0.4 arc s) off the line between A and B. Young *et al.*[7] have suggested that the first two points are consequences of the existence of a caustic for an extended gravitational lens. In their picture, the B image is formed very close to the caustic and is, therefore, anomalously amplified, while the extended emission lies beyond the caustic so no second images are formed. This model has the additional consequence that the B image must itself be multiple. The VLBI observations of Porcas *et al.*[11] and Haschick *et al.*[12] show the existence of compact components in both A and B, but have insufficient dynamic range to give useful details of their brightness distributions. The high dynamic range of the observations presented here enable us to constrain a possible double nature of B. There is no evidence for a broadening of B relative to A at a level of 5% of the beamwidth. Thus, if two images B and B′ are of equal intensity ($I = I'$), their separation $\delta\theta$ is less than 0.16 arc s. We are, therefore, unable to rule out model 'c' of Young *et al.* in which $I/I' = 1.45$ and $\delta\theta = 0.15$ arc s.

Young *et al.* have emphasized that the cluster as a whole may play an important role in forming the image, and they attribute property (4) above to the effect of the cluster. As a result of the cluster, one of their models results in the observed B image plus a very faint B′ image nearly coincident with G1. This may be the correct interpretation of the small radio source G. If in fact G is north of the nucleus of G1, G cannot be the third image B′. In addition, note that the absence of second images of the extended emission must be used to constrain the role of the cluster, and Young *et al.* did not consider the radio data in constructing their models.

Improved VLBI experiments currently underway will constrain models in which B is double with separation less than the 0.16 arc s detectable in the current VLA data. In addition, measurement of the time delay between the arrival of the A and B images will help ascertain the importance of the cluster in the image formation. The differential delay, expected to be of the order of months in the absence of the cluster, could be multiplied by a factor of the order of 5 by the effect of the cluster[7]. In principle, this sensitive probe of the cluster could yield information on any 'hidden' mass in the cluster[5]. The intensity ratio $I_A/I_B = 1.23 \pm 0.02$ in the data presented here, while it was 1.32 ± 0.02 in October 1979 (ref. 5), so there seems to be measurable variability in the underlying quasar, making a time-delay measurement feasible. Finally, we note that cD galaxies such as G1 can have double or multiple nuclei, and hence may have appreciable non-radial refraction effects. Thus it may not be necessary to invoke strong bending due to the cluster in order to understand the slight misalignment of A–G1–B.

The National Radio Astronomy Observatory is operated by Associated Universities, Inc. under contract with the NSF. The research at the Massachusetts Institute of Technology was supported by a grant from the NSF.

A new class of extraterrestrial material has recently become available for study: interplanetary dust particles (2–30 μm in size) collected in the atmosphere at 20-km altitude by inertial impactors mounted on NASA U-2 aircraft in the programme of sampling initiated by Brownlee *et al.*[1]. The extraterrestrial nature of a compositionally 'chondritic' subset of these particles has been verified by measurements of the elemental and isotopic abundances of noble gases[2,3]. We report here the first optical absorption spectra of these interplanetary dust particles (IDPs). We show that absorption features in the visible at ~9,800 cm^{-1} and in the IR at ~1,000 cm^{-1} are present in spectra of these particles. An ~1,000 cm^{-1} feature is present in optical spectra of meteorites, comet dust and interstellar dust, although its cause in the latter two is a subject of some debate[4,5]. Future experimental work on these laboratory samples promises to shed light on the alternatives, at least for particles in the Solar System dust cloud.

Particle handling techniques are described elsewhere[6]. After removal from collectors supplied by Brownlee, particles were individually cleaned of the silicone oil collecting medium by immersion in a running stream of hexanes. They were mounted and characterized briefly by optical microscopy, scanning electron microscopy and energy dispersive X-ray analysis before

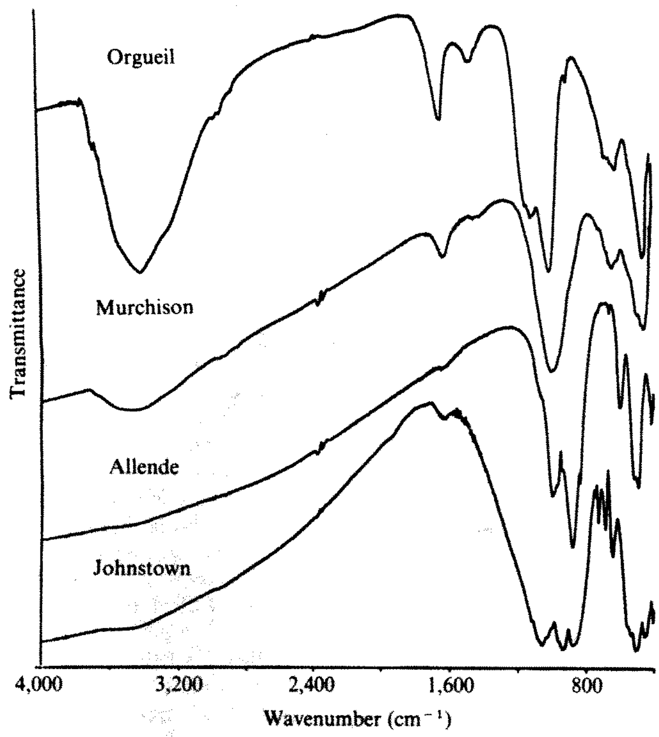

Fig. 1 IR transmission spectra of different meteorites at room temperature. The samples were prepared by mechanically grinding a 1-mg sample with 100 mg of KBr and forming a clear pressed pellet by the standard IR-KBr pellet preparation technique. A commercial Nicolet 7199 FTIR spectrometer equipped with a globar source and mercury–cadmium–telluride detector was used to record the IR specta.

being crushed and mounted for the measurement of optical properties using Fourier transform spectroscopic methods.

Absorption spectra of meteoritic materials in the mid-IR show a wealth of detail. Figure 1 shows room temperature (25 °C) IR spectra from several different meteorites between 4,000 and 400 cm^{-1} obtained using large (10^{-3} g) samples. Similar spectra have been published previously[4]. The structured absorption feature centred near ~1,000 cm^{-1} is probably due to Si–O stretch bands of meteoritic silicates. The spectra of these samples were then recorded at near liquid nitrogen temperature (−196 °C) to simulate the lower temperatures found in space. Figure 2 compares the low temperature (−168 °C) and room temperature spectra of the Orgueil meteorite. At low temperature, the weaker bands become sharper and better resolved, but the distinguishing spectral features are not significantly altered.

An IR spectrum of pieces from three IDPs (total sample ~10^{-9} g) is shown in Fig. 3*a*. A broad feature in the region 1,300–800 cm^{-1} is clearly present. Figure 3*b* shows a comparison spectrum of small particles from the Orgueil meteorite taken under similar circumstances. Possible causes for the IDP feature include mafic silicates[4] and carbonaceous material[5] which are known to be present in these particles[7–9].

Figure 4 shows the visible/near IR spectra of several carbonaceous meteorites, and of a sample composed of five crushed IDPs (total sample ~3×10^{-9} g). The well studied feature centred at ~9,800 cm^{-1} in the meteoritic spectra is due to crystal field transitions of iron[10]. Comparisons of the IDP and the carbonaceous chondrite spectra show that the absorption spectra are different, in spite of the similarities in elemental abundances of the two classes of object[7]. A weak iron crystal field absorption band is present in the IDP spectrum.

A prominent ~1,000 cm^{-1} feature is a commonly observed feature of dust found in different astrophysical settings[4]. Although it may never be possible to establish definitively the nature of the material (or materials) responsible for such an absorption in interstellar dust, it seems likely that the problem

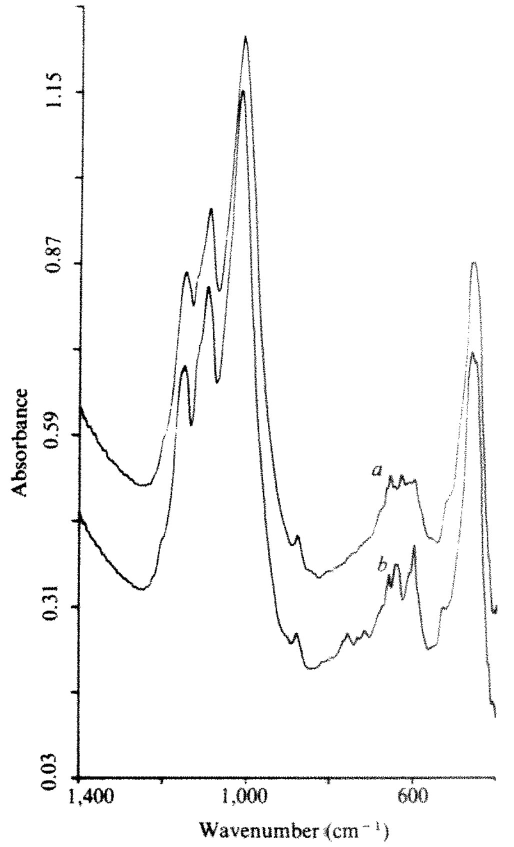

Fig. 2 IR transmission spectra of the Orgueil meteorite: *a*, at room temperature (25 °C); *b*, at −168 °C.

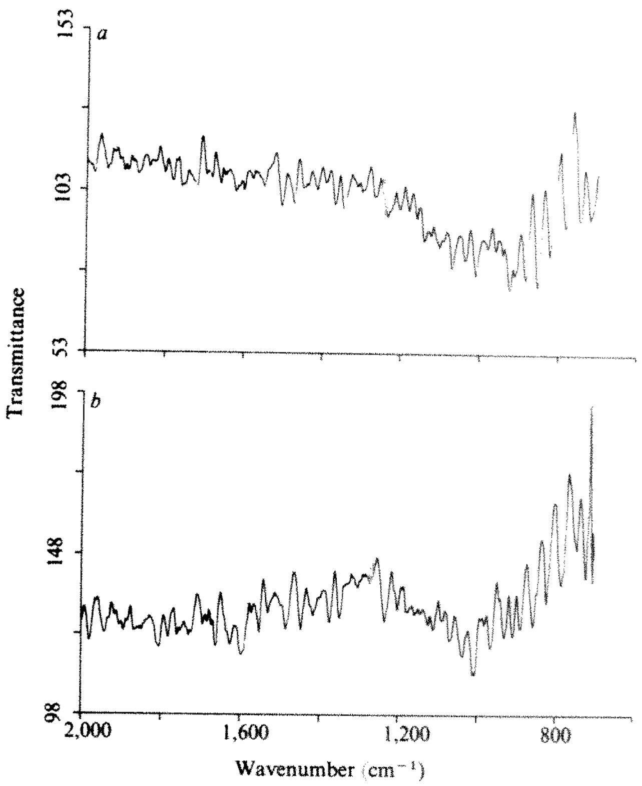

Fig. 3 IR transmission spectra of: *a*, IDPs; *b*, a particle from the matrix of Orgueil. Spectra were acquired by crushing the particles onto a thin (~100 μm) freshly cleaved KBr plate using a glass slide and centering them in a 50 μm aperture[11]. The sample mount was then placed in a 4× beam condenser using an *f*/1 KBr lens and aligned by adjusting the sample position until the detector signal was maximized. Spectra were obtained by 20,000 time averaged scans with 8 cm^{-1} resolution.

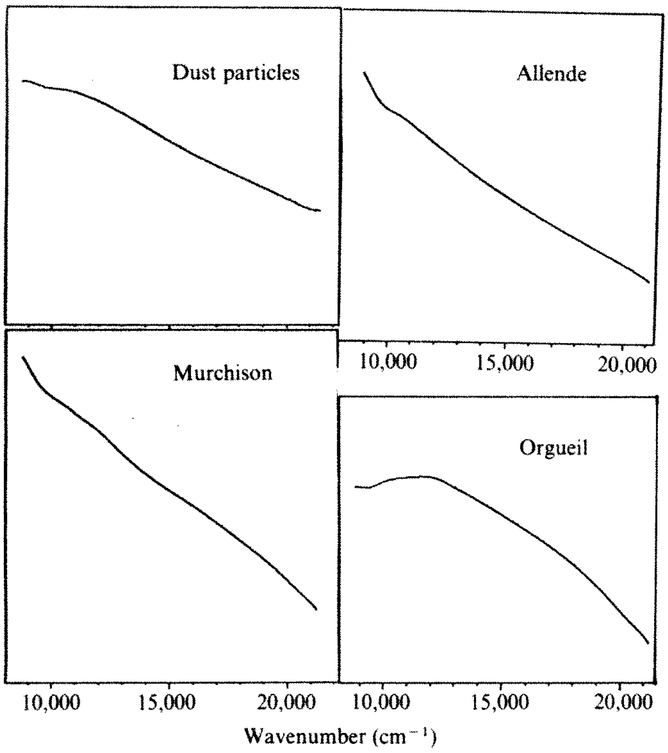

Fig. 4 Visible/near-IR spectra of powdered samples from IDPs and several carbonaceous chondrites. Ordinate values are proportional to the ratio of light transmitted through the sample and light transmitted through a blank. The spectra were obtained using the solar FTS at the Kitt Peak National Observatory. The instrument is a dual beam FTS having input and output focal lengths of 2.9 and 2.3 m, respectively. The beam splitter was silver on quartz and an entrance aperture (*f*/50) of 4 mm was used. Transmission measurements were made on powdered samples which were immersed in silicone oil and sandwiched between glass slides, separated by spacers. Illumination was provided by a 150 W tungsten–halogen lamp.

can be solved for interplanetary dust. Although the collected IDPs have certainly experienced some thermal alteration during deceleration in the Earth's atmosphere, the particles seem to retain absorption features found in cosmic dust. Work is in progress to separate, or at least remove selectively, the various constituents of the IDPs to evaluate separately their contribution to the absorption. A severe constraint is posed by the small size of the particles and their present rarity. The particles are also known to differ considerably in their mineral assemblages from one particle to the next[9]. Fourier transform spectroscopy on individual particles may prove to be an important future technique for the nondestructive classification of particles according to type.

We thank Dr J. Brault for assistance at the Kitt Peak National Observatory, Drs C. Anderson, D. Huppler and D. W. Vidrine of Nicolet Instrument Corporation for their help, and particularly Dr D. Brownlee who made IDPs available for this study, and G. Flynn for helpful discussions. This work was supported by NASA grant NGL 26-008-065.

Solar variability and climatic change during the current millennium

Minze Stuiver

Departments of Geological Sciences and Zoology, Quaternary Research Center, University of Washington, Seattle, Washington 98195

Claims of a Sun–weather relationship[1] can only be evaluated properly when the history of solar change is known in detail. The most obvious feature of solar variability is the change over time in the number of sunspots on the visible half of the Sun. A less visible indicator of solar change is the ^{14}C content of tree rings. The atmospheric ^{14}C levels derived from tree ring measurements can be tied to the Sun's modulation of the cosmic ray flux in the vicinity of the Earth, and thus provide a history of solar change.[2] We report here a comparison of climate records with the record of solar change obtained from atmospheric ^{14}C variations. This yielded 'negative' results, that is, a relationship between the climatic time series and the ^{14}C derived record of solar change could not be confirmed.

The modulation of the cosmic ray flux (and the associated atmospheric ^{14}C production rate Q in atoms s^{-1} cm^{-2} of the Earth's surface) by the Sun occurs through changes in the magnetic shielding properties of the solar wind. However, this is not the only cause of atmospheric ^{14}C change. The Earth's geomagnetic field also influences the pathways of the charged particles that constitute cosmic radiation. Both solar modulation and longer-term geomagnetic field changes have to be taken into account when decoding the atmospheric ^{14}C signal. A carbon reservoir model[2,3] that describes terrestrial carbon exchange between the atmosphere, ocean and biosphere can be used to calculate from the atmospheric record the production rate changes ΔQ_M. In carbon reservoir modelling, the long-term trend in the atmospheric ^{14}C attributed to Earth geomagnetic dipole changes is removed by deducting the sinusoidal approximation given by Houtermans[4]. The remaining ^{14}C variations are used to calculate the ^{14}C production rate changes ΔQ_M around the steady state value of 1.57 atoms cm^{-2} s^{-1} from the model. The magnitude of the ΔQ_M changes caused by solar modulation depends on the Earth's geomagnetic field intensity because the average global ^{14}C production becomes less sensitive to solar modulation when the Earth's geomagnetic field increases[5,6]. The ΔQ_M values given here are normalized to the present-day Earth's geomagnetic field intensity by using the correction factor $[M(0)/M(t)]^{0.63}$ derived from data given by O'Brien. The magnetic field changes were obtained from data given by Barton *et al.*[7].

Climate-related changes in carbon reservoir exchange rates may also cause atmospheric ^{14}C levels to change. The calculated record of ^{14}C production rate changes (ΔQ_M) may, therefore, contain 'fictitious' rate changes that are not related to solar modulation, but to climate changes. The contribution to the ΔQ_M record of such fictitious ΔQ_M changes is difficult to evaluate, but it can be argued that climate variability is not a dominant factor in producing century-type atmospheric ^{14}C variations[2,8].

The changes in calculated ^{14}C production rates generally agree with the evidence for solar change obtained from historical observations of sunspot number and aurorae. For instance, there are three intervals in the post AD 1200 sunspot record where visual sunspot observations are lacking (the Wolf, Spörer and Maunder minima). For each interval of reported low incidence of sunspots, the ΔQ_M record reaches a maximum. There is also covariance between ^{14}C production rate changes and sunspot numbers for the eighteenth and nineteenth centuries[2].

When discussing the ^{14}C changes, note that the standard deviation in the ^{14}C measuremens is ~1.5–2 ‰. This corresponds to an average standard deviation in the calculated

0028-0836/80/350868—04$01.00

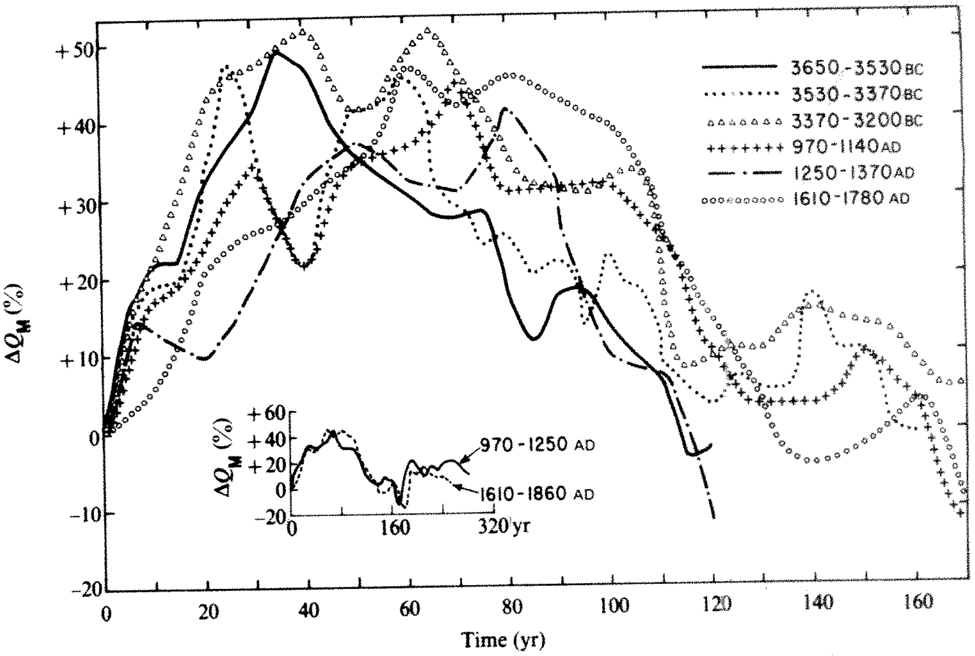

Fig. 1 ^{14}C-production rate changes ΔQ_M of solar oscillatory modes that are similar to the Maunder minimum mode. The ΔQ_M values are the increases over the preceding lowest ^{14}C production rate. The ^{14}C production rate changes were normalized on the present-day Earth geomagnetic field intensity (see text).

ΔQ_M values of ~4%. It is possible to recognize many similarities within the stated precision in the ^{14}C pattern. The ^{14}C production rate changes are, therefore, not random fluctuations.

Two of the ΔQ_M oscillations in the current millennium are, within the experimental error, copies of each other. These are the variations encountered between AD 970 and 1250, and between AD 1610 and the end of the nineteenth centry (see Fig. 1). The similarity of the Fig. 1 curves implies that the 'grand medieval maximum' of the twelfth century[9] has the same level of solar activity as the AD 1740–1840 interval. The Sun switches near AD 1250 to the quiet Wolf minimum, whereas the Sun is still active after AD 1890. The agreement between the curves terminates, therefore, after 280 yr.

The close correspondence of some of the ^{14}C record puts limitations on the theories of solar dynamo behaviour. Dynamo theories may include the possibility that the envelope of the solar cycle, and the associated magnetic field in interplanetary space, is inherently unpredictable[10]. The repetitive pattern seen in the ^{14}C record argues against this interpretation.

Many of the oscillations are similar to the late seventeenth century Maunder minimum pattern. The ΔQ_M oscillations between AD 970 and 1100, AD 1250 and 1370, and AD 1610 and 1750 all have the same magnitude, approximate duration and shape (Fig. 1). The geomagnetically normalized ΔQ_M variations, calculated from a ^{14}C record[11] between 3650 and 3300 BC are also given in Fig. 1. The 3650–3520 BC, 3530–3370 BC, and the 3370–3260 BC oscillations again have similar magnitudes and duration. The times necessary to reach the maximum production rate change are different. This rise-time is 40 yr for the BC oscillations and 50–70 yr for the more recent ones.

Three of the four major oscillations of the current millennium are of the Maunder minimum type, lasting 120–140 yr. The remaining oscillation is the Spörer minimum, lasting nearly twice as long (240 yr). The Spörer oscillatory mode is seen less frequently than the Maunder mode. The ^{14}C record given by Suess[12] suggests that the preceding Spörer mode occurred as long ago as 700 BC.

A spectral analysis of the post-AD 730 record yields the curve in Fig. 2*a*. The probability of exceeding, in a random distribution, the peak sizes with periods of about 130 and 200 yr are, respectively, 1.4 and 4.9 ‰.

The so-called 'Little Ice Age' in Europe in the seventeenth century is sometimes attributed to the solar changes that took place during the Maunder minimum[9]. If indeed the Sun does influence climate in this manner, then there should be many more Little Ice Ages because the solar Maunder mode is quite prevalent. One would then also like to postulate a cooling of double duration for the less frequent double Maunder (Spörer) mode. In fact, with four major oscillations during a millennium, it would be conceivable that 40-odd little ice ages existed during the current Interglacial. Furthermore, one would expect similarities in climatic response for certain periods, such as the AD 970–1250, and the AD 1610–1890 intervals.

Figure 3 shows the solar-related ΔQ_M record compared with eight climate records. Two of these are based on oxygen-isotope ratio measurements in ice cores. The derivation of the ages of

Table 1 Correlation coefficients r derived from cross-correlating the ^{14}C production rate record given in Fig. 3 (ΔQ_M curve) with the climate records listed below

Fig. 2	Locality	r	r_{max}	Δt (yr)	r_{max}	Δt (yr)
a	Oxygen isotopes ice core, Devon island[14]	+0.08			+0.25 (5%)	50
b	Oxygen isotopes ice core, Camp Century, Greenland[15]	−0.19	−0.43 (3.5%)	−30	+0.33 (19%)	90
c	Oxygen isotopes ice core, Crete, Greenland[16]	−0.01			−0.26 (5%)	50
d	Tree ring width, Lapland[17]	−0.01	−0.33 (6%)	−90	+0.36 (3%)	50
e	Winter severity index, Russia[18]	−0.14	−0.43 (1.6%)	−30		
f	Tree ring density, Lauenen, Switzerland[19]	+0.05	−0.31 (10%)	−90		
g	Winter severity index, UK[18]	−0.03				
h	Mean annual temperature, UK[18]	−0.06				
i	Deuterium isotopes tree rings, White Mountains, Nevada[20]	−0.11				
j	Tree ring width, White Mountains, Nevada[21]	−0.32	−0.32 (5%)	0	−0.32 (5%)	0

The r_{max} values are obtained by assuming (1) climate lags the ΔQ_M curve (Δt positive) or (2) climate-influencing variables precede the Q changes (Δt negative). The probabilities of exceeding the listed r values in a random series are given in parentheses. r_{max} values are only listed for time lags of 100 yr or less.

the Camp Century core (Fig. 3*b*) and Devon Island (Fig. 3*a*) are mainly based on ice flow dynamics. The time scale of all other curves is based on either tree ring counting or historic dating. Ages determined in this manner should be considered more accurate than those assigned to the oxygen isotope curves.

The climate curves in Fig. 3 were constructed from available records that are listed in Table 1. These records give information on regional climate only. They are used for a comparison with the solar record because other, more representative, indicators of global climate are not available over such a long interval.

A downward move of the climatic parameters in Fig. 3 implies in all instances a colder environment. The solar ΔQ_{M} record is plotted on an inverse scale, mainly to facilitate a visual investigation of a possible relationship between reduced solar activity (higher ^{14}C production rates) and colder climate.

Conclusions that can be drawn from the comparisons made in Fig. 3 are:

(1) The detailed work of Schweingruber *et al.* on tree ring density[19] does not agree with contemporaneity of the Maunder minimum and the climatic cooling of the seventeenth century that is often referred to as the Little Ice Age. The tree-ring density record points to an extended cold episode between AD 1570 and 1640. This interval coincides with the period of high solar activity (low ΔQ_{M} values) between the Spörer and the Maunder minimum. Several of the other climate records given in Fig. 3 also have a tendency towards colder weather during this interval of high solar activity.

(2) During the Sun's switch to the less active Spörer and Maunder minimum modes, Russia especially experienced colder winters.

Correlation coefficients derived from cross-correlating the climate and solar curves are small in nearly all cases. These coefficients r are given in Table 1, which also lists the oxygen isotope record of Crete, Greenland[16] and a Lapland tree-ring width series[17], not shown in Fig. 3, for which the r values are both -0.01. The White Mountains' ring width data cross-correlate with the solar record at the 5 % significance level. The other correlation coefficients indicate a complete absence of a direct relationship between the solar Q and climate curves.

By assuming a time lag between climate and the solar curves, it is possible to obtain larger correlation coefficients for several of the time series listed in Table 1. There are two possibilities: either climate lags the solar curve (Δt positive) or the solar properties that possibly influence climate precede the Q changes (Δt negative). Table 1 lists those Δt values ($|\Delta t \leq 100$ yr) for which r reaches a maximum value $r_{\max}$.

Because the Q record has substantial autocorrelation (it takes a 50-yr lag for the autocorrelation coefficient to approach zero) the normal test of significance is no longer applicable. Autocorrelation reduces the number of independent observations used in interpreting the derived cross-correlation coefficients. The effective number N of independent observations were calculated for each time lag according to the procedures discussed by Quenouille[22]. The number N was subsequently used in deriving the probabilities of exceeding the Table 1 $r_{\max}$ values.

Table 1 lists nine climate series of different regions (series *h* is partially derived from series *g* and has not been included in the following discussion). One hundred and eighty-nine comparisons were made by lagging the data up to 100 yr (21 comparisons with the Q record for each climate series). In a

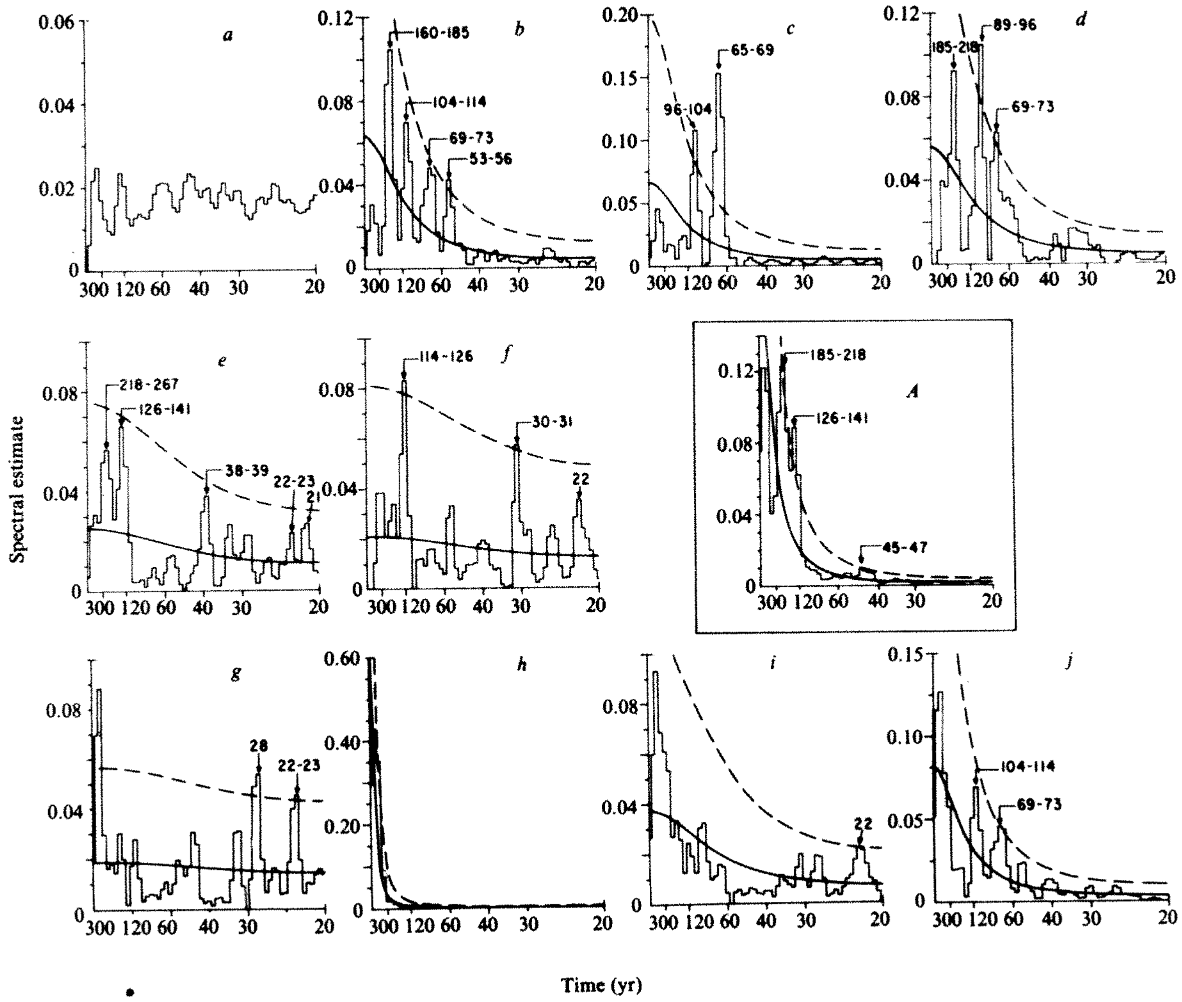

Fig. 2 Spectral distribution of the post-700 AD ^{14}C production rate record (curve *A*) and climate records (curves *a*–*j*). The various climate records are described in Table 1. The dashed line gives the 2σ confidence limit whereas the solid line gives the red noise continuum[13].

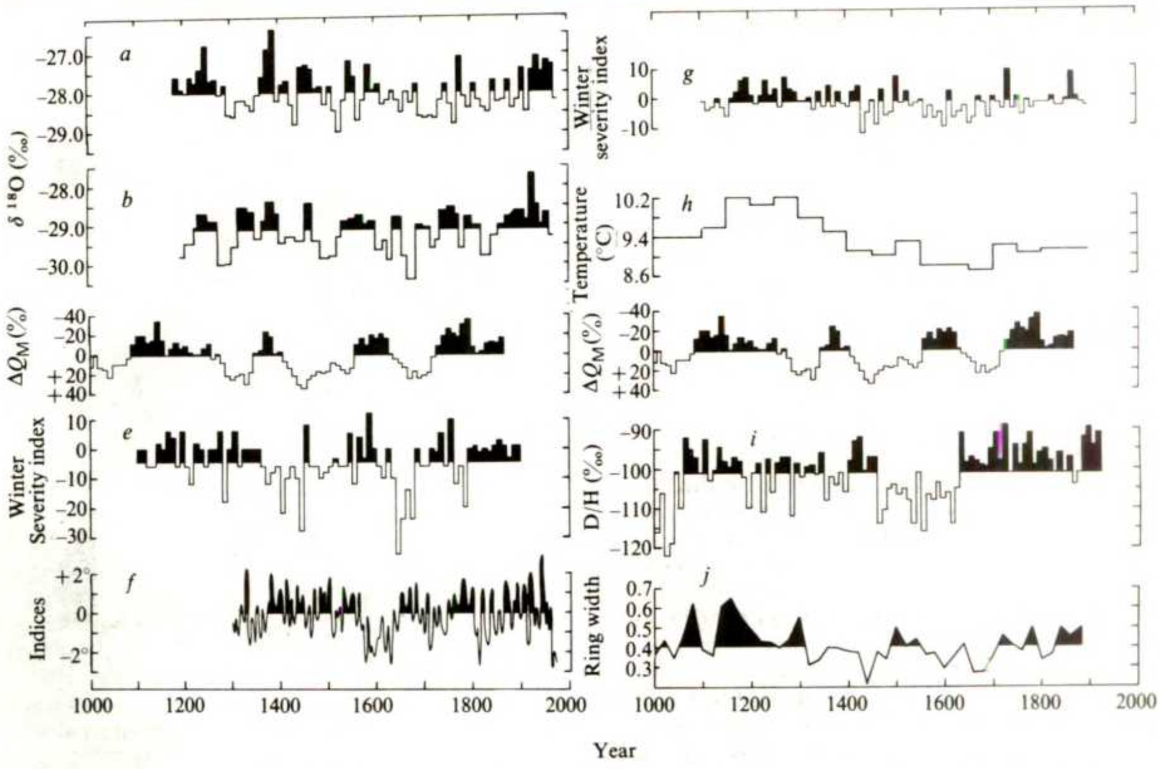

Fig. 3 A comparison of climate and ^{14}C production rate records. The various climate records are described in Table 1.

comparison of non-related time series, the distribution of correlation coefficients should be 1, 9, 51 and 128 for, respectively, the 0–0.3%, 0.3–5%, 5–32% and 32–100% probability intervals. The Q and climate comparisons yield a distribution of 0, 12, 50 and 127 correlation coefficients for the intervals listed above. The combined lagged climate records therefore do not cross-correlate with the Q record beyond random statistics.

Another approach to the investigation of a Sun–weather relationship is to look for common periodicities in the solar related ΔQ_M record and the climate records. The climate records contain several periodicities (Fig. 2). The closest agreement in spectral distribution between the solar related ^{14}C (curve A) and climate records is obtained for the Russian winter severity index (curve e). The spectra of other high-latitude regions, such as Camp Century, Greenland (curve b) and Lapland (curve d) also partially agree. On the other hand, the climate spectra also have several periodicities that are not present in the ^{14}C derived solar record. One of these periods, near 70 yr, is found in four climate records. Note that the 22-yr cycle, already discussed by Epstein and Yapp for the D/H record (curve i) is also present in the winter severity indices of England and Russia (curves g and e), and the Swiss tree-ring record (curve f). The 22-yr cycle is absent in the ^{14}C production record (curve A) but this is due to a lack of sensitivity for the faster oscillations (a rapid decadal production rate change is attenuated more, and results in atmospheric ^{14}C variations of a few per mil only).

Earlier studies of the ^{14}C and climate record[9,23–25] suggested a direct relationship between the solar modulated atmospheric ^{14}C levels and climate. These studies did not take into account the variable time lag between the atmospheric ^{14}C levels and the ^{14}C production rate changes. The precision of the ^{14}C record used in those investigations also did not allow for a detailed study of a phase shift between solar input function and climate. The high precision ^{14}C measurements reported here do not support a statistically significant relationship between the combined regional climate and ^{14}C time series.

Many factors influence local climate change, and a solar influence on climate can perhaps be expected in a few areas only. The Camp Century and Russian climate records demonstrate on the basis of the statistical analysis a climate solar relationship (albeit 30 yr out of phase). A selective comparison of solar and climate records, however, can only be justified if a mechanism can be found that explains the postulated increased sensitivity to solar changes of these areas. Perhaps jet stream oscillations that seem to relate to the 11-yr solar cycle[27] may provide some answers in this direction.

The length of the records discussed above does not allow for the investigation of a solar–climate relationship with periodicities of the order of millennia[26]. Sun–weather effects may still also be tied to other parameters of solar change, such as the umbra–penumbra ratios discussed by Hoyt[28].

This work was supported by the NSF Climate Dynamics Program grant ATM 7821608. P. M. Quay calculated ^{14}C production rates through carbon reservoir modelling and P. Reimer developed the computer program for spectral analysis.

Modern climate–tree-growth relationships and climatic reconstruction in sub-Arctic Alaska

Harriet L. Garfinkel & Linda B. Brubaker

College of Forest Resources, University of Washington, Seattle, Washington 98195

Statistical comparisons between tree-ring width sequences and climatic records provide a means of identifying climatic limitations on tree growth and allow the reconstruction of past climates. This information is especially important in the North American sub-Arctic where climate–growth relationships are poorly understood and instrumental weather records are very short, typically less than 75 yr. Dendroclimatic reconstructions before 1900 are essential for estimating a realistic range of high latitude climatic variation, because twentieth century climate is now thought to be somewhat anomalous[1]. While some dendroclimatic studies have been carried out in the sub-Arctic[2–8], none has made full use of current multivariate statistical techniques. This study, as part of a multidisciplinary investigation of treeline fluctuations in the Brooks Range of Alaska, uses ring-width sequences of white spruce (*Picea glauca* [Moench] Voss) to define climatic limitations on radial growth at treeline and to reconstruct past climatic variables for Fairbanks, Alaska. Multiple regression techniques were used to analyse climate–growth relationships and the results suggest important modifications to the theory that growth at treeline is limited primarily by summer temperature[2,8,9]. For example, we have found that radial growth is directly related to summer and autumn temperature and precipitation during certain months, but is inversely related to winter–spring temperature. The same ring-width sequences were used to reconstruct average May–July temperature at Fairbanks, Alaska, for the period 1829–1930. This reconstruction, which more than doubles the length of the existing climatic record, was verified by statistically comparing it to independent instrumental data. It indicates that the Fairbanks area has been warmer in the twentieth century than in the nineteenth century during these months. As the longest annual record of temperature from northern Alaska, this reconstruction provides quantitative evidence for a climatic warming similar to that occurring throughout large portions of the Northern Hemisphere during the past 100 yr (refs 10–12).

Fourteen ring-width chronologies were obtained according to standard dendrochronological techniques[13] from sites (67–68° N, 153–155° W) within continuous forest and treeline environments in the Walker Lake–Alatna River valley area of the Brooks Range. Each chronology represents the average of age-standardized ring widths[14] of two increment cores from each of 15 or more trees. To examine climate–growth relationships, the chronology of each site was used as the dependent variable in a stepwise multiple regression analysis with monthly climatic data from the Interior Basin climatic division[16] within which the sites are located. This analysis, termed response function analysis by Fritts *et al.*[17], defines the correlations of radial growth with monthly temperature and precipitation during and preceding the actual growing season. Months before the growth season are included in the analysis because climatic conditions during this period can affect growth during the subsequent summer[15]. The growth variance accounted for by temperature and precipitation in the 14 analyses ranges from 11.2 to 54.7% and averages 36.0%.

The basic form of the response function was similar at all sites and these results are summarized in Fig. 1. This set of climate–growth correlations suggests physiological processes which limit growth in the sub-Arctic. In addition to the expected positive correlation with current summer temperature, growth exhibits a strong positive correlation with previous autumn temperature and negative correlations with previous summer, winter and spring temperatures. The positive response of growth to current summer temperature suggests that warm temperatures can increase rates of net photosynthesis and enhance growth in treeline environments during the growing season. The prominent positive correlation with previous autumn temperature suggests that warm autumn temperatures lead to increased photosynthesis after the end of the growing season, resulting in greater reserves of carbohydrates for the next year. Note that this correlation exists for periods after growth has ceased in the preceding summer, suggesting that photosynthates are put into reserve rather than used for late-season growth. In fact, climatic conditions that hasten the cessation of growth during one summer may actually promote increased growth during the next. This hypothesis is consistent with the negative correlation of growth at all sites with previous July temperature, as low temperatures near the end of the growing season can cause early termination of growth[18,19].

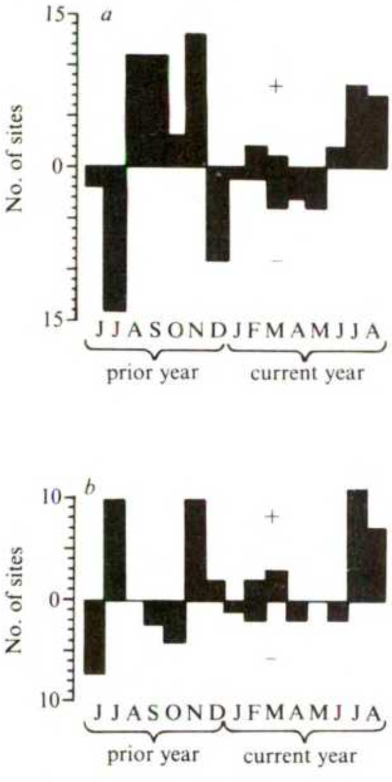

Fig. 1 Response function summary for: *a*, temperature; and *b*, precipitation. The vertical scale represents the number of sites exhibiting significant ($P < 0.05$) positive (upper half of scale) or negative (lower half of scale) correlation with each climatic variable. The climatic variables are mean monthly temperature and total monthly precipitation for the June before the growth season through August of the current year.

The negative correlation of growth with winter–spring temperature may reflect the adverse effects of winter desiccation[19–21]. Thawing of foliage precedes thawing of the stem and soil during periods of above average temperature. As a result, transpiration is activated while water uptake is inhibited, leading to severe water stress. Coupled with this is an increase in respiration which, if prolonged, will lead to death of foliage[23].

While precipitation during certain months is strongly correlated with growth, the responses do not follow clear seasonal trends and are not as easy to interpret as the temperature responses. The water relations of high latitude trees, particularly during the dormant months, has not been studied extensively, making evaluation of these responses difficult. However, the positive correlation for current summer months suggests that internal water stress can limit photosynthesis at sub-Arctic treeline sites when temperatures are high. Relationships of this

0028–0836/80/350872—03$01.00

type are commonly found on arid or semi-arid sites where moisture stress limits growth[15]. The south flank of the Brooks Range is, in fact, a dry environment, as it receives an average of only 332 mm of precipitation per year[16].

These response function results suggest that ring-width sequences from Interior Alaska contain significant climatic information and can be used to reconstruct past climatic fluctuations. Dendroclimatic reconstruction is a multistep process developed over the past decade by Fritts and others[6,17,24]. In this study, principal component analysis was performed on the tree-ring chronologies to concentrate the information present in the data into a small number of variables (eigenvectors) and to satisfy the statistical assumption that regression variables are linearly independent.

Annual values (amplitudes) associated with the first five eigenvectors served as the tree-growth data set in the reconstruction procedure. Numerical relationships between these amplitudes and selected Fairbanks climatic variables[16] were defined by stepwise multiple regression analysis in a process termed calibration. Fairbanks, though nearly 400 km south-east of the study area, has the longest climatic record in the Interior Basin Climatic Division. In each regression equation, the monthly temperature or precipitation measurements were expressed in terms of the tree-growth eigenvector amplitudes for the period 1931–74. Climatic variables were reconstructed by entering eigenvector amplitudes for the period 1828–1932 into the regression equations. Finally, the reconstructions were verified by statistically testing their similarity to Fairbanks instrumental records for 1906–30 which had been withheld from the calibration. Reconstructions of May, June and July temperature passed ($P<0.05$) two, three and four of the four verification tests respectively. The individual reconstructions of these months were averaged for a simplified reconstruction of early growth season temperature which passed three of the tests. February temperature and December precipitation each passed one of the verification tests, lending some validity to these reconstructions. However, this is not considered sufficient verification for climatic interpretation. These results, along with the R^2 values for the corresponding calibration equations are presented in Table 1.

Table 1 Calibration and verification statistics

Climatic variable	R^2	Correlation	Sign test	Product mean	Reduction of error	No. of tests passed
February temperature	0.394	—	—	*	—	1
May temperature	0.654	*	—	*	—	2
June temperature	0.628	†	*	*	—	3
July temperature	0.475	†	*	*	‡	4
December precipitation	0.369	—	—	*	—	1
Average of reconstructed May–July temperature		†	*	*	—	3

—, Not significant; *, significant at $P<0.05$; †, significant at $P<0.01$; ‡, no significance test available; positive value considered significant (H. C. Fritts, personal communication).

The agreement between instrumental climatic data and the values predicted by the regression equation for the calibration period is reflected in the R^2 value. This statistic can be interpreted as the percentage of the climatic variance accounted for by the tree-ring data. The regression model included the amplitudes of the first five tree-ring eigenvectors, which account for 90.8% of the tree-growth variance as independent variables in the regression. Eigenvectors beyond five account for little variance individually and are assumed to represent random variation. Additional predictive power was gained by lagging these amplitudes 2 yr behind and 1 yr ahead of the climatic data for 20 possible independent variables (five eigenvectors at four lags). The final regression equation is

$$y_t = (b_1)(x_{1,t}) + (b_2)(x_{2,t}) + \cdots + (b_{20})(x_{20,t})$$

where y_t is the predicted value of mean monthly temperature or total monthly precipitation for $t = 1932$–72. (Here, if June–August represent the growing season of year t, the preceding nine months are also considered to be in year t, even though September to December are actually part of the preceding calendar year.) b_i Is the regression coefficient for the amplitude $i = 1, 20$, and $x_{i,t}$ is the amplitude value for $i = 1, 20$ and $t = 1932$–72. Again, the 20 coefficients for year t correspond to the amplitudes of eigenvectors 1–5 for years $t-1$, t, $t+1$ and $t+2$. In the stepwise multiple regression, only those variables with an F ratio >1 were used as predictors in the final equation. Four verification tests were performed on each reconstruction to evaluate the correspondence of reconstructed values with actual climatic data. (1) The correlation test is a standard measure of the predictability between reconstructed and actual climatic data before the calibration period. (2) The sign test is a nonparametric procedure which counts the number of agreements and disagreements in sign changes between adjacent years in the two series. (3) The product mean assesses both the sign and the magnitude of the departures from the calibration period averages. (4) The reduction of error (RE) is a very rigorous test of association between a series of actual values and their estimates. It compares the sum of squares of the differences between the reconstructed and actual data with the sum of squares of differences between the actual data and their mean. The degrees of freedom used to test the significance of the correlation and product mean tests were adjusted downward to correct for serial correlation present in the reconstructed and instrumental time series[28]. These tests are described in detail elsewhere[15].

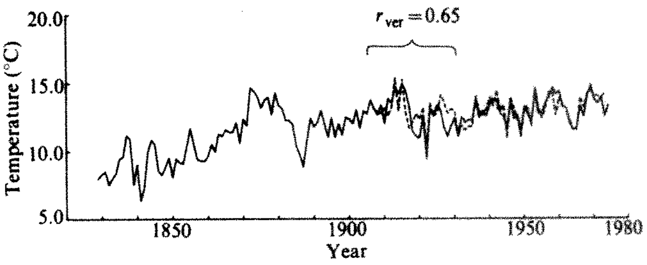

Fig. 2 Climatic reconstructions (———) and Fairbanks weather station data (------) for mean May–July temperature. r_{ver} Is the correlation between the reconstructed and instrumental values for the verification period (1906–30).

The reconstruction of average May–July temperature (Fig. 2) indicates that the twentieth century has been approximately 2.1 °C warmer than the nineteenth century during these months.

This reconstructed warming episode is consistent with our knowledge of treeline fluctuations in Alaska. In the study area, healthy seedlings are presently abundant above the treeline, and upper elevation stands of white spruce are apparently not greatly stressed. These findings indicate a current advance of treeline, already noted in other parts of Alaska[25,26], and Scandinavia[27]. The expansion of the boreal forest, coupled with the warming trend reconstructed for the past 100 yr, is evidence of the widespread warming which has been observed in other areas of the Northern Hemisphere during this period[10–12]. The magnitude of the climatic warming also supports the finding that climatic fluctuations at northern latitudes tend to be more pronounced than simultaneous variations in temperate regions[10,11].

This study demonstrates the usefulness of Alaskan tree-ring sequences and climatic records for dendroclimatic reconstruction. In particular, climatic data from distant stations may be used successfully, so that sampling need not be restricted to those few areas near meteorological stations with long records. Our reconstructions can be extended at least 200 yr by the collection of longer chronologies from the Brooks Range. Refinement of the statistical models will give additional months of temperature and precipitation to the reconstructed data set producing a more complete view of past climatic fluctuations in northern Alaska.

Observations of dilatancy-induced polarization anomalies and earthquake prediction

Stuart Crampin[*], Russ Evans[*], Balamir Üçer[†], Mark Doyle[*][‡], J. Peter Davis[*][§], Galia V. Yegorkina[||] & Alistair Miller[*][¶]

[*] Institute of Geological Sciences, Murchison House, West Mains Road, Edinburgh EH9 3LA, UK
[†] Kandilli Observatory, Çengelköy, Istanbul, Turkey

Much of the search for earthquake prediction schemes has centred on the expectation that rocks in the impending source area will show dilatancy: the opening of cracks at high stress-levels. Recent developments in the theory of seismic wave propagation in cracked media[1] demonstrate that shear-wave splitting will occur in seismic-wave propagation through cracked structures, when the cracks have any overall alignment. This splitting causes polarization anomalies in the seismograms, and it has been suggested[1] that dilatancy, induced by the build-up of stress before earthquakes, might be recognized and monitored by analysis of these anomalies. We present here new observations which support this hypothesis.

The crust and upper mantle of the Earth are thoroughly permeated by cracks. Sedimentary rocks contain joints and fractures, which can lead to pronounced seismic velocity-anisotropy in shallow beds[2,3]. Igneous rocks in the crust, and possibly the crystalline upper-mantle[4], contain microcracks within grains and along grain boundaries[5]. These various cracks are essentially closed and transparent to seismic waves under high isotropic confining-pressure and low pore-pressure[4]. The primary action of non-hydrostatic stress on rock will be to modify the existing lines of weakness (cracks) in the rock, and the effects will depend on whether the cracks are initially open or closed, and on the relative confining and pore-pressures. At low ambient-stress and low pore-pressure, systems of open cracks may be differentially closed[6], and at high ambient-stress, systems of closed cracks may be differentially opened, if the pore pressure and non-lithostatic stresses are sufficiently high. The term 'dilatancy' is used here to cover both these differential processes, in addition to the usual meaning of the opening of fresh cracks under high local stress-levels. This differential opening of existing cracks may occur over substantial distances, and is probably the direct cause of many of the precursory phenomena, which are sometimes observed hundreds of kilometres from impending epicentres[7]. Laboratory experiments demonstrate that, in stressed rock-samples, existing cracks[6] and newly opened cracks[8–10] both take up pronounced alignments, and certainly all stress-induced dilatancy in the Earth will open cracks in preferred directions. Note that there is now a hypothesis that gas at high pore-pressure may exist at deep levels in seismic regions[11], so that dilatancy cracks could be gas filled even in the upper mantle.

The wavelengths of seismic waves are so much greater than the likely dimensions of any stress-induced cracks, that the velocity variations of seismic waves propagating through a dilatancy zone of aligned cracks can be modelled by propagation through purely-elastic anisotropic media[1]. Theoretical and numerical calculations demonstrate[1,12,13] that, except in a few specific symmetry-directions, anisotropy writes a characteristic signature into the polarization of the shear wavetrain. This signature is a distinctive feature of seismic waves propagating through anisotropic media and will persist for any following isotropic-segments of the path. A plane shear-wave splits on entry into a dilatancy zone into two orthogonally-polarized phases, which are not, in general, parallel to either the vertical or horizontal directions (curved wavefronts show more complicated effects). These split waves travel with different velocities, and result in the shear-wave particle-motion being resolvable into nearly-orthogonally polarized components[1,13]. The arrival of these 'split' shear-waves may be identified by abrupt changes in direction (anomalies) of the particle motion, when plotted in polarization diagrams[1]. The time delay between the phases may be estimated from suitable rotated seismograms, or more directly from polarization diagrams. This delay is proportional to the degree of differential shear-wave anisotropy, and the length of the path through the anisotropic rock, which for long paths will be the dimensions of the dilatancy zone. Consequently, the delay is not very sensitive to small errors in epicentral location or focal depth. However, it is sensitive even to quite weak crack-anisotropy[1], and seems to be a way of monitoring the whole dilatancy episode from initiation of the stress-induced cracking, through the possible influx of water[14], to the conclusion of the earthquake sequence. An example of the sensitivity is that saturation of dry cracks by water would approximately double the differential shear-wave anisotropy for about half of all directions of propagation through any given system of cracks[1]. This should be recognizable on the seismograms, and may help to resolve whether cracks are gas filled at depth in the crust, and whether the influx of water is an essential part of the source process. Thus, if they can be observed, shear-wave polarization-anomalies could lead to a better understanding of the whole earthquake source-process.

We believe that such anomalies have now been observed. For several years, delays between shear-wave arrivals on pairs of unrotated horizontal-component seismograms have been recorded[15] on arrays of three-component seismometers in seismic regions in Armenia, and Fergana, USSR. The delays were observed on between 5 and 10% of all seismograms from local and regional events at all azimuths and at distances up to 450 km. These delays were interpreted[15] as being due to shear-wave splitting caused by anisotropy directly induced by the build-up of stress before an earthquake. Recently, the magnitudes of these delays have been shown to vary before large earthquakes, and to be correlated with the directions of nearby geological faults[16]. However, we consider that anisotropy due to crack dilatancy is likely to dominate any anisotropy directly induced by stress in the Earth.

Gupta[17] probably observed similar anomalies to those of Yegorkina *et al.*[15] from several series of earthquakes in Nevada, US, at distances of >100 km from a single three-component seismic station. However, the small range of azimuths did not allow any convincing interpretation[18], and Gupta was misled

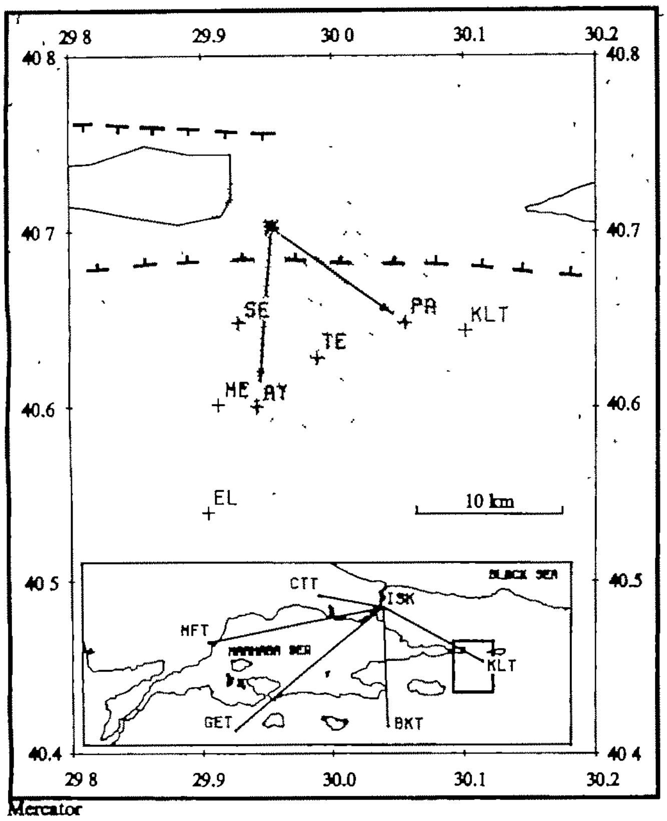

Fig. 1 Map showing the TDPNET three-component stations, with inset of MARNET stations. Most of the local earthquakes occurred within the shaded area, and the epicentre of the earthquake used for Fig. 2 is marked by an asterisk. The heavy dashed line shows the approximate lines of the Northern Anatolian Fault, which in this area appears to be a graben structure.

into seeking shear-waves split only into SV and SH components, when the seismic traces clearly did not display such polarizations. Gupta's observations will be discussed in detail elsewhere.

Similar delays have been observed on records from a small closely-spaced network in Turkey, TDPNET (Fig. 1), of three-component seismometers specifically designed to monitor polarization anomalies. A centre of low-magnitude seismic activity was identified near the Northern Anatolian Fault from MARNET records (MARNET is a radio-linked seismic network spanning the Marmara Sea, Turkey). A collaborative project between the Institute of Geological Sciences and Kandilli Observatory deployed TDPNET over the swarm activity for eight weeks during the summer of 1979. High-quality recordings were obtained from several hundred small earthquakes at epicentral distances of <20 km, and depths between 8 and 15 km. The analogue magnetic-tape records were digitized at 100 samples s^{-1}, and display impulsive P- and S-wave arrivals very suitable for polarization analysis. A few records show shear waves arriving at different times on the unrotated horizontal-seismograms from events at all azimuths, similar to the observations of Yegorkina *et al.*[15,16]. The majority, however, show shear waves arriving at the same time on both horizontal traces, and display shear-wave splitting only when plotted in polarization diagrams.

Figure 2 shows examples of both types of record from the same earthquake at different stations. The seismograms are typical of the data set: almost every shear wavetrain with sufficient signal-to-noise ratio (several hundred examples) shows shear-wave splitting in polarization diagrams, and a few show splitting in the unrotated horizontal-seismograms, as in the observations of Yegorkina *et al.* Figure 2*a* shows separate shear-wave arrivals on the two horizontal-components, despite the azimuth to the epicentre being 40° from the instrument orientations: the shear arrival on the east-west component is about 0.2 s later than the arrival on the north-south. Figure 2*b* shows shear waves arriving simultaneously on both horizontal components. Splitting is not easily identified on the original or the rotated seismograms, but is clearly visible in the horizontal projection of the polarization diagrams.

The horizontal polarizations diagrams show abrupt changes in the direction of the particle motion. We interpret these anomalies as the arrival of phases with different linear polarizations due to shear-wave splitting in propagation through anisotropic material. Any other explanation is untenable: the anomalies cannot be caused by isotropic discontinuities, because no isotropic structure can split shear waves propagating in almost all directions; and it is unlikely to be a source effect, when the sources are small and the P-wave arrivals comparatively simple. There are very few previous studies of short-period particle-motion so it is difficult to know what sort of phenomena to expect. Local and regional earthquakes that we have examined in a region of low seismicity (Scotland) have elliptical shear-motion without the characteristic abrupt turning points of the TDPNET records. Orthogonal changes in polarization are sometimes observed in local and regional events, when there is a mixture of Rayleigh and Love surface-waves present. However, this cannot account for orthogonal polarizations in the first half-second following the initial shear-arrival, particularly when the paths are direct rays with little possibility of head-wave, channel-wave, or surface-wave interactions. We consider that some form of anisotropy must be the cause of the split shear-arrivals.

We suggest that dilatancy is the only possible explanation of this anisotropy. Stress on cracked rock (all crustal rocks are heavily cracked[2-5], although many of these cracks may be initially sealed) causes the cracks to open and close anisotropically[6], and such dilatant structures are expected to cause shear-wave splitting[1]. Dilatancy is the only possible explanation of anisotropy, which can have such large, if not dominating, effects in such otherwise heterogeneous regions as Turkey and Armenia. A demonstration that the delays between the shear waves vary with time (stress) would confirm our interpretation.

Clearly, such splitting is not easy to analyse. However, some conclusions can be drawn from the existing data: many of the shear waves in the TDPNET records (Fig. 2*a*) and Armenia[15] do not split parallel to SH or SV, but into more general orientations. This supports the hypothesis that the splitting is not caused by isotropic conversions. It also suggests that the dilatancy is unlikely to consist of horizontal cracking as suggested by Wang[19], which would result in transverse isotropy and splitting only into SH or SV components.

Figure 2 shows several abrupt changes in direction of the shear-wave polarizations. These may be due to complicated local structure, but may also be due to a curved wavefront propagating through a structure with comparatively strong anisotropy. The group-velocity vector is not, in general, parallel to the phase-velocity vector in anisotropic media[12]. Consequently, the map of the positions reached by the energy of two shear-waves radiating from a point in a given time, the wave surface, may be extremely complicated, with three-dimensional cusps, ridges, and multiple points. Cusps, in particular, are very common features of shear-wave energy propagation in anything other than very weak anisotropy. Rays propagating in directions within a cusp may have four shear-wave arrivals, with different velocities, different polarizations, and wavefronts which are not parallel. The density of cracks in Earth structures is large enough to produce strong anisotropy: the only detailed field measurements of velocity anisotropy known to us[2] were interpreted[3] as due to two sets of intersecting cracks, each with crack density of the order of 0.2. The large crack densities were due to large dimensions and aspect ratios. Thus, some crack anisotropy in the Earth is strong enough to produce complicated wave-surfaces containing cusps, and this is preferred explanation for the several abrupt changes of polarization in Fig. 2.

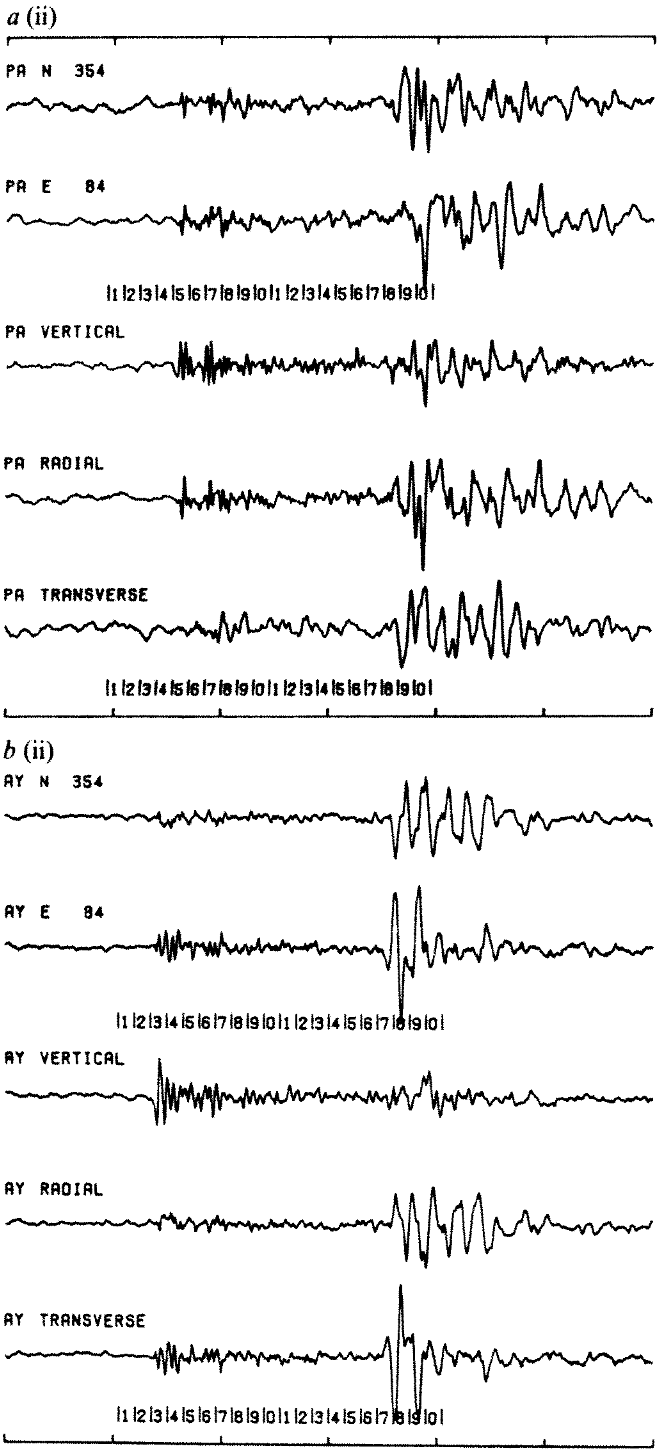

Fig. 2 Examples of seismograms and polarization diagrams for a small earthquake on 15 September 1979 with epicentre 40°42′10″ N, 29°57′13″ E, depth 13 km, and magnitude $M_L = 1.5$. The seismograms are, from the top: unrotated horizontals N 354° E and N 84° E, vertical, and rotated radial and transverse components. The numbered polarization-diagrams for P- and S-wave arrivals are the projections of the particle motion on to three orthogonal-planes for the correspondingly numbered 0.15-s time-windows marked either side of the rotated traces. Directions: U, up; D, down; T, towards; A, away from the source. L, left; R, right in the direction of the station. Each set of three diagrams has been normalized and the relative multiplication factor is marked at the bottom left of each diagram. The heavy arrows on the horizontal projection of the S waves mark the first S-wave arrival, and the subsequent arrivals of phases with different polarizations. Cross bars marked on the polarization diagrams at every 1/100 s, allow delays to be estimated. *a*, Seismograms at PA: hypocentral distance 17 km; azimuth of arrival N 305° E. *b*, Seismograms at AY: hypocentral distance 18 km; azimuth of arrival N 5° E.

Our comparatively simple hypothesis of extensive dilatancy links several previously unrelated earthquake phenomena, and seems to be present to the several seismic regions of North Anatolia, Armenia, Fergana, and possibly Nevada. Our suggestion that stress in the Earth can be monitored by examining shear wavetrains in polarization diagrams would be very important for earthquake prediction studies. All previous precursors, including V_P/V_S anomalies[1], are probably indirect effects of this dilatancy, and seem to occur unpredictably. The TDP experiment suggests that polarization anomalies may occur in almost all shear wavetrains propagating through dilatancy zones, and might be generally available for estimating changes in the Earth's stress.

We thank Dr J. C. Savage for helpful comments. This research has been supported by various organizations, but mostly by the Natural Environment Research Council and Kandilli Observatory. This letter is published with the approval of the director of the Institute of Geological Sciences.

Tritium in the deep North Atlantic Ocean

William J. Jenkins & Peter B. Rhines

Woods Hole Oceanographic Institution, Woods Hole,
Massachusetts 02543

A distinct core of tritium (from nuclear weapons testing in the atmosphere) marks the southward flowing jet of the deep western boundary current of the North Atlantic circulation at 30 °N latitude. The concentrations, of the order of 0.5–1.0 TU (1 tritium unit = 1 ^{3}H atom per 10 ^{8}H atoms), indicate a roughly 10-fold dilution of source waters in the far north. This thin jet, 50 km in width, carries water into subtropical regions which, until recently, were free of anthropogenic tritium. It underlies the more extensive distributions of tritium found in more rapidly renewed waters above the permanent thermocline.

The deep waters of the world's oceans have descended from the sea surface in a very few regions of the far northern and southern Atlantic. Stable density stratification constrains the actual sinking processes to be locally intense and variable, but the great mass of deep ocean is such that the replenishment process proceeds on a time scale of centuries. This planetary-scale thermohaline convection thus provides a long time-constant for many aspects of the ocean–atmosphere system.

Both climatic change and the dispersal of pollutants and trace chemicals in the biosphere are influenced by the slow overturning of the sea.

Observations[1-5] (Fig. 1*a*) and theory[6-7] suggest that the deep and abyssal flow proceeds initially equatorwards, away from the sources of sinking water, along concentrated paths lying near western continental or topographic boundaries. A complementary poleward and upward circulation occurs, apparently, as a broad, weak flow in the interior of the ocean basins. The combination of this circulation with turbulent exchange between boundary current and interior establishes the large-scale gradients of chemical properties, such as the saline tongue[8] in Fig. 1*a*. The flow at this temperature horizon (1.9 °C) is traceable to both Arctic and Antarctic sinking regions.

The decisive influence of boundary currents on the global distributions of trace material has motivated an observational programme, described elsewhere[9], at a site where the deep boundary current is particularly well defined, Fig. 1*b*. In this programme current meters, CTD profilers, XBT probes and, by chance, visitation, drifting surface- and deep floats were used to examine the core of the current, and its relationship with the basin-wide circulation.

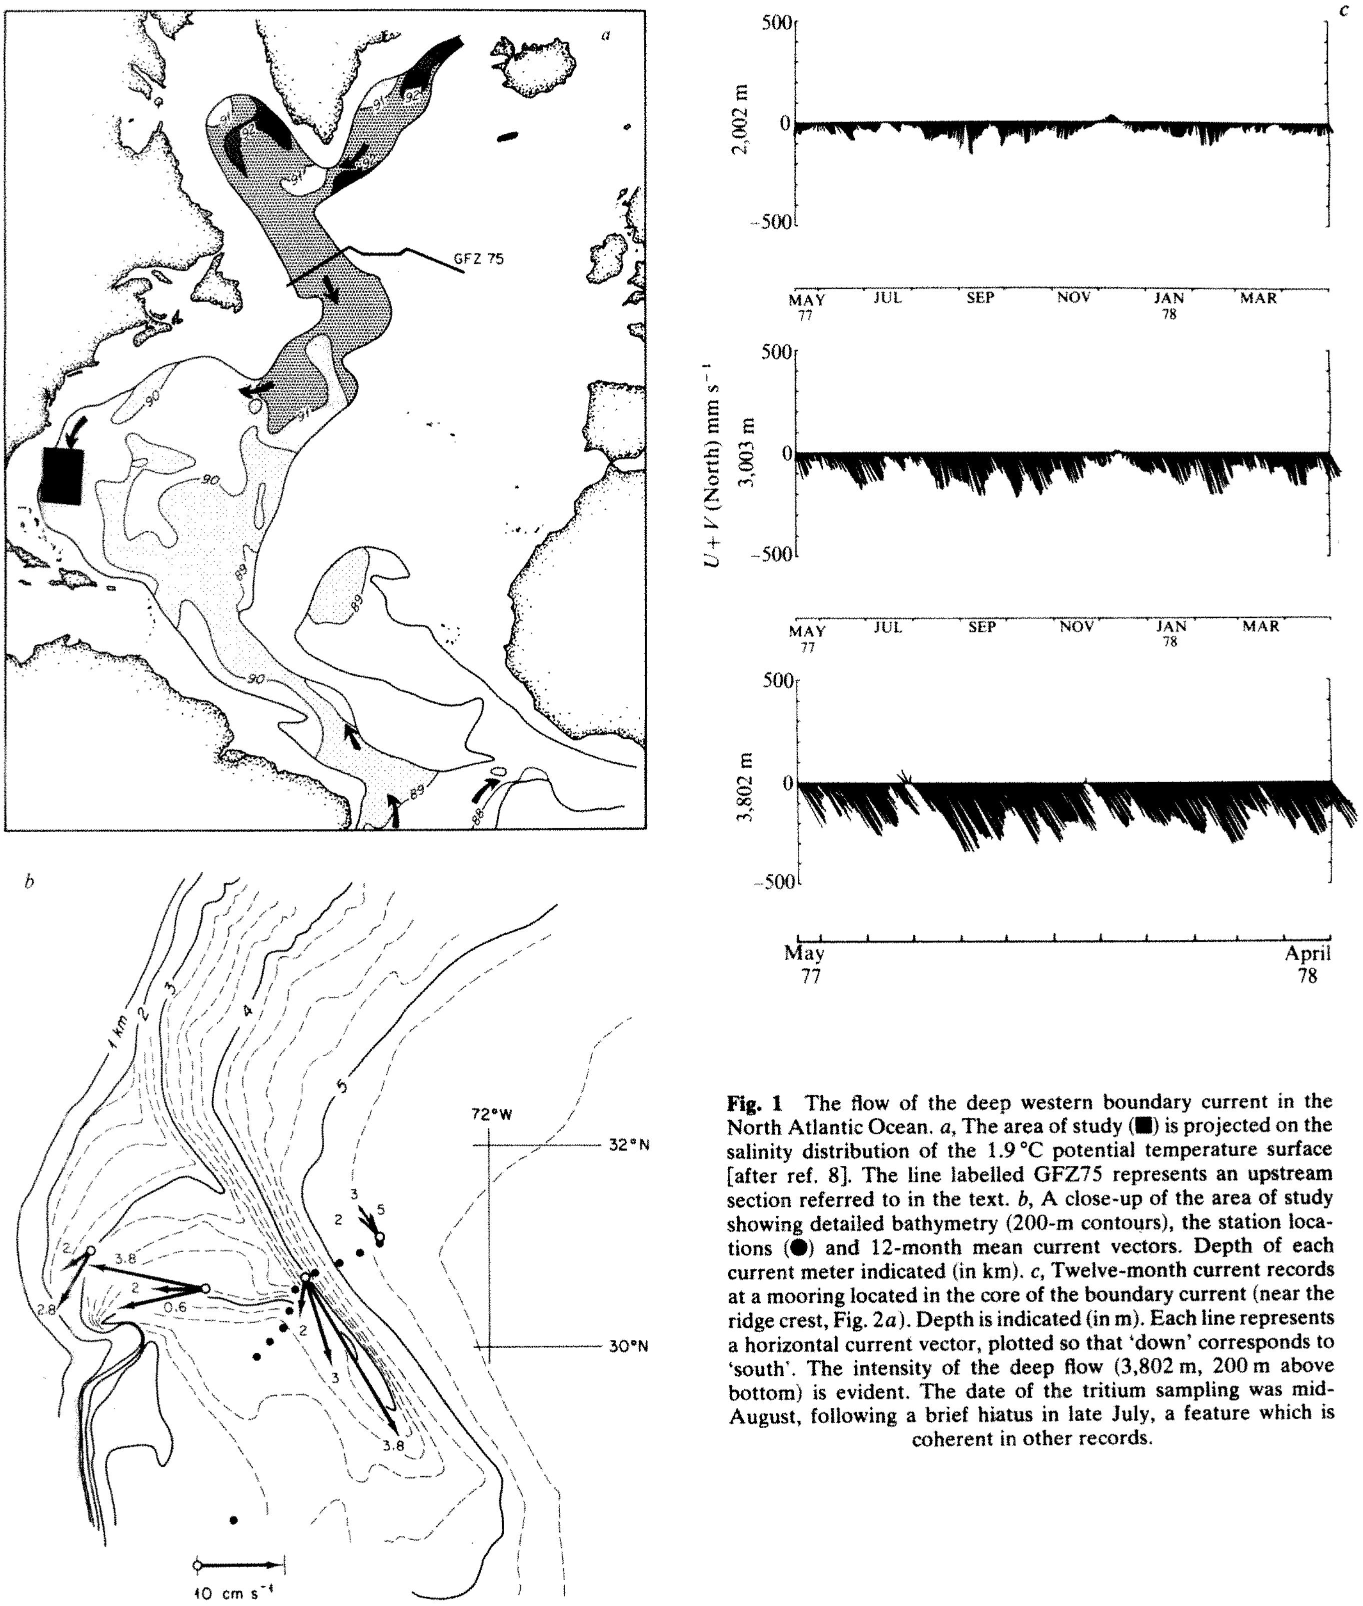

Fig. 1 The flow of the deep western boundary current in the North Atlantic Ocean. *a*, The area of study (■) is projected on the salinity distribution of the 1.9 °C potential temperature surface [after ref. 8]. The line labelled GFZ75 represents an upstream section referred to in the text. *b*, A close-up of the area of study showing detailed bathymetry (200-m contours), the station locations (●) and 12-month mean current vectors. Depth of each current meter indicated (in km). *c*, Twelve-month current records at a mooring located in the core of the boundary current (near the ridge crest, Fig. 2*a*). Depth is indicated (in m). Each line represents a horizontal current vector, plotted so that 'down' corresponds to 'south'. The intensity of the deep flow (3,802 m, 200 m above bottom) is evident. The date of the tritium sampling was mid-August, following a brief hiatus in late July, a feature which is coherent in other records.

As a part of the geochemical programme, 280 samples were taken for tritium analysis. Being part of the water molecule, tritium represents an ideally passive tracer. There are no known chemical or biological processes in the deep sea that alter or scavenge it. Tritium has well-defined but time-dependent boundary conditions and its lifetime (12.26 yr half life) is comparable to the circulation time scale of the western deep North Atlantic. Unlike the relatively steady-state nature of other geochemicals, the natural inventory of tritium has been dwarfed by massive production by recent nuclear weapons testing[10]. This tritium 'spike' entered the surface oceans primarily at high northern latitudes[11,12] in the form of tritiated water. Natural surface water tritium concentrations were about 0.2 TU. Present subtropical surface water concentrations are of the order of 5 TU, and were higher than this in 1964–65, soon after the peak in weapons testing. Östlund *et al.*[13] reported tritium measurements from the 1972 GEOSECS expedition which clearly showed the sinking and southward penetration of tritium. South of 40 °N, however, the North Atlantic GEOSECS track left the western boundary, and no further abyssal tritium was apparently recorded. At shallower depths other studies have documented the downward penetration of tritium into the main thermocline[14,15].

In the present experiment we sought to determine how much water flows equatorwards at the mid-latitude western boundary, and how much of this water is of far-northern origin. The observations were sited near the Blake–Bahama Outer Ridge at 30 °N latitude. This prominent sedimentary ridge acts as the western boundary of the ocean at levels deeper than ~3,500 m. The 12-month average currents seen at four moorings show clearly the boundary current winding along contours of constant depth (Fig. 1*b*). The easternmost mooring exhibits a weak flow counter to the jet (northwestward), thus establishing the width of the jet at ~50 km.

A sample current record[9] (Fig. 1*c*) shows the increase in intensity of the jet with depth, on the eastern flank of the ridge. Despite surges of 40 cm s^{-1} and occasional periods with no southward flow, the mean velocity, 21 cm s^{-1}, is quite representative. The time of tritium sampling, 4–8 August 1977, occurred shortly after a hiatus, but is characterized by velocity typical of mean conditions.

Samples were taken using a 24-bottle, 1.2-l Niskin rosette sampler mounted on the CTD frame. The samples were transferred to GEOSECS-type clamped copper tubes[16]. Tritium was determined by the ^{3}He regrowth technique[17] to an accuracy of 1.5% and a detection limit of 0.04 TU.

The deep western boundary current is distinctly outlined by a high concentration of tritium, Fig. 2*a*. The core overlies the ridge at ~4 km depth. Tritium levels decrease dramatically both above and to the east of the jet, but with some evidence of activity in the westernmost part of the section. The potential isotherms (dashed) superimposed on Fig. 2 are banked up on both sides of the ridge, consistent with the strong southward flow on the eastern side, and northward flow on the western side.

The most intense (highest tritium level) part of the core is noticeably smaller than the region of banked isotherms. The tritium isopleths extend over the ridge-crest, more or less along potential isotherms. If this were an ideal flow directly parallel to the depth contours, the currents on the western and eastern sides of the crest would be effectively 400 km apart, in the downstream sense. The continuity of the tritium core, however, suggests that some cross-ridge flow is taking place. This flow is verified both in current-meter and drifting float data (note the veering with depth of the mean current vectors, Fig. 1*b*). The eastward turn in the depth contours is apparently too sharp to be negotiated by the jet, which rides over the crest.

The tritium data are plotted against potential temperature in Fig. 2*b*. For reference we have also plotted the mean data for the *Panulirus* station off Bermuda (32° N, 64.5° W)[15], and for a section across 53° N[18]. This section is labelled GFZ-75 on Fig. 1*a*. The *Panulirus* data were taken at essentially the same time as the present section, whereas the 53° N section occurred 2 yr

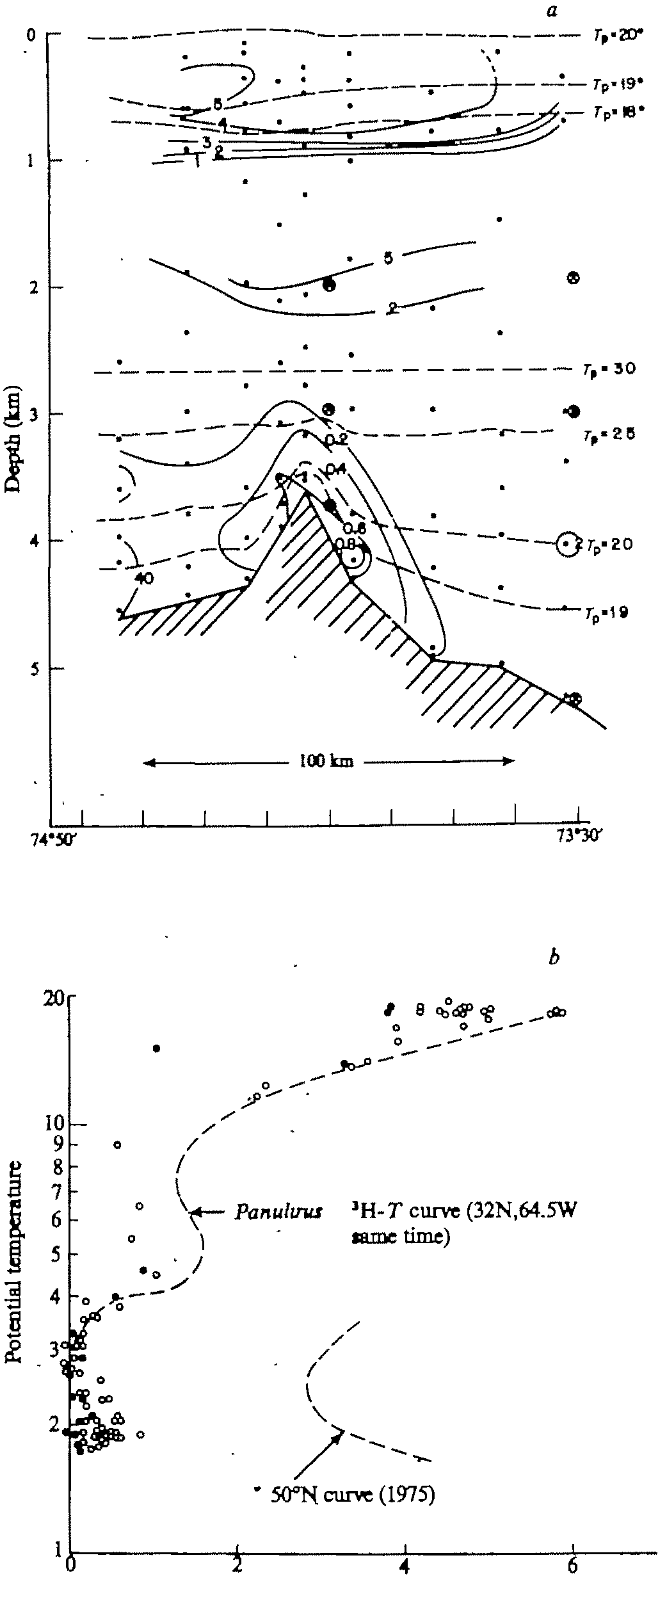

Fig. 2 The tritium results for the section. *a*, The tritium isopleths (solid lines) for the undercurrent hug the ridge, and extend over the ridge in a manner parallel to the isotherms (dashed lines). The far-northern water, marked in this way, occupies only a small part of the broader southward flow at this time. Note also the westward enhancement of the shallow (350 m) tritium maximum, and the associated thermal structure (that is, the dip in the 18 and 19 °C isotherms). ⊗, Current meter positions. *b*, The temperature–tritium relation for the stations. ●, Stations outside of the current; ○, corresponds to undercurrent stations. For comparison, the T_P–^{3}H curves for a central Sargasso Sea station (*Panulirus*) and an upstream section (see Fig. 1*a*) are shown.

earlier. The principal source for the deepest levels is the Denmark Strait overflow of waters from the Greenland–Norwegian Sea, with lesser contributions from the Iceland–Scotland overflow farther to the east. If the far northern section indeed represents the upstream boundary conditions for the deep flow at the Blake–Bahama Outer Ridge, then we are observing an effective dilution of those waters by a factor of 5–10.

Above the tritium core the concentrations decrease essentially to zero at $\sim$2.8 °C or 3,000 m depth (0.01 ± 0.03 TU, seven analyses). It is remarkable that this zero layer occurs at these temperatures, for a persistent southward flow is observed at 2,000 m and below (Fig. 1*b*), and the penetration of North Atlantic Deep Water at these levels throughout the world ocean requires southward transport at this latitude. At the time of this section, the water in the 'zero layer' had apparently been entrained from subtropical mid-ocean, rather than having flowed simply from the far north. SOFAR float data of Rossby exhibit several chance occurrences of this kind of entrainment at 1,900 m depth. An upper limit to the amount of 'northern component water' at this depth is found by comparing the <0.07 TU (95% confidence limit) in this water with the >2 TU found in the corresponding source waters, giving a maximum contribution of a few per cent. The dynamics of the mean circulation changes greatly with depth, as shown by this cut-off of tritium. The role of mesoscale eddies may be important, both in determining the time-mean circulation[19] and in causing sampling problems in sections like this one.

Above the 'zero layer', at temperature >3.4 °C, the tritium increases to a slight maximum in the range 4–6 °C. This feature corresponds closely to the feature observed in the *Panulirus* data[15], but it is less intense. The two data sets merge below this maximum (3–4 °C) and also within the main thermocline (10–15 °C). In the upper thermocline the mean gyre is larger in extent, and eddy stirring more intense, than in the deep water. One expects tritium to be more broadly distributed, therefore, at upper levels, just as Fig. 2*b* suggests. Above 18 °C the present data tend to drop to lower tritium concentrations. The subsurface maximum is evidence of southward penetration of freshly ventilated 18°-water away from its formation region, just south of the Gulf Stream. A westward tritium enhancement can be seen in section in Fig. 2*a*, at a depth of 300–500 m. Analysis of the current meters and XBT data[9] associates this upper pattern with a particularly large, energetic, anti-cyclonic eddy of the 18°-water. It may be that upper-level Gulf Stream rings and other thermocline eddies carry distinct tritium markings.

The detection of a substantial tritium signal in the core of the deep western boundary current at 30 °N establishes a transit time of $\leqslant 15$ yr for water from the far northern ocean surface, with from 5- to 10-fold dilution. The transit time along the deep western boundary, itself, would require only of the order of 2 yr, at speeds of the order of $10\ \mathrm{cm\ s^{-1}}$. Abyssal tritium has not, to our knowledge, been seen before equatorwards of the polar front. Because of the eddy mixing and eddy-induced deep circulation, particularly that beneath the Gulf Stream, we could not be certain that the core of northern water would occur in the boundary current. In fact, a neighbouring section, 150 km to the south, showed far weaker anomolies of dissolved silicate, implying that other markers of northern origin like tritium would, in that instance, be weak as well. Conversely, we expect tritium to appear intermittently outside of the boundary current, in mid-ocean (although none was reported at this latitude, at 50° W longitude, in the GEOSECS section[13]).

The strong differences in eddy stirring, mixing, and mean circulation, from one depth to the next, are mirrored in the tritium concentration. Further sampling may help to establish the broader patterns of penetration across the Gulf Stream front. The results reported here underline the value of combining a variety of measurement techniques (current meters, XBT and CTD transects, floats and standard geochemistry) with radiochemical measurements. It would be of great import to problems in deep-water circulation and to the related problems in climatology (through oceanic heat-flux), atmospheric chemistry and dynamics, to obtain more such data before the tritium transient expires.

This work was performed under the auspices of contract N00014-76-C-0197, NR 083-400 with the Office of Naval Research and grant nos OCE 76-81774 and OCE 76-81190 from the NSF. Contribution no. 4439 from the Woods Hole Oceanographic Institution.

New constraint on the maintenance of Mn nodules at the sediment surface

David Z. Piper & Bradford Fowler
US Geological Survey, Menlo Park, California 94025

Investigations into the association of manganese nodules with pelagic sediment in many areas of the deep ocean have mainly considered either (1) the source of metals in nodules, or (2) the occurrence of nodules predominantly at the sediment surface. The second problem is duscussed here. The mechanisms previously proposed have failed to consider that nodules retain their orientation at the sediment surface for several hundred-thousand years, during which time several tens of centimetres of sediment are fluxed down beneath them. Although we have no conclusive evidence, we consider the most plausible explanation for the surface occurrence of nodules to be bioturbation by infauna.

Approximately half of all nodules occurring in the upper few metres of pelagic sediment are at the sediment surface[1,2]. Radiometric and non-radiometric techniques[3–5] require that these nodules accrete at a rate of ~ 1–$10\ \mathrm{mm\ Myr^{-1}}$. The fine-grained fraction of sediment on which nodules rest, consisting mostly of lithogenic debris and biogenic SiO_2 and CaO_3, accumulates[5] at a rate of ~ 1–$10\ \mathrm{mm\ kyr^{-1}}$. Why then are nodules not buried by this 'avalanche' of fine-grained sediment?

Nodules, usually spherical to discoidal, have a diameter between $\sim$5 and 100 mm, but average[7] about 30 mm. Assuming an approximate growth rate of $5\ \mathrm{mm\ Myr^{-1}}$, which is independent of size[8], nodule ages are of the order of 1–10 Myr. In most areas, the surface sediment on which they rest is still accumulating. What is the mechanism which redistributes the continuously accumulating fine-grained fraction of sediment beneath nodules? In some exceptional areas, however, nodules rest on ancient sediment[9] where erosion may currently be occurring.

Because nodules are denser than the underlying sediment, this suggests that nodules should sink through the upper layer of unconsolidated clays, which consist[10] of 80%, or more, interstitial water. Hypotheses explaining the surface occurrence of nodules have been coupled with explanations of how nodules

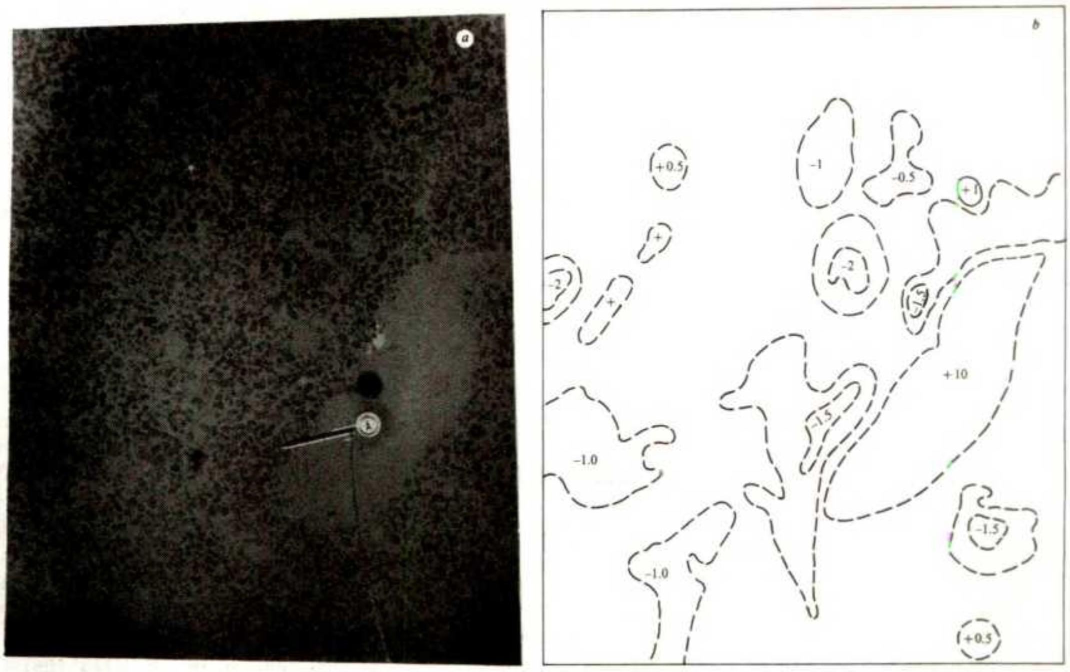

Fig. 1 *a*, Bottom photograph taken at 126°05′ W, 15°08′ N, 4,520 m depth. *b*, Relief map of the sea floor. The numbers in the enclosed contours give the approximate elevation (+) and depth (−) of these areas from the intervening area. The compass face is 7.5 cm in diameter. The compass is approximately 1 m above the bottom. Nodule coverage is often greatest in depressions; see, for example, the 2-cm depression north of the compass vane. The south-facing slope of this depression has low nodule coverage, suggesting that nodules have moved down slope into the depression. The area immediately surrounding the 10–cm mound has a nodule coverage similar to the rest of the area, suggesting that nodules have not been moved laterally during its construction.

are pushed up against this apparent tendency to sink. This approach requires active means of moving nodules upwards. There are several objections to these active mechanisms of keeping nodules on top of the sediment, but first we consider density.

According to Archimedes' principle, an object wholly or partially immersed in a fluid floats if its density is less and sinks if its density is greater than the fluid density. As the wet densities of nodules and sediment are ~2.4 and 1.3 g cm^{-3} respectively, why do nodules not sink through the upper layer of sediment? This layer, consisting of the most recently fallen sediment, is unconsolidated.

Vane shear measurements show that this sediment layer has solid- as well as fluid-like properties. Comparing these measurements with calculated loads exerted by nodules indicates that the sediment strength is much greater than that required to support surface nodules. Measurements have been made on box cores from the three Domes areas in the equatorial North Pacific[10]. Only the heaviest nodules and weakest sediment were considered. At a depth of 7 cm, the sediment has a strength 40–170-fold greater than that required to support surface nodules (Table 1). Shear strength measurements on the upper few centimetres of sediment are rare but they suggest a decrease towards the surface of ~75%. However, in the upper 7 cm of sediment, where nodules are most abundant, the critical load, the total load that sediment is capable of supporting before its failure, is six times greater than the measured shear strength, owing to the shear pattern developed during failure[11]. Thus, once nodules are positioned at the surface, the sediment strength is more than adequate to support them, that is, to prevent their sinking.

Table 1 Comparison of sediment shear strength at a depth of 7 cm in five box cores* and the load exerted by the largest nodules within each box core.

Dome cores station-box core[7]	Nodule load (p.s.i.)	Sediment strength (p.s.i.)
47–12	0.012	2.04

* The cores were collected in the equatorial North Pacific at the three Domes sites. See ref. 10 for exact locations and depths.

Previous explanations of the sea floor occurrence of nodules can be divided into two groups of mechanisms, physical and biological. The physical group considers that nodules are picked up and/or rolled over by bottom currents[12], or maintained at the surface by seismic activity[13]. Glasby[12] considered the force that bottom currents might apply to a nodule and found that it is comparable with the force necessary to maintain a nodule at the surface. However, it is not clear how a horizontally moving bottom current could move a partially buried nodule in a vertical direction without also suspending a quantity of fine sediment, which, on redeposition, would bury the nodules deeply. There are two other arguments against this mechanism.

First, if currents are responsible for rolling nodules over, large nodules are more likely to be buried than small nodules. Heath[8] has shown, however, that burial of nodules is independent of nodule size. Second, nodules retain the same orientation in the sediment for several 100,000 yr. According to Glasby, development of the different surface textures observed on the top and the bottom of nodules requires ~2.5×10^5 yr. Radiometric analysis of nodule tops and bottoms[14,15] also requires that nodules maintained a single orientation for $0.5–5\times10^5$ yr. Polynucleated nodules are frequently recovered from the sea floor. If 0.5 mm of concretion is needed to hold two nodules together, several 100,000 yr are required during which the two nodules could not have moved with respect to each other. Thus nodules are thought to turn over no more often than every 250,000–500,000 yr. The amount of sediment accumulating during this time in most nodule areas is several tens of centimetres, enough to bury nodules deeply. Thus, any dynamic process that turns nodules over cannot maintain them at the surface.

The possible effect of seismic activity[13] cannot be discounted, but nodules occur[16] in oceans in some of the World's most seismically quiet areas[17].

The role that organisms might have has been variously discussed. Menard[18] has examined bottom photographs which show organisms partially protruding from under nodule edges. He suggested that these organisms may be pushing nodules up. It has been suggested[19,24] that organisms may maintain nodules at the surface by rolling them over. This mechanism has the same difficulties as any dynamic process. Epifaunal organisms may remove sediment from nodule tops, possibly as part of their feeding activity[20]. This activity may keep the nodules free of sediment temporarily but it does not contribute to the down fluxing of sediment beneath nodules. In the absence of sediment down fluxing, the sea floor would soon develop a waffle-like pattern, with a nodule occupying the depression. No such evidence has been found in hundreds of stereophotographs taken of the seafloor in the equatorial North Pacific. Instead, sediment in internodule areas is lower than the nodule tops.

Bottom photographs indicate that organisms actually bury nodules. In many bottom photographs that show a nodule coverage of 25%, areas barren of nodules often correspond to mounds. These mounds, either circular or elongate, in plan view and a few centimetres high, often have a small caldera at the top. Mounds of this type are never surrounded by nodule concentration significantly different from that observed throughout the photograph (Fig. 1*a*). Clearly these mounds are constructed by infauna that excavate sediment from beneath and pile it on top of the nodules. This mechanism may allow nodules to drift downward, and become buried. It would also allow nodules to turn, or rotate, during any downward plunge of a few centimetres, provided that undermining was not laterally uniform.

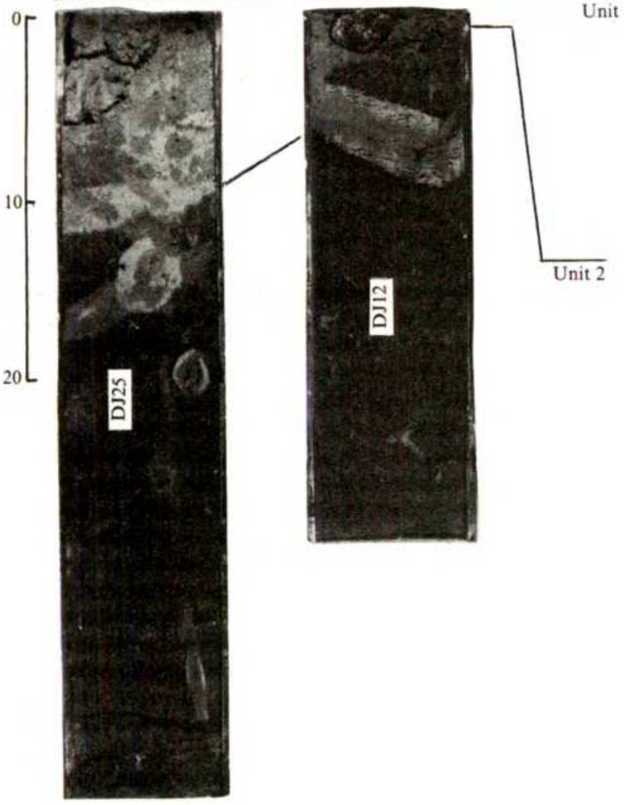

Fig. 2 Subcores from box cores DJ-25 and -12 at Domes Site A, 8°27′ N, 150°47′ W, ~5,200 m. Intersecting burrows are present in DJ-25 at a depth of 10 cm and 14 cm. The nodule in DJ-12 rests on ~0.2 cm of light-coloured surface sediment, which also fills the large burrow at 6 cm depth. Scale, 20 cm. *Unit 1*: 0.2–10 cm thick; strongly mottled; greyish-orange and pale yellowish-brown; 95% Quaternary radiolaria; surface nodules have granular texture and 2–10 cm diameter. *Unit 2*: Greyish-brown mottling with surface sediment; dominantly Miocene–Eocene radiolaria with <1–5% Quaternary radiolaria.

These mounds are superimposed on a sea floor topography consisting of ridges and depressions which have a relief of ~5 cm. These depressions, 15–25 cm across and having a relatively high nodule coverage, are usually surrounded by a ridge which slopes more steeply into than away from the depression. The steeper slope often has a relatively low nodule coverage, suggesting that nodules have drifted down slope into the depression.

How do nodules remain unburied at the sediment surface without reorientation for up to 500,000 yr and how does sediment end up beneath a relatively motionless nodule? The mechanism must transport sediment beneath the nodule at a rate fast enough to overcome sedimentation of new material as well as to overcome the activity of mound-building organisms. Bioturbation might provide the appropriate downward sediment flux which leaves the nodules exposed and undisturbed.

Bioturbation by infauna can transport sediment with two possible effects. (1) Organisms can excavate a volume of sediment at depth and fill in with an equal volume of sediment. The fill material may or may not be more compacted than the original sediment. It will probably contain a fraction of recently deposited surface sediment as this sediment should contain the greatest percentage of labile organic matter. Replacement by more compacted sediment produces a net downward flux but does not lift the sea floor. (2) Organisms can wedge through the subsurface sediment and fill in with some fraction of the uppermost surface material. This option results in lifting of the sea floor, that is, nodules and the surface veneer of sediment. At a depth as great as several millimetres below the nodules, wedging and filling might well leave surface nodules undisturbed.

Bioturbation and downfluxing of sediment through internodule areas are strongly supported by mottling (Fig. 2) and by the frequent occurrence of mixed fauna in the uppermost few tens of centimetres of sediment. Quaternary species decrease in relative abundance with depth in the sediment. Quaternary plankton often are mixed with those of Tertiary age, and the Quaternary species decrease in relative abundance with depth in the sediment[21]. Examination of 25 box cores taken at the three Domes sites supports excavation, however, as opposed to wedging. In three cores where cross-cutting burrows are well preserved (Fig. 2), the older burrow seems to be undeformed by the younger burrow.

For manganese nodules to remain at the surface of the sea floor, sediment must be transported and redistributed beneath them in a way that does not allow the nodule to move with respect to its immediate surroundings. Several tens of centimetres of sediment must be fluxed downward through internodule areas, during which time the orientation of the nodule is not changed. Active mechanisms, which require rotation of the nodules, cannot account for their occurrence at the surface of the sea floor. Wedging through the sediment by infauna such as annelid worms and pelecypods—organisms common to the abyssal environment[22]—and infilling with surface material could provide the mechanism. This type of activity within the pelagic environment, may account for the occurrence of ridges and depressions, which have a relief of a few centimetres (Fig. 1b). Wedging by earthworms has been documented by Darwin[23], but this mechanism for the deep ocean is supported more by default of other processes than by observations.

We thank J. Bischoff and H. Cook for constructive comments and the Domes office of NOAA for its support.

The extent of racemization of amino acids provides valuable information on the chronology of various fossil materials[1-3]. In bone, aspartic acid has received the most attention, and the D/L ratio of this amino acid has been used to estimate ages of human skeletal remains[4-9]. These estimates were, however, based on the degree of racemization determined for total remnant aspartic acid which may exist in various forms (that is, protein, peptide and free amino acid). The effect of the chemical state of amino acids on amino acid racemization rates or ages in calcareous marine sediments[10] and shells[11] has been discussed. In bones, the non-dialysable material in a heated modern sample has a lower racemization rate (isoleucine) than the total organic matrix[12]; free amino acids in fossil bone are more highly racemized than are bound (HCl-insoluble) amino acids[13]. The present investigation was designed to assess such fluctuation of aspartic acid racemization age for a given bone specimen as caused by the variability of the form in which the amino acid is present.

Bones for amino acid analysis were taken from the layers 20, 23B and 25B of the Taishaku Kannondo cave site, Taishaku Ravine, Hiroshima Prefecture in western Japan. All the specimens were long bone fragments of deer or wild boar. A radiocarbon date for a cultural horizon comparable to the layer 20 is 10,085 ± 320 yr BP (I-943)[14,15]. On the basis of stratigraphical and tephrochronological comparisons[14,16], we assume that the layer 23B is dated 16,000 yr BP. Layer 25B is of unknown age, but is overlain by the calcic layer of 24A, which was radiocarbon-dated[17] at 20,150 ± 300 yr BP. An outline of the archaeological contexts of the Taishaku Kannondo site is given elsewhere[14,15].

A small piece (~0.3 g) of transverse section of *Substantia compacta*, cut from each fossil bone, was carefully cleaned by ultrasonication in 0.1 M HCl, ether and double-distilled water. After cleansing, the bones were pulverized and mixed in layers to make an homogeneous powder weighing 1–2 g. Amino acid fractions were isolated using the procedure outlined in Fig. 1. The ratios of D to L-aspartic acid were determined by gas–liquid chromatography of the *N*-trifluoroacetyl isopropyl esters on a 30 m × 0.28 mm i.d. glass capillary coated with *N,N'*-[2,4-(6-ethoxy-s-triazine)diyl]-bis-(L-valyl-L-valine isopropyl ester)[18] (AE-402, from Gasukuro Kogyo, Inc.).

Figure 2 shows a chromatogram obtained for the Tot fraction in the sample from the layer 23B. Table 1 includes the D/L aspartic acid ratios for Ins, Sp and Tot fractions. Insufficient quantities of amino acids, except glycine, for analysis were available in any Sf fractions, and even the glycine was <0.2% relative to that in Ins fraction. This would be due to removal of free amino acids by percolation of ground water or by the ultrasonic cleansing[2].

The interconversion of aspartic acid enantiomers is a reversible first order reaction, represented by:

$$\text{L-Asp} \underset{k}{\overset{k}{\rightleftharpoons}} \text{D-Asp}$$

where k is the rate constant. Expressed in the integrated form as a function of time (t), the racemization age equation can be written as

$$\ln \alpha_t - \text{constant} = 2kt$$

where $\alpha = (1 + \text{D-Asp}/\text{L-Asp})/(1 - \text{D-Asp}/\text{L-Asp})$ at time t after the start of the reaction. The integration constant is a correction mainly due to the small amount of racemization that takes place during sample preparation procedures. For example, the value of this constant for Tot fraction, calculated from our datum (D/L = 0.063) obtained for a modern bone, is 0.126. However, where it is possible to use two bones from a single site, the dates (t_1, t_2) of which lie at a time interval suitable for 'calibration[4]', the rate constant of racemization during the interval $t_1 \sim t_2$ is given by:

$$2k = (\ln \alpha_{t_1} - \ln \alpha_{t_2})/(t_1 - t_2).$$

When $t_1 > t_2$, and t_2 is the age of the start of the Holocene (~11,000 yr), this equation yields the pre-Holocene k value. Thus the k values in Table 1, calculated with the samples from the layers 20 and 23B used for 'calibration', correspond approximately to the pre-Holocene rate constants for the respective fractions. This procedure eliminates the need of setting the enantiomeric ratio for modern bone in the aspartic

acid racemization age equation, thus minimizing the errors that result from the changes in, for example, concentrations of noncollagen proteins[19,20] and metal ions in bone with the lapse of time in geological environments. Note that our k values are not directly comparable with the late Pleistocene k values presented by Bada *et al.* (see, for example, ref. 1), as we subtract out the greater part of the Holocene k value.

As Table 1 shows, the order of racemization rates is Sp fraction > Tot fraction > Ins fraction, comparing well with that observed in foraminifera[10] or in shell[11]. This result is also consistent with what Bada[12] found for the total bone organic fraction versus the non-dialysable fraction.

The racemization age of the layer 25B sample is calculated from

$$t = t_2 + (\ln \alpha_t - \ln \alpha_{t_2})/2k.$$

Substituting 10,085 for t_2, and with the other relevant data, we have 23,700 yr BP (Ins fr.), 19,900 yr BP (Sp fr.) and 22,900 yr BP (Tot fr.). The D/L Asp data in Table 1 give the proportions of aspartic acid in peptide to protein form (Sp/Ins–Asp) in bone. These values are 41, 48 and 63% for the samples from the layers 20, 23B and 25B respectively. The increase in SP/Ins–Asp value in the longer-buried bones suggests the continuous degradation of collagen. The introduction of the collagen-breakdown product (less racemized) into the Sp fraction may induce the lower age estimate for this fraction. Preliminary analyses of main components of amino acid extracts showed that these Sp fractions are collagenous in composition, although the Hypro/Pro and Ala/Pro ratios in Sp fractions are ~17% and 23% reduced relative to those in respective Ins fractions. The above findings would have a notable bearing on the radiocarbon dating of bone. The HCl-insoluble fraction, which is usually used for ^{14}C dating, becomes less and less abundant with time. Hence, it would be very interesting to radiocarbon-date the HCl-soluble fraction to which little attention has previously been paid.

The two racemization ages of the Ins and the Tot fractions are compatible with the radiocarbon date of the layer 24A. However, the age estimate based on the total aspartic acid could vary with the proportion of this amino acid in soluble to insoluble state. Variance of Sp/Ins–Asp value in the layer 25B sample, for example, from 50 to 70% should yield the racemization age of 20,000–24,000 yr BP for the Tot fraction.

Such fractional amino acid analyses provide a way of aspartic acid racemization-dating of fossil bone. Where the Sp fraction has a collagenous origin, it is useful for estimating a minimum (or maximum in the case of dating bone with an age less than that of the calibration sample) age, which because of its faster racemization rate is particularly promising for the younger fossils. The aspartic acid racemization reaction for the Ins fraction seems to be a basis to give reliable age estimates for older fossil bones with ages ranging several hundred thousand yr BP. For the Tot fraction, the degree of amino acid racemization could be depenedent on the dynamics of collagen decomposition. Provided that the ratio of partially degraded to pure collagen exhibits a steady increase with burial time (as is supposed to be the case with bones from a single site), a measurement of the extent of racemization on the total hydrolysate would still have archaeological significance. Where the same calibration is applied to fossil samples with different environmental factors involving the disintegration rate of collagen (probably mainly due to humidity in the site), assuming the effective temperature for racemization is nearly identical, then misleading age estimates would be generated.

Table 1 Aspartic acid racemization in fossil bones from the Kannondo cave site

	Layer	D/L Asp	Aspartic acid age (yr BP)
Ins fraction			
	20	0.084	$k = 1.70 \times 10^{-6}$ yr^{-1}
	23B	0.094	
	25B	0.107	23,700
Sp fraction			
	20	0.199	$k = 9.08 \times 10^{-6}$ yr^{-1}
	23B	0.250	
	25B	0.283	19,900
Tot fraction			
	20	0.115	$k = 4.30 \times 10^{-6}$ yr^{-1}
	23B	0.140	
	25B	0.169	22,900

Analysable amounts of aspartic acid have not been contained in any Sf fractions.

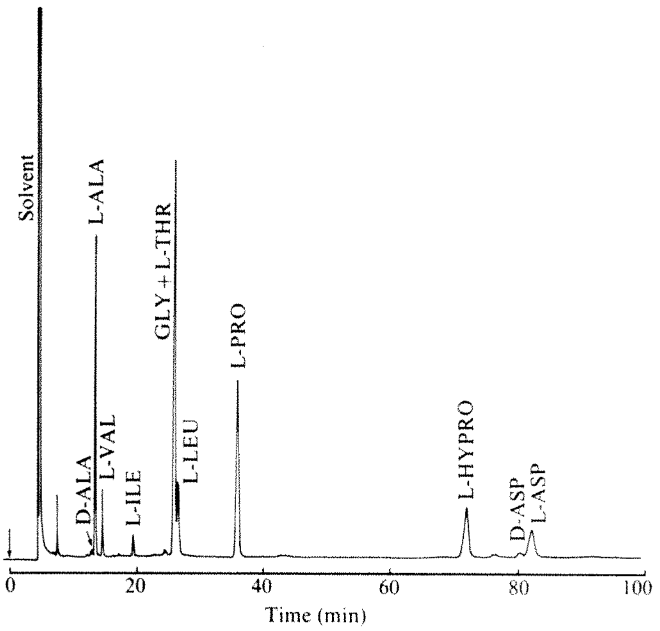

Fig. 2 Gas chromatogram of N-trifluoroacetyl isopropyl esters of amino acids recovered from the total hydrolysate of the layer 23B sample from the Kannondo cave site. Chromatography: 30 m × 0.28 mm i.d. column coated with N,N'-[2,4-(6-ethoxy-s-triazine)diyl]-bis-(L-valyl-L-valine isopropyl ester); temperature, 135 °C isothermal; He pressure, 7 p.s.i.; FID detector.

The present approach would also be useful in overcoming the obstacle caused by the difference in the 'leaching effect'[21] and in improving the reliability of the racemization dating method.

We thank Dr Y. Seyama for his interest and co-operation, Dr E. Gil-Av for advice, Dr J. L. Bada for criticisms, and Miss A. Nakatsuka for drafting help. Bone specimens were provided by the Research Group of Taishaku-kyo sites.

Enhanced plant growth by siderophores produced by plant growth-promoting rhizobacteria

Joseph W. Kloepper*, John Leong†, Martin Teintze† & Milton N. Schroth*

*Department of Plant Pathology, University of California, Berkeley, California 94720
†Department of Chemistry, University of California, San Diego, La Jolla, California 92093

Specific strains of the *Pseudomonas fluorescens-putida* group have recently been used as seed inoculants on crop plants to promote growth and increase yields. These pseudomonads, termed plant growth-promoting rhizobacteria (PGPR), rapidly colonize plant roots of potato, sugar beet and radish, and cause statistically significant yield increases up to 144% in field tests[1-5]. These results prompted us to investigate the mechanism by which plant growth was enhanced. A previous study indicated that PGPR increase plant growth by antagonism to potentially deleterious rhizoplane fungi and bacteria, but the nature of this antagonism was not determined[6]. We now present evidence that PGPR exert their plant growth-promoting activity by depriving native microflora of iron. PGPR produce extracellular siderophores (microbial iron transport agents)[7] which efficiently complex environmental iron, making it less available to certain native microflora.

Plant growth-promoting fluorescent *Pseudomonas* strains A1, BK1, TL3B1 and B10, isolated from potato periderm or roots, exhibited *in vitro* antibiosis on King's medium B[8] agar plates (KB) against the bacterium *Erwinia carotovora*, which causes potato soft rot and seedpiece decay (Fig. 1). When KB plates were amended with 1 μM $FeCl_3$, the antibiosis against *E. carotovora* did not occur, nor was the yellow-green fluorescence of PGPR produced. The above PGPR also exhibited on KB plates *in vitro* antibiosis against *Escherichia coli* K-12 AN193, which does not produce its native siderophore, enterobactin, but not against its enterobactin-producing parent, *E. coli* K-12 AN194. These results suggested that in iron-deficient conditions, PGPR were producing fluorescent siderophores which were responsible for antibiosis against *E. carotovora* and *E. coli* K-12 AN193. Yellow-green fluorescent siderophores have previously been isolated from iron-limiting cultures of *P. fluorescens*[9-11].

We next investigated the effect of iron on plant growth-promoting activity by PGPR in soils. When potato seedpieces were dipped into PGPR suspensions (10^9 Colony-forming units (CFU) per ml) immediately before planting in field soils in a previously described greenhouse assay[5], statistically significant increases in plant growth (total plant wet weight) occurred 2 weeks after emergence. Average increases (six replications with three plants each) were 47% for strain A1, 63% for strain B10 and 74% for strain BK1. The control was an autoclaved suspension of strain A1. In contrast, when 120 ml of 100 μM ethylenediaminetetra-acetatoferrate (III) (Fe^{III} $EDTA^-$) per 600 g of soil were added on alternate days to soils planted with PGPR-inoculated potato seedpieces, PGPR did not statistically increase growth (±4%). Addition of iron alone to soils did not significantly increase plant growth over the control. The effect of iron (III) on colonization of roots by PGPR was examined with strain A1 as previously described[2,6]. Although the addition of Fe^{III} $EDTA^-$ resulted in no increase in plant growth, the bacteria, nevertheless, colonized roots at populations averaging 3.2×10^3 CFU per cm root as compared with 4.4×10^3 CFU per cm without iron.

These results suggested the intriguing proposition that a fluorescent siderophore from PGPR may mimic the biological action of PGPR. To test this, we isolated a yellow-green fluorescent pigment capable of binding iron (III) from broth cultures of strain B10 grown in an iron-deficient medium containing glycerol and proteose peptone no. 3. The pigment was purified to homogeneity by a procedure similar to that of Meyer and Abdallah[10]. This pigment exhibited properties typical of a siderophore, including complete repression of production in culture media containing micromolar amounts of iron (III). Furthermore, both the pigment and its ferric complex reversed iron starvation of strain B10 on KB plates induced by the synthetic ferric complexing agent, ethylenediamine-di-(*o*-hydroxyphenylacetic acid) (EDDA), which is not utilized by the cells[12]. As the chemical and physical properties of this siderophore seem to be different (J.L. and M.T., unpublished results) from those of others isolated earlier[10,11,13-15], we name this new siderophore, pseudobactin. When paper disks containing 20 μl of 200 μM pseudobactin were applied to KB plates previously seeded with *E. carotovora*, 3-mm radial growth inhibition zones about the disks were observed within 12–16 h. Red-brown ferric pseudobactin caused no antibiosis against *E. carotovora* up to millimolar concentrations. These results suggest that the *in vitro* antibiosis of PGPR against *E. carotovora* is caused by iron deprivation induced by the PGPR's siderophore. *E. coli* K-12 AN194 was not susceptible to PGPR because enterobactin may be able to reverse iron starvation precipitated by PGPR's siderophore.

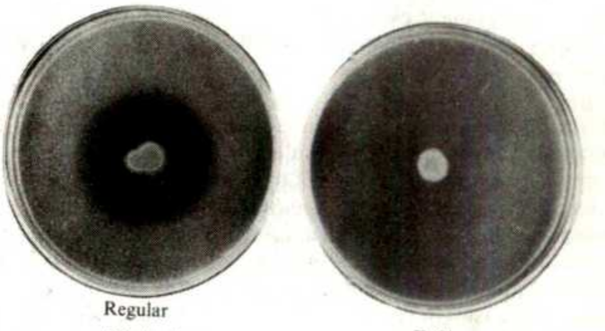

Fig. 1 Plant growth-promoting rhizobacterial antibiosis against *Erwinia carotovora* eliminated by iron (III). Both King's B agar plates were inoculated in the centre with 10 μl of a suspension of fluorescent *Pseudomonas* strain B10 (~10^6 CFU ml^{-1}), incubated for 24 h at 28 °C, and sprayed with a suspension of *E. carotovora* (~10^6 CFU ml^{-1}). The plate on the right contained 10 μM $FeCl_3$, whereas the plate on the left contained no added iron (III). The zone of growth inhibition of *E. carotovora* and the fluorescence of strain B10 were examined at 24 h. Similar results were obtained with fluorescent *Pseudomonas* strains A1, BK1 and TL3B1.

The effect of pseudobactin on plant growth and rhizoplane fungal colonization was determined in the greenhouse assay (Table 1). Both B10 suspensions and pseudobactin at 10 μM caused significant plant growth increases compared with water-treated controls. Ferric pseudobactin at 50 μM and B10 with 50 μM Fe^{III} $EDTA^-$ did not increase plant growth. In addition to increasing plant growth, pseudobactin and B10 treatments resulted in statistically significant reductions of fungal populations on the rhizoplane relative to the water-treated control. Fungal colonization of the rhizoplane, measured by the method of Huisman *et al.*[16], averaged 5.5 CFU per 10 cm root on water-treated plants compared with 2.3 CFU per 10 cm (−59%) on B10-treated plants and 1.4 CFU per 10 cm (−74%) on pseudobactin-treated plants.

Based on these results, we propose the following scenario to account for the enhancement of plant growth by PGPR.

0028–0836/80/350885—02$01.00

Following inoculation and planting of crop seeds, PGPR rapidly colonize roots of the developing plant. As a result of a limited supply of iron in the rhizoplane, PGPR produce siderophores which sequester iron in the root zone, making it unavailable to certain rhizoplane microorganisms. These microorganisms are unable to obtain essential quantities of iron for growth either because they do not produce siderophores, produce comparatively less siderophores than those of PGPR, and/or produce siderophores which have less affinity for iron than those of PGPR. The populations of these microorganisms, some of which are quasi-pathogens (T. V. Suslow and M.N.S., unpublished results), are reduced, and a more favourable environment for root growth is created. Our results with mutants of PGPR support this hypothesis. Certain mutants obtained by treatment with *N*-methyl-*N'*-nitro-nitrosoguanidine or UV light at 254 nm were non-fluorescent, did not exhibit antibiosis against *E. carotovora* and did not promote growth increase of potato in the greenhouse assay even though they were able to colonize plant roots[6]. At least five mutants derived from strains BK1, TL3B1 and TL3B2 were examined. These mutants did not produce siderophores, in contrast to their parents. An alternative hypothesis that plant growth-promoting rhizobacterial siderophores bind iron and make it directly and perhaps more readily available to the plant seems unlikely because ferric pseudobactin did not promote plant growth (Table 1).

Table 1 Enhanced plant growth of potato by pseudobactin in greenhouse assay

Treatment	Average plant weight (g)
H_2O control	1.0
50 μM Fe^{III} $EDTA^-$ control	0.9
B10	2.3*
B10 + 50 μM $Fe^{III}EDTA^-$	0.9
10 μM pseudobactin	2.5*
50 μM ferric pseudobactin control	1.1

Potato seedpieces were planted in field soil (sandy loam) from Moss Landing, California. In treatments with fluorescent *Pseudomonas* strain B10, seedpieces were dipped in approximately 10^9 CFU ml^{-1} suspension before planting. Pots were watered with 120 ml of the appropriate solution on alternate days, and a total of nine applications were made. Plants were harvested 10 days after emergence. An average of six replications with three plants per replication were obtained.

* Statistically significant increase ($P = 0.01$) compared with controls.

We thank Laurence A. Fishel and Susan M. Shoemaker for experimental assistance. This investigation was supported in part by PHS grant AI14084 from the NIH and by the California Potato Research Advisory Board.

Antiquity of the vertebrate pattern of activity metabolism and its possible relation to vertebrate origins

Vertebrates generally possess well developed capacities for anaerobic metabolism, resulting in formation of lactic acid. Those capacities have traditionally been interpreted in terms of adaptation to hypoxic environments or to special situations such as diving. However, anaerobic metabolism in striated muscle tissue is frequently a major source of ATP utilized during periods of intense activity. The evolutionary significance of anaerobically supported activity has not been discussed, although the interrelationships of capacities for aerobiosis and activity have received considerable attention[1]. We present here evidence that the pattern of activity metabolism utilized by extant species probably dates back to the earliest vertebrates. It is also postulated that the evolution of extensive capacity for anaerobically supported burst activity may have been closely related to the evolution of vertebrates from invertebrate chordates.

Many animals use glycolysis, the anaerobic process by which glucose is degraded to lactic acid. Most invertebrate species resort to significant utilization of glycolysis only in the absence of sufficient environmental oxygen to maintain adequate rates of ATP generation via aerobiosis, or oxidative phosphorylation[2]. However, many vertebrate species rely on prodigious rates of glycolysis for ATP generation during periods of maximal activity[3–6]. Such a pattern of activity metabolism enables many vertebrates to reach 'burst' levels of activity otherwise unattainable if they were solely dependent on aerobic metabolism. Heavy reliance on anaerobic metabolism also has its drawbacks: it is inefficient in utilizing substrate, and is invariably associated with muscle fatigue[7]. In addition, resultant intramuscular lactic acid accumulation and subsequent diffusion of lactate into the cardiovascular system[4] disrupts maintenance of blood and tissue *p*H which may well affect enzymatic activity, protein configuration and so on[8]. This exercise-related *p*H depression may persist in lower vertebrates for several hours, or longer, following cessation of strenuous activity[9].

Although some crustaceans generate moderate quantities of lactate during exercise[10,11], most invertebrates produce little, if any, lactate during maximal activity. For example, during periods of intense activity, the insects are highly dependent on aerobiosis[12] and molluscs anaerobically generate octapene and succinate to supply themselves with sufficient ATP[13]. Hence, the vertebrate capacity for lactate generation during activity should not be considered an adaptation for anaerobiosis *per se*: it is not merely a primitive relict of the occupation of oxygen-depleted environments, but is a specific and relatively unique exploitation of glycolysis to support intense activity.

Lactic acid formation during activity has been demonstrated in many extant gnathostomes (sharks[14], teleost fish[6], amphibians[3], reptiles, mammals[5]). Those data indicate that heavy reliance on lactate formation during activity is widespread among vertebrates. However, the antiquity of this pattern of activity support is still unclear; is it a primitive characteristic dating back to, or even previous to, the origin of vertebrates? To

Table 1 Whole body lactic acid concentration and blood *p*H before and after activity in two species of cyclostomes and whole body lactic acid concentration before and after activity in amphioxus

	Lactic acid concentration (mg per g tissue)		Blood *p*H			
Species	Rest	Active	Rest	30 min post activity	60 min post activity	180 min post activity
Pacific hagfish (*Eptatretus stouti*)	0.14±0.01 (*n* = 4)	1.51±0.14 (*n* = 4)	8.03±0.03 (*n* = 5)	7.60±0.12 (*n* = 5)	7.48±0.14 (*n* = 5)	7.31±0.19 (*n* = 5)
Pacific brook lamprey (*Lampetrus pacifica*)	0.17±0.01 (*n* = 5)	1.65±0.18 (*n* = 7)	7.91±0.04 (*n* = 5)	7.16±0.06 (*n* = 5)	— —	— —
Amphioxus (*Branchiostoma caribaeum*)	0.14±0.03 (*n* = 4)	0.29±0.04 (*n* = 8)	—	—	—	—

Post-active depression of blood *p*H probably results from protracted diffusion of lactic acid into the cardiovascular system from striated musculature as well as slow subsequent removal of lactate from the circulatory system. Adult *Lampetra* (36) were obtained by dip net in Oak Creek, Benton County, Oregon, in May 1979. Adult *Eptatretus* (28) were caught in 'fike' traps at a depth of 150 m, 1,000 m off the coast of Coos Bay, Oregon in December 1978. Adult *Branchiostoma* (12) were collected in Tampa Bay, Florida, in December 1979. Animals were maintained in 160-l capacity tanks, situated in thermally controlled rooms set at 12 °C on an 11-h photoperiod. Tank water was kept fully aerated at all times. Experiments were performed 4–6 days after animals were captured. Twelve *Lampetra* (mean mass 6.6 g), 9 *Eptatretus* (mean mass 52.2 g) and 12 *Branchiostoma* (mean mass 0.14 g) were used to determine whole body lactate content either at rest or immediately after maximal activity. Animals were placed individually in a 1 m × 1 m × 0.25 m tank of water equilibrated to 12 °C. They were then stimulated to activity by persistent, noxious but harmless prodding. Reaction of all animals to stimulus was intense, and was assumed to represent maximal activity levels. During stimulation, both *Lampetra* and *Eptatretus* underwent an initial period of vigorous activity lasting 2.5–3.5 min. In both species, this consisted of frantic lateral undulations interspersed with frequent attempts to 'bite' the probe. During the following 1.5–2.5 min, animals appeared to tire but continued to exhibit similar types of behaviour. In addition, mucus was secreted from the slime glands of *Eptatretus* during the entire exercise period. This was removed from the tank approximately every 30 s in such a manner that movements by animals were not hindered. During the initial 10–15 s of the exercise period, *Branchiostoma* underwent intense lateral undulation. Thereafter, they appeared to tire significantly and remained essentially refractory to further stimulus. After 5 min of stimulation, animals were decapitated, homogenized in 0.6 *M* perchloric acid for 2 min in an Oster blender and total body lactate was measured spectrophotometrically by the method of Bennett and Licht[4]. Similar analyses were also made on unstimulated animals to determine lactate levels for resting individuals. Ten *Lampetra* and 20 *Eptatretus* were used to determine the effect of this activity on blood *p*H. Blood samples of 75 µl were taken in heparinized syringes from five previously undisturbed individuals of each species. Samples were withdrawn from tail incisions in *Lampetra* and from the caudal sinus in *Eptatretus*. Elapsed time between first handling and sample procurement was less than 15 s; struggling by animals was minimal during this time period. The *p*H of the sample was measured immediately with a Radiometer Copenhagen BMS3Mk2 blood micro unit connected to a Radiometer Copenhagen PHM 71 Mk 2 acid–base analyser. The temperature of the electrode was regulated at 12 °C ± 0.5 °C. This measurement was assumed to represent the *p*H of the animals' blood at rest. Different individuals of each species were then stimulated to activity for 5 min as described in the previous experiments. Blood samples were collected and analysed (as described for resting individuals) 30 min after cessation of activity in both species. Additional samples were taken 60 and 180 min after activity in *Eptatretus*

elucidate this question, we investigated patterns of activity metabolism in some living agnathans (Cyclostomata) and the protochordate, amphioxus (Cephalochordata). Morphological evidence indicates long evolutionary isolation of cyclostome and gnathostome lineages as well as independent derivation of both groups from the earliest vertebrates, the ostracoderms of the early Palaeozoic (Fig. 1)[15]. Thus, parsimony dictates that occurrence of a particular trait (burst activity supported by anaerobiosis) in both cyclostomes and gnathostomes might be the result of retention of a primitive characteristic present in the common ancestor of both groups.

Activity physiology in extant protochordates, especially cephalochordates, may well be reflective of activity metabolism in the chordate ancestors of vertebrates. Cephalochordates are thought to resemble closely protovertebrates in many aspects of their morphology and in their sedentary, microphagous filter-feeding lifestyle[16]. Consequently, their activity physiology may also be similar.

Cyclostomes investigated in this study included the Pacific brook lamprey (Petromyzontidae: *Lampetra pacifica*) and the Pacific hagfish (Myxinidae: *Eptatretus stouti*). The Pacific brook lamprey is a small, non-parasitic lamprey inhabiting streams west of the Cascade Mountains of the north-west US. These are strictly freshwater forms that never migrate to marine environments. The Pacific hagfish occurs off the west coast of North America from southern California to south-east Alaska in silty-bottom environments at depths of 18–940 m.

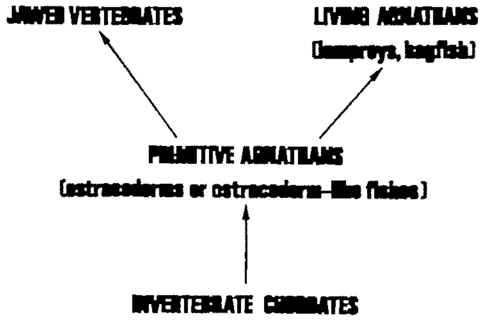

Fig. 1 Phylogenetic relationships of the vertebrates (based on refs 15, 19)

The cephalochordate investigated here was *Branchiostoma caribaeum* (Branchiostomidae). This is a small, burrowing, filter-feeding inhabitant of sandy-bottomed marine environments from Chesapeake Bay to the West Indies.

Both cyclostomes utilized glycolysis extensively during the exercise period (Table 1): lactate concentrations were approximately 10 times greater after 5 min of activity than at rest ($P < 0.05$, *t*-test). In addition, both species experienced a concomitant, protracted decline in all post-active blood *p*H measurements ($P < 0.05$, *t*-test) (Table 1). Quantities of lactate formed as a result of activity and the accompanying extended post-active decline of blood *p*H in these species closely parallel previously described modes of activity physiology among gnathostomes[7,9].

Consequently, utilization of the pattern of activity metabolism described here must be of considerable antiquity, perhaps as old as vertebrates themselves. Figure 1 illustrates the generally accepted phylogenetic relationships of the vertebrates. If these relationships are correct, we must assume the pattern of activity metabolism exhibited by living vertebrates is a result of either (1) convergent evolution between cyclostome and gnathostome lineages; or (2) retention of a primitive vertebrate characteristic. Insofar as premise (2) is the most parsimonious, it must be considered the most likely to describe the actual sequence of events.

The implications of that conclusion for the evolution of vertebrates are manifold. For example, parameters of anaerobically supported activity (such as capacity for high levels of burst activity, fatigue, extended post-active blood and tissue *p*H alteration) have probably vitally affected adaptive radiation of the morphology, physiology and behaviour of virtually all the major groups of vertebrates. In fact, only with the evolution of homeothermy in birds and mammals have aerobic potentials been expanded to the point where, for example, they can support very high levels of activity without consequent fatigue[17].

In contrast, the chordate ancestors of vertebrates may not have possessed such well developed capacities for burst activity as early vertebrates. The cephalochordate studied here was incapable of any more than 10–15 s of intense lateral undulation and generated only minimal quantities of lactate during exercise (Table 1). This pattern of activity physiology is hardly surprising:

cephalochordates, like all adult invertebrate chordates, lead a sedentary, filter-feeding existence and seldom, if ever, take any more than the briefest of forays into the water column. Thus, if current interpretations regarding vertebrate origins are correct (see above), one might reasonably postulate a similarly minimal metabolic capacity for intense activity in the chordate ancestors of vertebrates.

Those differences in capacity for activity between invertebrate chordates and the earliest vertebrates might indicate concomitant and interdependent evolution of vertebrate activity physiology and the appearance of the vertebrates themselves. Halstead[18] and others have rightly emphasized that the earliest vertebrates lacked a vertebral column, but differed from invertebrate chordates in that the latter group never exhibits a high degree of cephalization. Accordingly, as described above, all adult invertebrate chordates are at least relatively sedentary, whereas vertebrates are among the most active of the Metazoa. Thus, vertebrate cephalization may have developed in response to selection for increased sensory and locomotor control as a more active lifestyle evolved. We suggest that the expanded vertebrate capacity for burst activity contributed significantly to that active mode of existence. Consequently, evolution of the vertebrate pattern of activity metabolism may well have been a selective factor contributing to cephalization in protovertebrates and the appearance of vertebrates themselves.

Human cell-surface glycoprotein with unusual properties

M. Bishr Omary*, Ian S. Trowbridge* & Jun Minowada†

* Department of Cancer Biology, The Salk Institute for Biological Studies, Post Office Box 85800, San Diego, California 92138
† Cell Culture Laboratory, Department of Immunology and Immunochemistry Research, Roswell Park Memorial Institute, New York State Department of Health, 666 Elm Street, Buffalo, New York 14623

We report here the identification of human cell-surface glycoprotein with unusual and interesting properties. We initially detected this glycoprotein on the surface of cultured human haematopoietic cell lines by means of a monoclonal antibody. Although it is expressed on all cultured human haematopoietic cell lines tested, including the inducible promyelocytic tumour cell line HL-60 (ref. 1), it is not present in readily detectable amounts on most normal or leukaemic human haematopoietic cells. HL-60 cells, on exposure *in vitro* to appropriate chemical inducers, undergo morphological and functional differentiation along the granulocytic pathway or into macrophage-like cells[2–6]. One consequence of *in vitro* induction is the specific loss of the glycoprotein from the surface of HL-60 cells. The molecule does not, however, seem to be a highly tissue-specific differentiation antigen because it is also found on human tumour cell lines derived from non-haematopoietic tissues. Rather, its expression seems to be related to cell proliferation. Preliminary chemical characterization suggests that the glycoprotein may be identical to the abnormal glycoprotein previously reported by Bramwell and Harris to be associated with malignancy[7,8].

The IgG monoclonal antibody used in these studies is designated B3/25. It was obtained from fusion of BALB/c mouse spleen cells immunized against the human haematopoietic cell line K562 (ref. 9), with the non-producer myeloma cell line S194/5.XX0.BU.1, by standard procedures[10,11].

Trace antibody binding assays[12] showed that B3/25 antibody reacted with 7/7 cultured human T-leukaemic cell lines, 11/11 B-cell lines including 'normal' B-cell lines, B-cell tumours and Burkitt's lymphoma cell lines, and 10/10 non-T-, non-B-leukaemic cell lines. The antibody precipitated a labelled molecule from NP40 lysates of iodinated HL-60 cells which migrated with an apparent molecular weight of about 110,000 on SDS-polyacrylamide gels in reducing conditions (Fig. 1). Similar results were obtained in immunoprecipitation studies with other haematopoietic cell lines. This molecule, which on the basis of metabolic labelling studies and lectin affinity chromatography is a glycoprotein, seems to exist in the membrane as a disulphide-bonded dimer, as in nonreducing conditions it migrates in SDS-polyacrylamide gels with an apparent molecular weight of 200,000 (Fig. 1).

Although the glycoprotein was detected on the surface of all the human haematopoietic cell lines tested, we could not detect it on peripheral blood mononuclear cells, granulocytes or a variety of peripheral blood leukaemic cells either by fluorescence-activated cell analysis or by trace antibody binding. A more extensive survey of the distribution of the glycoprotein on normal and leukaemic haematopoietic cells was carried out by immunofluorescence microscopy. The molecule was not present in detectable amounts on a significant fraction of thymocytes, bone marrow or peripheral blood mononuclear cells, nor on leukaemic cells from patients with chronic myeloid leukaemia or chronic lymphatic leukaemia, except for apparently specific staining of a small population of cells morphologically resembling erythroblasts. The majority of blast cells from patients with acute myeloid or lymphocytic leukaemia were also negative. In some cases, however, a small fraction (0–30%) of the blast cell population was positive. In two exceptional cases, one a T-cell acute lymphocytic leukaemia, the other an erythroleukaemia, almost all the blast cells reacted strongly with B3/25 antibody.

In addition to its unusual cellular distribution, we found that the glycoprotein defined by B3/25 monoclonal antibody had another interesting property. Although the molecule is expressed on non-induced HL-60 cells, we detected a dramatic decrease in the amount of glycoprotein on cells induced to differentiate by growth in the presence of 1.25% dimethyl sulphoxide (DMSO) or 0.5 mM sodium butyrate for 5 days (Fig. 2 and ref. 1). The fact that the radioactivity bound to induced HL-60 cells incubated with B3/25 antibody in the trace antibody binding assay is barely above background indicates that the induced cells express little or no antigen. Two other low molecular weight compounds, *N*-methyl acetamide and phorbol ester, that also induce morphological and functional differentiation of HL-60 cells[2–6], cause a similar decrease in the expression of the glycoprotein on HL-60 cells.

0028–0836/80/350888—04$01.00

We studied the expression of B3/25 glycoprotein on HL-60 cells in more detail by quantitative immunofluorescence using the fluorescence-activated cell analyser. The amount of the glycoprotein found on non-induced cells varied considerably (Fig. 3*a*), and this heterogeneity was not abolished by recloning the cell line. Approximately 70% of non-induced HL-60 cells expressed sufficient antigen to be detected above nonspecific background fluorescence. After treatment with DMSO for 5 days, only 5% of the cells were scored as positive and the fluorescence profile of the specifically stained cells was indistinguishable from that of the control (Fig. 3*b*). Kinetic studies showed that the loss of B3/25 glycoprotein was detectable within 24 h and essentially complete after 48 h (Fig. 3*d*). The disappearance of the glycoprotein precedes the arrest of HL-60 cells in G1 of the cell cycle and morphological differentiation, which is not maximal until at least 5 days after induction (Fig. 3*d* and refs 2, 13). Pulse-chase metabolic labelling experiments show that the loss of the glycoprotein is due entirely to the almost complete cessation of synthesis of the molecule and not to an increased rate of degradation (M.B.O. and I.S.T., unpublished results). As shown in Fig. 3*c*, we have obtained a variant subline of HL-60 cells that continues to grow in the presence of 1.25% DMSO without undergoing terminal differentiation. In these conditions the cells express similar amounts of B3/25 glycoprotein to non-induced wild-type cells. Thus, the change in expression of the glycoprotein seems to be directly associated with the arrest of growth and differentiation of HL-60 cells *per se*.

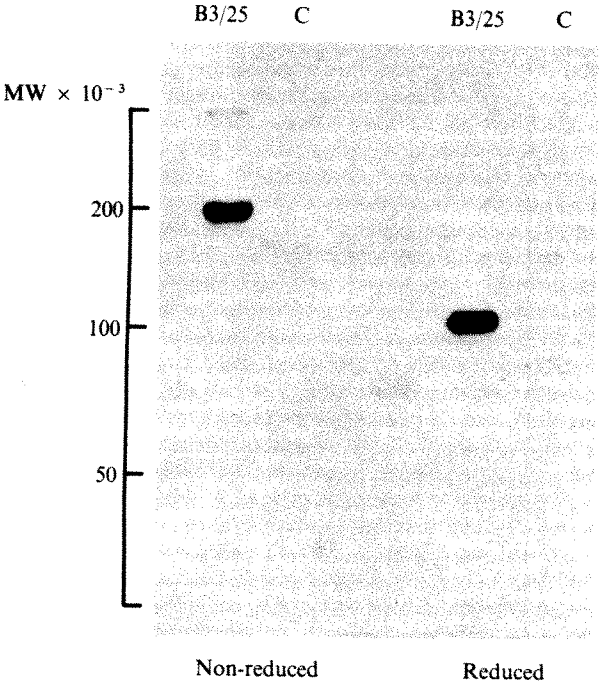

Fig. 1 SDS-polyacrylamide gel analysis of the cell-surface antigen recognized by B3/25 monoclonal antibody. HL-60 cells originally from Dr R. Gallo and recloned at the Salk Institute were iodinated by the glucose-oxidase modification of the lactoperoxidase technique as previously described[18]. Immunoprecipitates were prepared from cell lysates containing 1% NP40, 1% deoxycholate and 0.1% SDS using B3/25 antibody and adsorbing the immune complexes to *Staphylococcus aureus* essentially as described previously[19] except that goat anti-mouse IgG was used as the second antibody. Immunoprecipitates were analysed by SDS-polyacrylamide gel electrophoresis in 7.5% gels[20] after reduction with 2-mercaptoethanol or treatment with 100 mM iodoacetamide. Control immunoprecipitates from which B3/25 antibody was omitted were also prepared and analysed (gel tracks marked C). The autoradiograph shown was exposed for 1 h with the use of an intensifying screen[21] to enhance autoradiography. MW, Molecular weight.

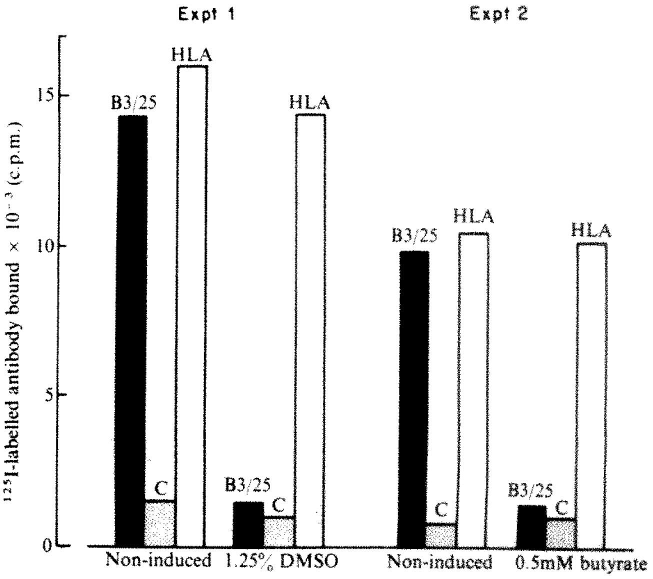

Fig. 2 Comparison of the binding of B3/25 antibody to induced and non-induced HL-60 cells. HL-60 were routinely maintained in RPM1 1640 medium supplemented with 10% fetal calf serum and 10 μM 2-mercaptoethanol. For induction experiments, cells were collected and resuspended at 2×10^5 cells per ml in fresh culture medium alone or containing either 1.25% (v/v) DMSO or 0.5 mM Na butyrate. After growth for 5 days, the cultures were collected and binding of B3/25 monoclonal antibody to non-induced and induced HL-60 cells determined by a trace antibody binding assay using ^{125}I-labelled affinity-purified rabbit F(ab′)$_2$ anti-mouse IgG antibody essentially as described by Morris and Williams[12]. In the negative control for nonspecific binding (column C), tissue culture medium was substituted for culture supernatant containing B3/25 antibody. Binding of a monoclonal antibody designated A3/10 which reacts with a common antigenic determinant on HLA molecules (M.B.O. and I.S.T., unpublished results) was used as a positive control. In expt 1, 5×10^5 cells were used per assay, in expt 2, 2×10^5 cells per assay were used and in both cases the results shown represent the average of duplicate determinations.

Although the cell-surface glycoprotein is not a cell cycle-dependent antigen in a conventional sense, as its expression on induced HL-60 cells changes before the cells arrest in G1 of the cell cycle, all the previous results are consistent with the molecule being selectively expressed on actively proliferating cells. We therefore examined whether or not the molecule was present on blast cells derived from lectin-stimulated peripheral blood lymphocytes. Trace antibody binding and quantitative immunofluorescence suggested that the glycoprotein was present on the blast cells, but in such small amounts relative to the cultured cells lines that we considered the results equivocal. However, the presence on lectin-induced blasts of a similar or identical glycoprotein to that found on cell lines could be clearly demonstrated by immunoprecipitation from lysates of iodinated cells (Fig. 4). Thus, the glycoprotein or a related molecule is clearly present on normal proliferating cells. There may, however, be quantitative differences between the expression of the glycoprotein on tumour cells and normal cells and there is no evidence that the glycoprotein on the blast cells is identical to the molecule found on the tumour cell lines. These considerations are particularly relevant because, although there has been no previous report of the presence on human haematopoietic cells of a glycoprotein with similar properties to those of the surface glycoprotein defined by B3/25 monoclonal antibody, it is probable that the molecule we are studying is related to a tumour cell-surface glycoprotein described earlier by Bramwell and Harris[7,8]. This glycoprotein seems to be expressed in greater amounts on malignant cells than on nonmalignant cells and may also be structurally modified in tumour cells.

The most compelling evidence that the two glycoproteins are closely related is that both have the same apparent molecular weight on SDS-polyacrylamide gels and share the unusual

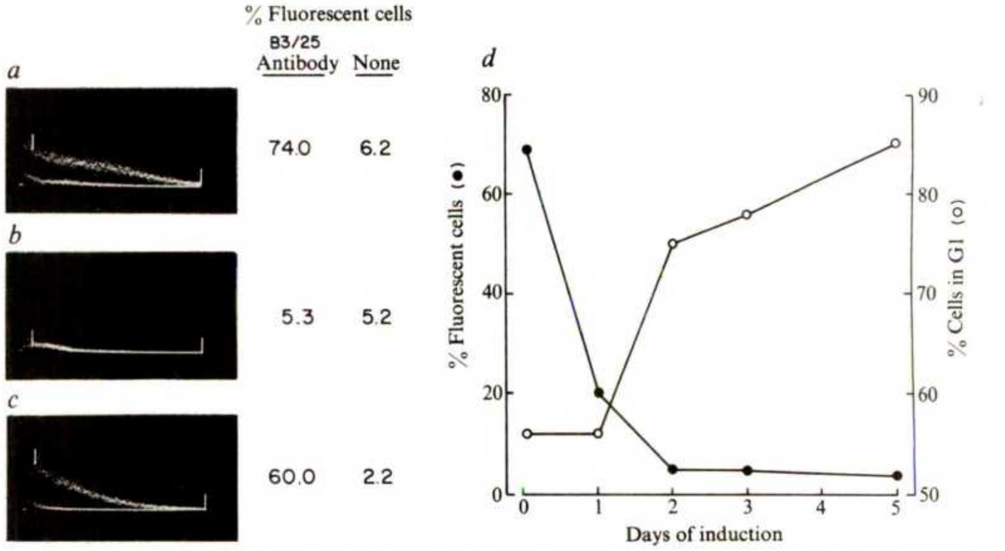

Fig. 3 Expression of B3/25 glycoprotein on induced and non-induced HL-60 cells measured by quantitative immunofluorescence. Cells were grown in the presence of 1.25% (v/v) DMSO for the period of time indicated and then stained with saturating amounts of B3/25 antibody and a fluorescein-conjugated affinity-purified goat anti-mouse IgG. Cells (50,000) were analysed on a Los Alamos-type fluorescence-activated cell analyser using a laser output of 900 mW, high voltage setting of 800 V, and a fluorescence gain of 1.0. Panels *a–c* show the histograms of non-induced HL-60 cells (*a*), HL-60 cells induced with 1.25% DMSO for 5 days (*b*), and a DMSO-resistant variant of HL-60 grown in 1.25% DMSO for 5 months (*c*) after staining with B3/25 antibody. Also shown are controls for nonspecific staining in which B3/25 antibody was omitted from the first incubation. The % of fluorescent cells within the channels indicated by the vertical bars are given. *d* Shows the % of B3/25 positive cells determined by flow microfluorimetry in the conditions just described after exposure of HL-60 cells to DMSO for various periods of time. The cell-cycle distribution of the same cells was determined from their DNA content measured by flow microfluorimetry after staining with mithramycin[22]. The % of cells in G1 is indicated.

property of existing in their native states as disulphide-bonded dimers. The glycoprotein we have studied is also similar to the molecule identified by Bramwell and Harris in other respects: it is acidic, binds to concanavalin A and wheat-germ agglutinin, and is expressed on Hela cells and other non-haematopoietic tumour cell lines (M.B.O. and I.S.T., unpublished results). Furthermore, by quantitative absorption we could not detect the glycoprotein on any normal tissue tested. Homogenates of liver, brain and kidney and red blood cells were used in the absorptions and the limit of detection was about 5% of the amount expressed on RPM1 8402, the human T-leukaemic cell line used as a positive control in these experiments.

Regardless of whether, as seems likely, the glycoprotein we have characterized is related to the one described by Bramwell and Harris, its properties warrant further investigation. Quantitative studies of the expression of the glycoprotein on normal tissues and *in vivo* tumours are required, as well as chemical characterization of the molecule isolated from both non-malignant and malignant cells. It may be possible to determine whether or not there is a causal relationship between the expression of the glycoprotein and cell proliferation by means of somatic cell genetics using HL-60 cells as a model system. It will also clearly be important to establish whether the glycoprotein is expressed on normal or leukaemic haematopoietic stem cells that can be detected by the appropriate *in vitro* assays[14–17]. The B3/25 monoclonal antibody and other monoclonal antibodies which we have obtained that react with different antigenic determinants of the same glycoprotein (I.S.T., unpublished results) will facilitate these studies.

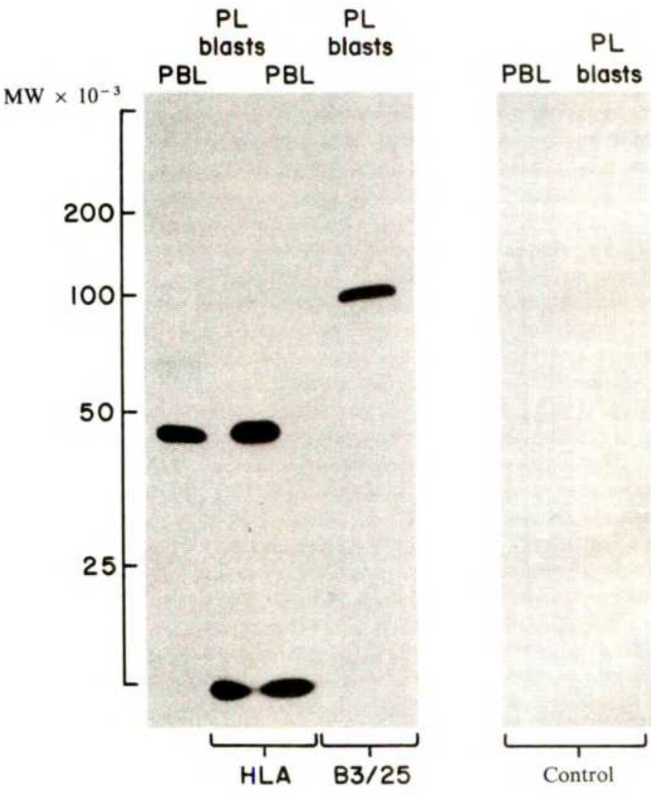

Fig. 4 Expression of B3/25 glycoprotein on lectin-stimulated peripheral blood lymphocytes (PBL). Mononuclear cells were isolated from defibrinated blood by centrifugation of Ficoll–Hypaque gradients. Fresh cells (PBL) or cells (2×10^6 per ml) stimulated for 5 days with 20 μg ml^{-1} pea lectin[23] in RPM1 1640 medium supplemented with 10% fetal calf serum (PL blasts) were iodinated and immunoprecipitates prepared and analysed as described in Fig. 1 legend except that a 10% polyacrylamide gel was used. A3/10 antibody was used to precipitate HLA as a positive control. A negative control in which B3/25 antibody was omitted from the first incubation is also shown. Exposure of the autoradiograph was 40 h.

Human synovium releases a factor which stimulates chondrocyte production of PGE and plasminogen activator

The mechanisms by which destruction of the tissues (cartilage, tendons, ligaments and bone) of joints affected by rheumatoid arthritis occurs are still poorly understood. Damage to the articular cartilage is a key event in the development of disability and deformity. Until recently it was thought that destruction of cartilage was primarily due to the release of a variety of proteolytic enzymes (collagenase and other neutral proteinases, and possibly lysosomal hydrolases) from the proliferating synovial pannus tissue[1]. Little attention has been paid to the involvement of chondrocytes themselves in the destruction of cartilage. Recently Fell and Jubb[2] have shown that when porcine synovium and cartilage are maintained in the same organ coculture system, destruction of the cartilage matrix occurs. They suggested that, in addition to inducing direct enzymatic breakdown of cartilage, synovial tissue might release a factor which activates chondrocytes to degrade their surrounding matrix. Steinberg *et al.*[3] have confirmed that synovium and cartilage interact in this way in tissue culture, with breakdown and release of proteoglycans in cartilage. The purpose of our present study was to examine whether this interaction between synovium and cartilage occurs with human tissue and to examine the mechanisms in more detail. We have, therefore, investigated the effects of normal and rheumatoid synovial tissue on chondrocytes derived from human articular cartilage. We find that the culture medium from explants of normal and rheumatoid human synovium contains a factor which stimulates the production of prostaglandin E (PGE) and plasminogen activator by chondrocytes.

Normal synovium (~1.5 g) was dissected from human knee joints obtained after surgical amputation for trauma or lower limb ischaemia. The synovial tissue was dissected into small pieces and placed in explant culture in 20 ml of Eagle's modified essential medium (MEM) with 10% (v/v) fetal calf serum (FCS) and penicillin plus streptomycin. After 1 day the medium was changed and reduced to 15 ml, with subsequent changes and collections at days 1, 6, 9, 13 and 16. Medium was stored at −20 °C. Chondrocytes were incubated with a 4% dilution of this conditioned synovial explant medium (SEM). PGE was assayed by radioimmunoassay in this medium and in the medium obtained after culture with chondrocytes. Since the antibody used detects PGB as well as PGE_1 and PGE_2, the media were subjected to silica gel microchromatography with the result that the prostaglandin produced in chondrocyte cultures was shown to be predominantly of the E-type[4].

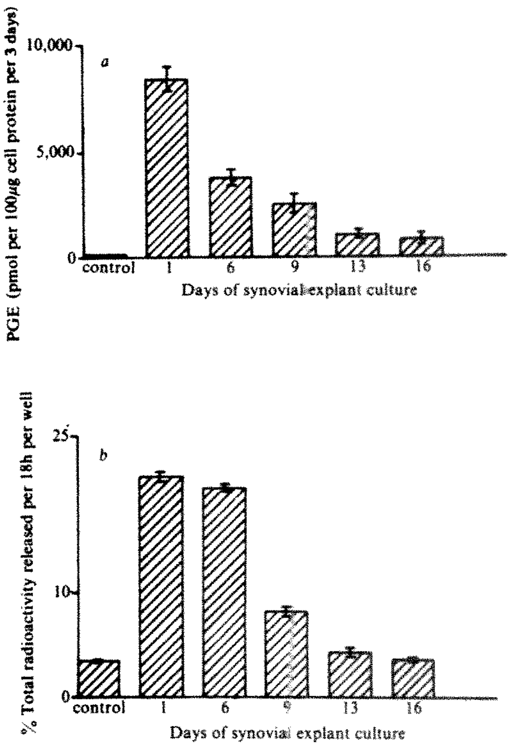

Fig. 1 *a*, Stimulation by SEM of PGE production by chondrocytes. The results represent the mean ± standard error of determinations in quadruplicate wells. A dilution of 1 : 25 (final concentration 4% v/v) of conditioned SEM in fresh MEM containing 10% FCS was added to each well containing confluent cultures of chondrocytes (second passage), derived from explants of human articular cartilage obtained from amputation specimens. Control cultures contained no SEM. Values have been corrected by subtracting the PGE present in the synovial medium (22.0% – 59.0% of total PGE measured in each well) and therefore represent the PGE produced by the chondrocytes themselves. *b*, Stimulation by SEM of production of plasminogen activator by human articular chondrocytes. Results expressed as mean ± standard error ($n = 3$ wells). Chondrocytes were grown to confluence in MEM containing 10% FCS and 20 mM HEPES buffer with 0.085% (w/v) $NaHCO_3$. Then the FCS was replaced by 10% (v/v) acid-treated FCS (acid treatment destroys the proteinase inhibitor, α_2-macroglobulin) and 4% (v/v) SEM was included in the medium. Controls did not contain SEM. Culture medium was removed after 18 h and counted for liberated ^{125}I. Residual fibrin was digested from the wells with 0.1% trypsin and this was also counted; fibrin degradation by chondrocytes was then calculated as a percentage of the total present. No significant release of ^{125}I was apparent during the preincubation of chondrocytes in normal FCS. Additional control wells containing SEM but no chondrocytes showed no significant release of ^{125}I (0.5% of the total, compared with 21.5% in the presence of chondrocytes). To demonstrate that a plasmin-like enzyme is responsible for the breakdown of fibrin, the concentration of acid-treated FCS was varied over 0–20% in the presence of a 1/25 dilution of SEM obtained after 1 day. Degradation of fibrin was shown to be dependent on the presence of serum, release of radioactivity was 0.8% ± 0.2% for cultures without serum, 5.1 ± 1.0% for those containing 5% serum and 12.9 ± 2.4% at a serum concentration of 20%. This requirement for serum to 'unmask' the fibrinolytic activity indicates that the proteinase responsible for fibrin degradation is plasmin and that the chondrocytes are releasing a plasminogen activator rather than another proteinase which directly degrades the fibrin and which would therefore act independently of the presence of serum.

To measure the release of plasminogen activator by chondrocytes, monolayer cultures were prepared using the method of Srivastava *et al.*[5], with the following modifications: fragments of cartilage were incubated in hyaluronidase (1 mg ml^{-1} in Dulbecco's Ca^{2+}- and Mg^{2+}-free phosphate-buffered saline) for 15 min, then in 0·25% trypsin for 30 min, and then digested overnight with bacterial collagenase [*Clostridium* peptidase, (Sigma type I) 3 mg ml^{-1} in MEM + 10% FCS]. Primary cultures were grown to confluence in MEM + 10% FCS, then subcultured after dislodging cells by exposure to trypsin. The cells were placed in multiwell dishes (16 mm diameter) coated with ^{125}I-fibrin[6]. Release of ^{125}I from the fibrin gel into the culture medium indicated the presence of plasminogen activator.

Our results indicate that a factor is produced in the synovial explant cultures which, when added to chondrocytes, stimulates the production of PGE (Fig. 1*a*). The medium obtained after one day of culture with SEM increased the production of PGE by about 50-fold and the stimulatory effect diminished with continued culture of the synovium so that after 16 days of culture the SEM produced only a five-fold elevation of PGE levels when added to chondrocytes. Figure 2 shows that the response of the chondrocytes to produce PGE is dependent on the concentration of the SEM added. Addition of dexamethasone to chondrocytes, together with SEM, suppressed this activation of prostaglandin biosynthesis (Fig. 3). Medium from explants of rheumatoid rather than normal synovium was added to chondrocytes in other experiments and exhibited similar stimulatory effects.

Figure 1*b* shows that the same SEM also markedly stimulated the production of plasminogen activator by chondrocytes. The stimulatory effect on the production of plasminogen activator also seemed to diminish the longer the synovium was kept in culture. The similarities in the profiles of activation shown in Fig. 1*a* and *b* suggest that a single stimulatory factor might be involved and that there may be a close functional relationship between the production of prostaglandin and plasminogen activator.

In addition to showing that the human synovium produces a substance(s) which stimulates chondrocytes in culture, our present experiments demonstrate the hitherto unrecognized ability of chondrocytes to produce relatively large quantities of prostaglandin in culture. Our preliminary results indicate that protein synthesis is required for production of the factor since treatment of rheumatoid synovium with cycloheximide (1 μg ml^{-1}) resulted in a 75% reduction in production of stimulatory activity (21.75 ± 2.29 as compared with 80.25 ± 5.07 ng PGE per 100 μg cell protein per 24h in the dialysed medium control. The SEM was dialysed before addition to the chondrocyte cultures to eliminate the cycloheximide).

Further work is needed to characterize the source and nature of the stimulating activity, which may be similar to the factor, named catabolin, partially characterized by Dingle *et al.*[7]. This protein, as released from porcine synovium in culture, has a molecular weight of approximately 20,000 and stimulates the breakdown of cultured bovine nasal cartilage. There is also a similarity to the mononuclear cell factor described by Dayer *et al.*[8] which stimulates production of PGE and collagenase by synovial cells and which we have found also to stimulate production of PGE by chondrocytes[9]. We have detected stimulatory activity from cultures of both normal and rheumatoid synovium which suggests that the factor is unlikely to be derived from inflammatory cells, which would only be present in appreciable numbers in pathological tissue. There are obvious similarities with a factor from rabbit macrophages which acts on rabbit chondrocytes to produce collagenase and other proteases[11,12].

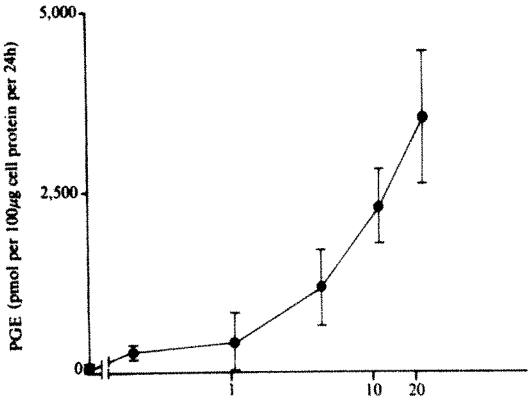

Fig. 2 The effect of SEM on PGE production by chondrocytes. The PGE originating from the SEM has been subtracted from each point. SEM collected at day 1 was incubated with chondrocytes for 24 h at dilutions between 1:250 and 1:5 (to give final concentrations of SEM in the culture fluid ranging from 0.4% and 20% as shown on the abscissa). Control cultures contained no SEM. The points shown are mean ± standard error of quadruplicate wells.

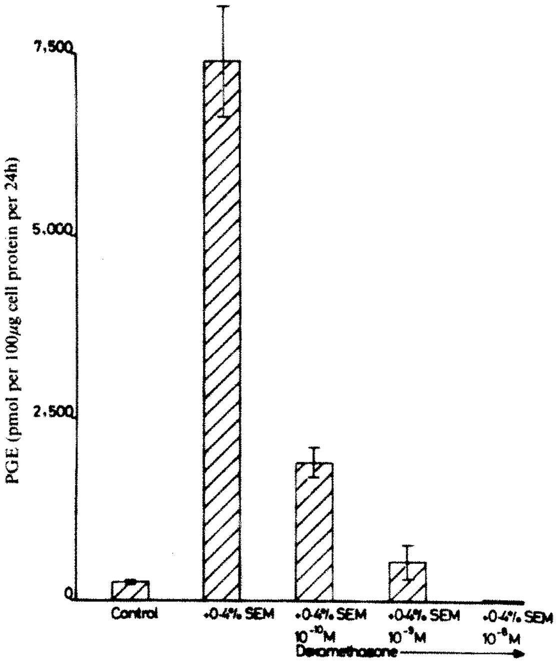

Fig. 3 Inhibition by dexamethasone of PGE production by human articular chondrocytes. Results are expressed as mean ± standard error of quadruplicate wells. Cultures did not contain FCS. SEM was collected on days 0–4 of culture and incubated with chondrocytes for 24 h. Controls did not contain SEM. PGE produced by the synovial explants has been subtracted from each point.

The release of this factor from synovium could be of considerable significance in the pathogenesis of joint disease. Enhanced production of prostaglandins by chondrocytes could contribute to the increased PGE concentration found in synovial fluids in inflammatory arthritis[10]. PGE derived from chondrocytes could alter vascular permeability in adjacent tissues and could also stimulate resorption of the subchondral bone. These prostaglandins might also influence the rate of proliferation of the synovial pannus and be involved in controlling the mobility and activity of inflammatory cells. The plasminogen activator released by chondrocytes could itself degrade cartilage matrix by direct proteolytic attack or could take part in the conversion of collagenase from latent to active form. This factor from synovial tissue could therefore be responsible for some aspects of the tissue damage seen in joints in rheumatoid arthritis. The mechanisms that prevent such a factor from acting in normal conditions and which might allow its release in pathological circumstances require further investigation. The remarkable potency of added steroid in inhibiting the action of the factor on cartilage suggest that this may be one way in which steroids exert their therapeutic action in rheumatoid arthritis.

We thank the Nuffield Foundation and the SRC for financial support for this work, Dr Hamish Humphrey (Glaxo) for the gift of ^{125}I-labelled fibrin plates and Dr L. Levine for prostaglandin antiserum.

Biosynthesis of hepatitis B virus surface antigen in *Escherichia coli*

Patrick Charnay, Monica Gervais, Anne Louise, Francis Galibert* & Pierre Tiollais

Unité de Recombinaison et Expression Génétique (INSERM U.163), Institut Pasteur, 28 rue du Dr Roux, 75724 Paris Cedex 15, France
* Laboratoire d'Hématologie Expérimentale, Centre Hayem, Hôpital Saint-Louis 2, place A. Fournier, 75010 Paris, France

Hepatitis B is a widespread viral disease[1]. In the absence of cell cultures capable of propagating the virus (HBV) an efficient vaccine has been prepared from viral envelopes isolated from the plasma of chronic carriers[2–4]. The major polypeptide of the envelope is one of molecular weight 25,000 which carries the surface antigen (HBsAg)[5–8]. Therefore, the biosynthesis of this polypeptide in *Escherichia coli* may offer an alternative procedure to produce HBsAg free from human proteins. Recently, the *HBV* genome has been cloned in *E. coli*[9–11]. Determination of its primary structure allowed the localization of the gene (called gene *S*) coding for HBsAg[12–15] and the synthesis of the core antigen in *E. coli* has been reported[9]. We have constructed a derivative of bacteriophage lambda carrying a fusion between the β-galactosidase gene (*lacZ*) and the HBsAg coding sequence (*λlacHBs-1*). Infection of *E. coli* with *λlacHBs-1* leads to the biosynthesis of a polypeptide of molecular weight 138,000 carrying antigenic determinants of HBV surface antigen.

Expression of an eukaryotic gene in *E. coli* can be obtained by fusion between the foreign gene and a bacterial gene carried by a plasmid or a phage. Thus the *lacZ* gene has already been used for hormone biosynthesis[16,17]. Sequential steps in the construction of the gene fusion between gene *S* and gene *lacZ* are illustrated in Fig. 1. By *Hha*I treatment of the previously cloned *HBV* DNA[10], we prepared a 1,084 base pair long DNA fragment which carried the entire gene *S*. Using S_1 endonuclease and *Eco*RI linkers 5'GGAATTCC, this fragment was cloned in *E. coli* using the plasmid pBR322 (ref. 20). The recombinant plasmid pBRHBs has only one *Xba*I restriction site located at the beginning of gene *S*. Digestion of this plasmid with *Eco*RI plus *Xba*I endonucleases, followed by a purification using agarose gel electrophoresis gave a DNA fragment of about 980 base pairs carrying a major part of gene *S*. After treatment with S1 endonuclease, addition of *Eco*RI linkers, and cleavage with *Eco*RI endonuclease, this 980 base pair DNA fragment was cloned in *E. coli* using the plasmid pBR322. Several clones were obtained; the DNA of three clones (p*XbaHBs-1*, p*XbaHBs-2* and p*XbaHBs-3*) was extracted and the 980-base pair *Eco*RI restriction fragment, called *HBs*-fragment, was purified in each case. Determination of the nucleotide sequence of the *Eco*RI extremity corresponding to gene *S* revealed that the nucleotide sequence was not identical in the three clones (Fig. 1*A*). The differences were possibly due to heterogeneity in the S1 endonuclease digestion. The bacteriophage λ*plac5-1UV5* genome[19] has only one *Eco*RI site located at the end of the *lacZ* gene. The reading frame of this gene at the *Eco*RI site can be deduced from the amino acid sequence of the β-galactosidase[21]. Based on the nucleotide sequence, the insertion of the *HBs* fragment from p*XbaHBs-1* into the *Eco*RI site of the *lacZ* gene of λ*plac5-1UV5* genome should lead to conservation of the reading frame of gene *S*. The recombinant bacteriophage should

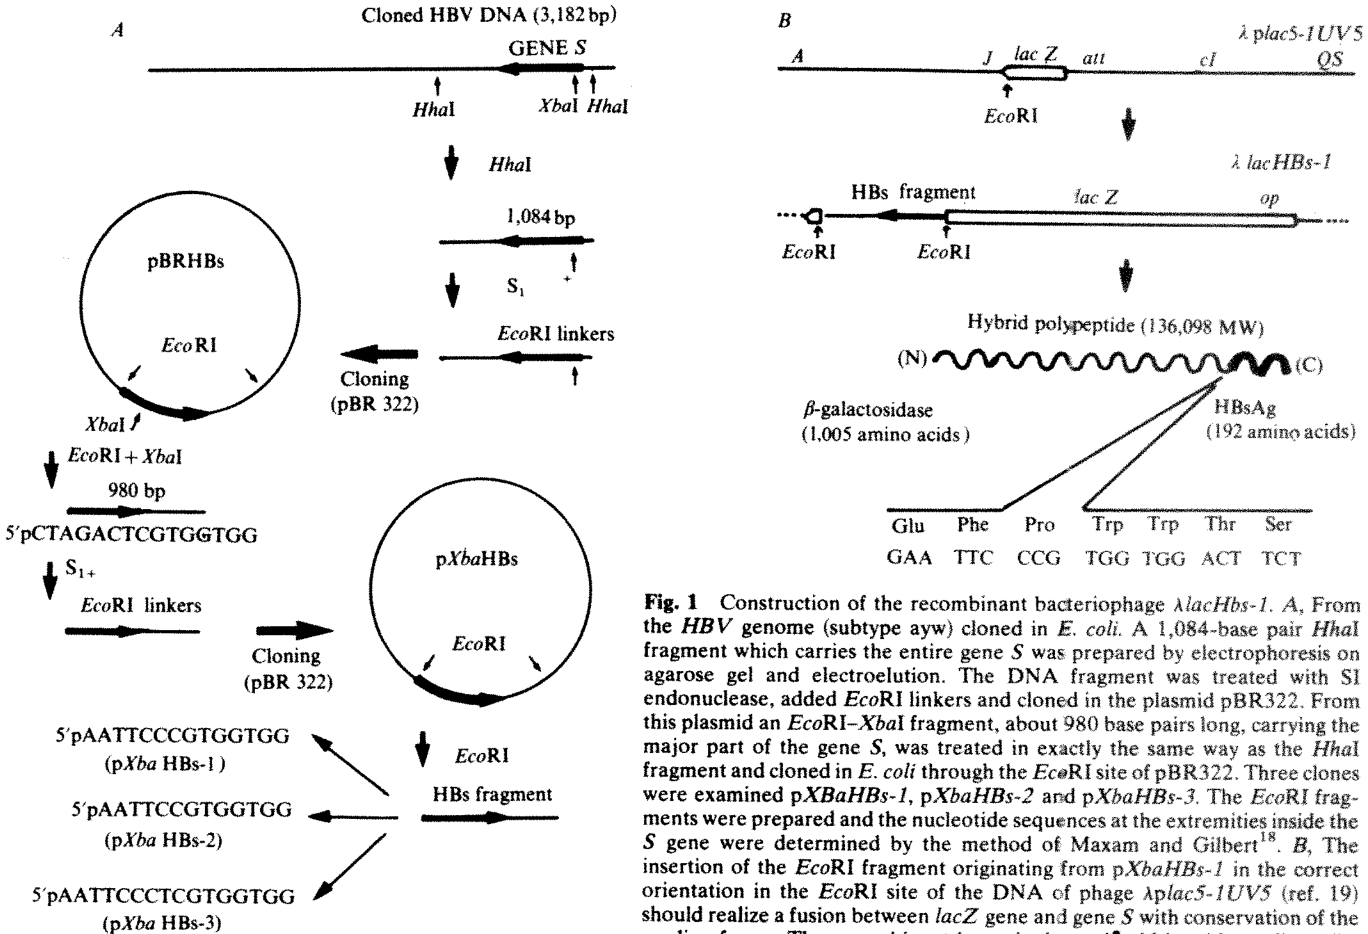

Fig. 1 Construction of the recombinant bacteriophage λ*lacHbs-1*. *A*, From the *HBV* genome (subtype ayw) cloned in *E. coli*. A 1,084-base pair *Hha*I fragment which carries the entire gene *S* was prepared by electrophoresis on agarose gel and electroelution. The DNA fragment was treated with SI endonuclease, added *Eco*RI linkers and cloned in the plasmid pBR322. From this plasmid an *Eco*RI–*Xba*I fragment, about 980 base pairs long, carrying the major part of the gene *S*, was treated in exactly the same way as the *Hha*I fragment and cloned in *E. coli* through the *Eco*RI site of pBR322. Three clones were examined p*XBaHBs-1*, p*XbaHBs-2* and p*XbaHBs-3*. The *Eco*RI fragments were prepared and the nucleotide sequences at the extremities inside the *S* gene were determined by the method of Maxam and Gilbert[18]. *B*, The insertion of the *Eco*RI fragment originating from p*XbaHBs-1* in the correct orientation in the *Eco*RI site of the DNA of phage λ*plac5-1UV5* (ref. 19) should realize a fusion between *lacZ* gene and gene *S* with conservation of the reading frame. The recombinant bacteriophage should be able to direct the synthesis of a hybrid polypeptide of molecular weight 136,098 with a NH_2 terminal portion consisting of almost the entire β-galactosidase and a COOH terminal portion consisting of a great part of the HBsAg major protein.

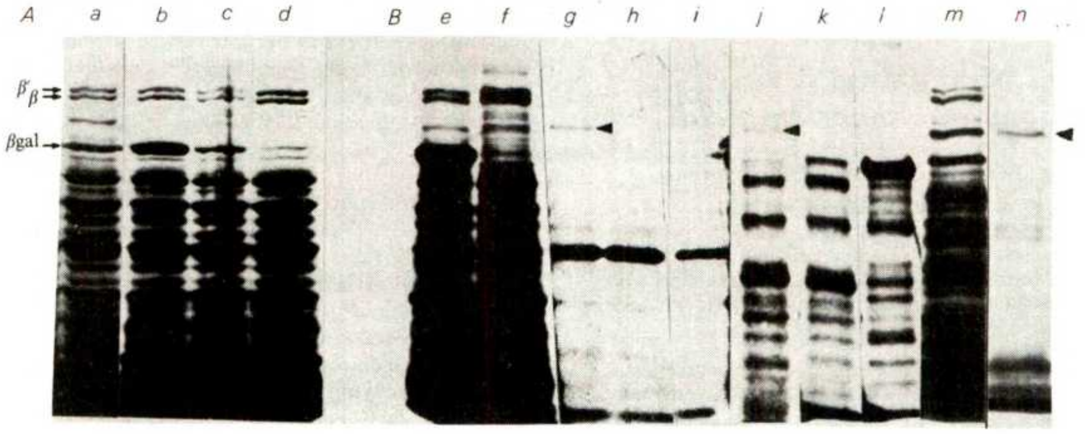

Fig. 2 Immunoprecipitation of the β-galactosidase–HBsAg hybrid protein. *A*, *E. coli* K12 3,000X74 was grown in Laemmli medium and concentrated to an absorbance of 10 units in $MgSO_4$, 10 mM. Phages were absorbed for 15 min at a multiplicity of infection of 4. Cells were diluted 10 times in Laemmli medium and incubated 25 min at 37 °C, centrifuged, resuspended in Laemmli final sample buffer[23] and boiled for 5 min. The proteins were electrophoresed on a 6% polyacrylamide–SDS gel[23] and stained with Coomassie blue. The proteins from cells infected with the following bacteriophages are shown: *a*, λ*lacHBs-1*; *b*, λp*lac5-1UV5*; *c*, λ*lacHBs-2*; *d* contains an extract of uninfected 3,000X74. The arrows show the position of size markers: β-galactosidase[21] and β,β′ subunits of RNA polymerase[24]. *B*, Infected cells were diluted 10 times in Laemmli medium (Bacto-Tryptone: 10 g, Bacto yeast extract: 5 g, NaCl: 10 g in 1 L *p*H 7.3) containing $[^{35}S]$ methionine (1050 Ci mmol^{-1}, 150 μCi ml^{-1}) and incubated for 25 min at 37 °C. Cells were centrifuged, resuspended in one-tenth volume (Tris *p*H 8 : 10 mM, EDTA : 5 mM, lysozyme : 0.5 mg ml^{-1}, PTSF : 30 μg ml^{-1}) and lysed by three freeze–thaw cycles. The suspension was then made up to 10 mM $MgCl_2$ and 20 μg ml^{-1} DNase was added; it was incubated for 15 min in ice and centrifuged. The supernatant was used for immunoprecipitation as follows: to 80 μl of this *E. coli* extract were added 120 μl TNT buffer (Tris *p*H 7.5 : 50 mM, NaCl : 150 mM, Triton X100 1%) and 2 μl antiserum and the mixture was incubated for 60 min at 37 °C. Then, 100 μl of a suspension of Protein A–Sepharose CL-4B (Pharmacia) in TNT buffer (100 mg ml^{-1}) was added and incubation was continued for 1 h at 0 °C. The beads were pelleted by a 3 min centrifugation in an Eppendorf microfuge and then washed once with 500 μl TNT buffer, three times with 500 μl LiCl buffer (LiCl 500 mM, Triton X-100 1%, SDS 0.1%) and twice with 500 μl Tris *p*H 8 : 10 mM. Finally, radioactive proteins were eluted from the beads by boiling for 5 min in 40 μl Laemmli final sample buffer[23]. They were electrophoresed on a 6% polyacrylamide-SDS gel[23] which was then treated for fluorography[25], dried and subjected to autoradiography with flash-activated Kodak Royal X-Omat films at −70 °C (ref. 26). The figure shows the proteins from cells infected with the following bacteriophages: *e*, λp*lac5-1UV5*; *f*, λ*lacHBs-1*; *g*, λ*lacHBs-1*, immunoprecipitation with human antiserum to HBsAg (subtype ayw) (generous gift from Dr J. Drouet); *h*, λ*lacHbs-1*, immunoprecipitation with the same antiserum to HBsAg in presence of HBsAg 100 μg ml^{-1}; *i*, λp*lac5-1UV5*, immunoprecipitation with the same antiserum to HBsAg; *j*, λ*lacHBs-1*, immunoprecipitation with rabbit antiserum to β-galactosidase (gift from Dr N. Guiso); *k*, λ*lacHBs-2*, immunoprecipitation with antiserum to β-galactosidase; *l*, λp*lac5-1UV5* immunoprecipitation with antiserum to β-galactosidase; *m*, λ*lacHBs-1QOS* (cells are incubated 90 min at 37 °C after infection); *n*, λ*lacHBs-1QOS*, immunoprecipitation with a sheep antiserum to purified HBs Ag of ad and ay subtypes (gift from Dr J. Pillot).

be able to direct the synthesis of a hybrid polypeptide of molecular weight 136,098 (Fig. 1*B*). The *HBs* fragment from p*XbaHBs-2* did not have a nucleotide sequence in the correct reading frame and it could be used as a control in further experiments. The *HBs* fragments from p*XbaHBs-1* and p*XbaHBs-2* were ligated with λp*lac5-1UV5* DNA previously cleaved with *Eco*RI endonuclease. The mixture was used to transfect *E. coli* strain C600*recBC rk*$^{-}$ *mk*$^{-}$. Since the insertion of a DNA fragment into the *Eco*RI site inactivates the *lacZ* gene[22], the *lac*$^{-}$ bacteriophage clones were purified on bacterial strain LA101[22]. The DNA of different bacteriophages was extracted and the orientation of the inserted DNA fragment was determined by electrophoretic analysis of the *Bam*HI restriction fragments. Two phage derivatives λ*lacHBs-1* and λ*lacHBs-2* corresponding to the plasmids p*XbaHBs-1* and p*XbaHBs-2* respectively had the *HBs* fragment in the correct orientation.

We infected strain 3,000X74 (Hfr Δ*lac*X74, Institut Pasteur Collection) with λp*lac5-1UV5*, λ*lacHBs-1* and λ*lacHBs-2*. The bacterial protein lysates were analysed by polyacrylamide–SDS gel electrophoresis[23] and Coomassie blue coloration (Fig. 2*A*). The comparison of the three electrophoretic patterns revealed two major differences: in the case of λp*lac5-1UV5*, a much more intense band was observed at a position corresponding to β-galactosidase (molecular weight 116,248) mobility[21]; in the case of λ*lacHBs-1* a new protein species (P138) of molecular weight 135,000–141,000 was detected. This protein was not present after infection with λ*lacHBs-2*.

Proteins synthesized after λ*lacHBs-1* and λp*lac5-1UV5* infection were labelled with $[^{35}S]$ methionine. Precipitation with human antiserum to HBsAg followed by autoradiography of the polyacrylamide–SDS gel revealed a band present in the case of infection with λ*lacHBs-1* and absent in the case of λp*lac5-1UV5* (Fig. 2*B*). This band disappeared specifically when the immunoprecipitation was carried out in presence of cold HBsAg. The precipitated protein co-migrated with the P138 protein. The same band was observed after immunoprecipitation with a sheep antiserum to purified HBsAg. A band was also present at the same position after immunoprecipitation with an antiserum to β-galactosidase (Fig. 2*B*).

These results demonstrate that *E. coli* infected with the bacteriophage λ*lacHBs-1* synthesizes a protein of approximate molecular weight 138,000 with antigenic determinants of both HBsAg and β-galactosidase. These characteristics are exactly those predicted for the fusion polypeptide. The quantity of hybrid polypeptide was estimated by scanning the stained gels. It represents about 10% of the quantity of β subunit of the RNA polymerase, and about 1.5% of the quantity of β-galactosidase obtained after infection with λp*lac5-1UV5*. Assuming that the β subunit represents less than 0.7% of the total cell protein[27] the quantity of the hybrid protein should account for approximately 0.05% of total cell protein. An explanation for the low amount of hybrid polypeptide obtained could be proteolysis. Indeed, when the bacteria are lysed in the absence of protease inhibitor, the amount of P138 protein is still lower. Nevertheless, the introduction of amber mutations into genes *Q* and *S*[22,28] of λp*lac HBs-1* genome, by genetic crossing with the bacteriophage λp*lac5imm434Qam501Sam7* (ref. 22) enhances the P138 polypeptide production by a factor of approximately five (Fig. 2*B*). The β-galactosidase–HBsAg hybrid polypeptide provides a model for coupling HBsAg with a carrier protein in an immunoreactive form ultimately useful in newer vaccine against HBV infection[28]. Moreover, the results presented reinforce the hypothesis that there is no intervening sequence in the HBsAg coding sequence[12,13].

Containment conditions for this study were recommended by the French National Control Committee. Growth of recombinant bacteriophages and plasmids was carried out in L3 conditions. We thank Drs P. A. Cazenave, D. Perrin, J. Thèze and G. N. Vyas for helpful discussions, J. Shapiro for reviewing the manuscript, and Drs A. Drouet and J. Drouet for critical suggestions and for providing antisera and HBsAg.

Different target antigens for T-cell subsets acting synergistically *in vivo*

Emile A. J. Wolters* & Robbert Benner†

After allogenic transplantation of lymphoid cells into immunologically incompetent recipients, a graft-versus-host (GvH) reaction can occur. The original observation that the GvH reaction is mediated by two interacting types of T cell[1] has led to the proposal that T cells must be subdivided into two subpopulations according to life span and migratory properties. These consist of T_1 cells, which are short-lived, sessile cells sensitive to adult thymectomy (ATx), and T_2 cells, which are long-lived, recirculating cells sensitive to anti-thymocyte serum (ATS)[2]. T_1–T_2 cooperation has also been demonstrated *in vitro* in murine[3] and rat[4] mixed lymphocyte culture. The question arises as to whether these T-cell subpopulations are activated by different or identical parts of the major histocompatibility complex (MHC). We report here that for optimal development of the anti-host immune response in a murine GvH reaction, T_2 cells have to be amplified by T_1 cells. The former cells are activated by a set of MHC gene products that are expressed mainly on immunological cells (H–2I-coded antigens), whereas the latter recognize a different set of MHC gene products that are expressed on almost all cells of the mouse (H–2K/D-coded antigens).

A delayed type hypersensitivity (DTH) assay was used to measure the development of specific anti-host directed T-effector cells[5]. The generation of these T-effector cells is induced by the host histocompatibility (H) antigens during a GvH reaction. Therefore, spleen and lymph node cells from mice which have been irradiated and reconstituted with allogeneic lymphoid cells are transferred intravenously (i.v.) into normal secondary recipients syngeneic to the original spleen cell donor. In these secondary recipients, the anti-host DTH reactivity is assayed by challenging the animals with the specific antigen and measuring the specific DTH response 24 h later.

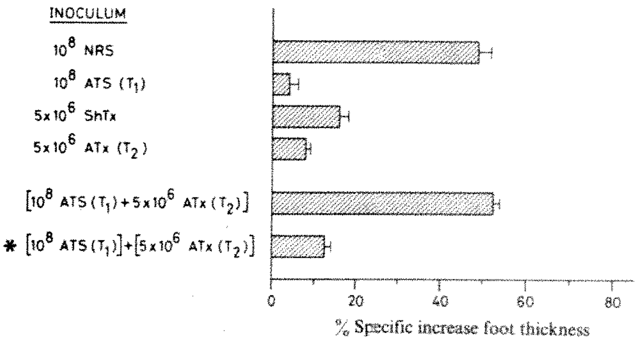

Fig. 1 GvH-related DTH responsiveness of spleen cells of lethally irradiated (C57BL/Rij × CBA/Rij)F_1 mice ($H{-}2^{b/k}$) reconstituted with T_1 and/or T_2 cells from DBA/2 mice ($H{-}2^d$). The DBA/2 donors were either treated *in vivo* with ATS (or NRS as a control) or were adult thymectomized (ATx) (or sham-thymectomized (ShTx) as a control) 6–8 weeks previously. ATS spleen cells were used as a source of T_1 cells, and ATx spleen cells as a source of T_2 cells. Five days after irradiation and reconstitution, the spleen cells of each recipient were i.v. transferred into a naive DBA/2 mouse. An asterisk means that T_1 and T_2 cells were separately injected into different lethally irradiated (C57BL × CBA)F_1 recipient mice. In that case, the spleen cells from both types of primary recipients were simultaneously transferred into the secondary DBA/2 recipients. All secondary recipients were challenged into the instep of the right hind foot with 2×10^7 (C57BL × CBA)F_1 spleen cells. These spleen cells were treated with mitomycin C (Kyowa Hakko Kogyo), 100 $\mu g\ ml^{-1}$ for 30 min at 37 °C. At 24 h after challenge, the anti-host DTH reactivity was measured as the difference in thickness of the hind feet. The relative specific increase is calculated as the relative increase in foot thickness of the immune mice minus the relative increase in foot thickness of control mice, which had only received the challenge injection. The swelling of these control mice was 12–20%. DTH responses are expressed as the specific percentage increase in foot thickness. Horizontal bars represent 1 s.e.m. ($n = 5$).

For the experiments reported here, T_1 cells were obtained by pretreatment of spleen cell donor mice with ATS *in vivo*. This pretreatment gives an enrichment of T_1 cells in the spleen by selective depletion of the pool of recirculating T_2 cells[6]. Long-lived T_2 cells were obtained either from the spleen of donors 6–8 weeks after ATx, or by isolation *in vivo* of recirculating, lymph node-seeking T_2 cells according to the method of Tigelaar and Asofsky[7].

We have previously shown that spleen cell transplantation across H-2 differences into lethally irradiated recipients did result in a transferrable anti-host DTH response[5,8]. After transplantation of as much as 10^8 ATS-treated DBA/2 spleen cells, as a source of T_1 cells, into lethally irradiated (C57BL × CBA)F_1 mice, no significant anti-host DTH-response developed (Fig. 1). In contrast, such a reactivity did appear after transplantation of 5×10^6 spleen cells from ATx DBA/2 mice as a source of T_2 cells (Fig. 1). In this combination, simultaneous transplantation of T_1 cells and T_2 cells gave a much higher anti-host DTH response than the T_2 cells only. Anti-Thy-1.2 treatment of cell suspensions containing either T_1 or T_2 cells could completely prevent amplifier and effector cell activity,

Table 1 The target H-2-subregion coded antigens for T_1 and T_2 cells

Inoculum	Recipient	H-2 subregion coding for immunizing antigen*	DTH response
10^8 C57BL NRS spleen	B10.G	K+I+D	25.9 ± 1.4
10^8 C57BL ATS spleen (T_1)	B10.G	K+I+D	−1.8 ± 3.2
1 LNS eq. C57BL (T_2)	B10.G	K+I+D	8.1 ± 1.4
10^8 C57BL ATS spleen (T_1) + 1 LNS eq. C57BL (T_2)	B10.G	K+I+D	25.2 ± 2.3
10^8 B10.AQR NRS spleen	B10.A × B10.T(6R)	K+I	33.4 ± 2.6
10^8 B10.AQR ATS spleen (T_1)	B10.A × B10.T(6R)	K+I	3.5 ± 2.5
1 LNS eq. B10.AQR (T_2)	B10.A × B10.T(6R)	K+I	11.4 ± 2.0
10^8 B10.AQR ATS spleen (T_1) + 1 LNS eq. B10.AQR (T_2)	B10.A × B10.T(6R)	K+I	26.8 ± 1.2
10^8 B10.AQR NRS spleen	B10.T(6R)	I	34.4 ± 3.3
10^8 B10.AQR ATS spleen (T_1)	B10.T(6R)	I	−0.9 ± 1.8
1 LNS eq. B10.AQR (T_2)	B10.T(6R)	I	19.6 ± 2.9
10^8 B10.AQR ATS spleen (T_1) + 1 LNS eq. B10.AQR (T_2)	B10.T(6R)	I	20.4 ± 1.6
10^8 A.TL NRS spleen	A.TH	I	31.2 ± 2.1
10^8 A.TL ATS spleen (T_1)	A.TH	I	0.1 ± 2.1
1 LNS eq. A.TL (T_2)	A.TH	I	16.5 ± 1.9
10^8 A.TL ATS spleen (T_1) + 1 LNS eq. A.TL (T_2)	A.TH	I	15.1 ± 2.0

GvH reactions were elicited by i.v. injection of the inoculum into lethally irradiated recipient mice. Recipients were lethally irradiated (700 rad) within 4 h before reconstitution. At 5 days after reconstitution a number of cells equivalent to the total cell yield obtained from spleen, inguinal, axillary and mesenteric lymph nodes of a recipient mouse were transferred i.v. to a secondary recipient syngeneic to the original spleen cell donor. Lymphoid cells from all primary recipients of a particular combination were pooled before secondary transfer. Immediately after transfer to the secondary recipients, these recipients were challenged in the right hind foot with 2×10^7 spleen cells syngeneic to the original irradiated recipients. At 24 h after challenge of the secondary recipients, DTH responses were measured. Numbers represent the arithmetic mean ± 1 s.e.m. of five mice. In view of the different donor-recipient combinations, the improvement of the T_2-cell-mediated DTH reactivity by admixing T_1 cells should be judged separately within each of the four different combinations. T_1 cells were obtained by pretreatment of donor mice subcutaneously with 0.2 ml ATS (or normal rabbit serum (NRS) as control). This amount was equally distributed over the inguinal and axillary areas. These injections were given 5 and 2 days before collecting the spleen cells. T_2 cells were isolated *in vivo*. 15×10^7 pooled spleen, peripheral and mesenteric lymph node cells of a particular donor strain were i.v. injected into syngeneic recipients which had been lethally irradiated 2 h previously. At 24 h after inoculation, only the peripheral lymph nodes were obtained from these recipients. Such peripheral lymph nodes contained about 4×10^6 more nucleated cells than lymph nodes from lethally irradiated, non-reconstituted mice. The cell yield from all peripheral lymph nodes of a single irradiated recipient is called one lymph node seeking equivalent (1 LNS eq.).

* H-2 subregion difference between inoculum donors and irradiated recipient mice. The origin of H-2 subregions (K, I-A, I-B, I-C, D) for the strains are as follows: A.TH, ssssd; A.TL, skkkd; B10.A, kkkdd; B10.AQR, qkkdd; B10.T(6R), qqqqd; C57BL, bbbbb; B10.G, qqqqq.

respectively[9]. When T_1 and T_2 cells were separately activated by H antigens and thereafter combined and simultaneously transferred into secondary recipients, no synergistic reactivity was observed (Fig. 1). This indicates that cooperation of T_1 and T_2 cells only occurs during the induction phase of the anti-host immune response and not during the inflammatory reaction in the challenged foot of the secondary recipients.

In Table 1, upper part, T_1–T_2 synergism is shown for the anti-host DTH response of C57BL lymphoid cells against B10.G mice (which differ at the K, I and D subregions of the H-2 complex), and after transplantation of B10.AQR lymphoid cells into (B10.A × B10.T(6R))F_1 mice (which differ at the K and I subregions). Also in these combinations, simultaneous transplantation of T_1 and T_2 cells gave a much higher anti-host DTH response than the T_2 cells alone. Because the anti-host DTH response after transplantation across a whole H-2 difference is directed exclusively to H-2I-coded antigens[8], and H-2K/D antigens by themselves are unable to evoke an anti-host DTH response[10], these results might suggest that T_1 cells are activated by H-2K and/or H-2D region-coded antigens, and amplify the anti-H-2I response by T_2 cells. This hypothesis was evaluated by testing the occurrence of T_1–T_2 synergism during the development of an anti-host DTH response in the case of transplantation across a H-2I difference only. This was done by transplanting T_1 and T_2 cells from B10.AQR mice into lethally irradiated B10.T(6R) mice and from A.TL mice into irradiated A.TH recipients. In both situations, no evidence for T_1–T_2 synergism could be found (Table 1, lower part). Thus, T_1 cells must be activated by H-2K/D antigens to display amplifier activity. The formal proof of this conclusion would be a positive response after transfer of mixtures of the two T-cell subpopulations after separate activation of the T_2 cells by I-coded antigens and of the T_1 cells by K/D-region coded antigens. However, such experiments are impossible because simultaneous transfer of separately activated T_1 and T_2 cells does not result in any detectable synergistic activity (Fig. 1).

The consequence of the differential specificity of receptors of T_1 (anti H-2K/D) and T_2 (anti-H-2I) cells is that both subpopulations must belong to different, parallel lines of T-cell differentiation. Recent observations[11,12] suggest that there are two separate lines of intra-thymic T-cell differentiation with regard to Lyt phenotype, one line leading to Lyt 1^+ T cells and the other to Lyt 123^+ T cells. The latter cells might further differentiate into Lyt 23^+ cells after their migration as Lyt 123^+ cells to the periphery[12,13]. A part of this post-thymic Lyt 123^+ population is ATx sensitive and may be identical to the T_1 population[14]. The data presented here indicate that post-thymic T_1 cells (probably Lyt 123^+ cells), on stimulation by K- and/or D-region coded antigens, can amplify the generation of anti-host DTH effector cells from T_2 cells (probably Lyt 1^+ cells), activated by I-region coded antigens. Such T_2-derived effector cells can release factors which lead to the expression of GvH-related DTH on transfer (in our system) or to help in humoral responses. The present results lead us to speculate that in the case of enhancement of T_2-helper cell activity by T_1-amplifier cells[15,16], both subpopulations are restricted by different H-2 subregions—T-helper cells by H-2I and T-amplifier cells by H-2K/D.

An immunoglobulin heavy-chain gene is altered in two T-cell clones

A. Forster, M. Hobart, H. Hengartner* & T. H. Rabbitts

MRC Laboratory of Molecular Biology, Hills Road,

* Experimentelle Pathologie, Universitätspital, 8091 Zürich,
Switzerland

Thymus-derived lymphocytes (T cells) show a high degree of discrimination in their responses to various antigens, very similar to the specificity repertoire of antibody-producing B cells. The nature of the T-cell receptor which mediates antigen recognition is obscure, but the ability to discriminate between antigenic specificities implies a range of receptor specificities. Many serological and genetic data suggest that T-cell receptors use the immunoglobulin heavy (H)-chain variable (V) region genes but do not carry the antigenic determinants of the immunoglobulin H-chain constant (C) regions; they also do not seem to carry conventional light (L)-chain V- or C-region determinants[1–3]. In B cells and derivatives the expression of immunoglobulin genes is manifested, at the DNA level, by an alteration of the restriction enzyme patterns of both the H and L immunoglobulin genes[4–9]. Specifically, V-gene integration involves joining of a V gene with a J segment (in the case of the H chain probably through an intermediate D segment)[4,6,7] so that sites for restriction enzymes will undergo changes in cells in which V–J joining has occurred. Here, we describe Southern filter hybridization experiments[10] using $C\mu$ and $C\kappa$ probes on the DNA of individual T-cell clones from mice, and present evidence for alteration of sequences adjacent to the $C\mu$ gene in the cells.

The T-cell clones used in this study were two killer cell lines (AD9 and HY72)[11]. Both the cell lines were derived from stimulated splenic T cells and display an H–2-restricted cytotoxic activity against cells bearing H–Y antigen (an activity which has remained unchanged over several months of culture). The cells also express the Thy-1 surface antigen. The T cells were derived from different strains of mice and we have therefore compared the size of the restriction fragment containing the $C\mu$ gene in liver DNA from various mouse strains using a cloned $C\mu$ cDNA probe (pμ/118)[12]. Figure 1 shows the result of a Southern filter hybridization experiment between *Kpn*I digests of liver DNA and nick-translated pμ/118. Considerable polymorphism can be seen between the different strains with respect to the *Kpn*I restriction fragment containing the $C\mu$ gene. We have also found polymorphism between γH-chain genes of different mouse strains but no differences in the $C\kappa$ gene of any of the strains studied (unpublished). A separate study has shown that the intervening sequence between V and $C\gamma1$ regions of an IgG1-producing myeloma cell contains short tandemly repeated sequences which may also occur in regions adjacent to $C\mu$, to the other $C\gamma$ and to the $C\alpha$ genes[13]. It is possible, therefore, that the polymorphism in the size of restriction fragment containing the CH genes is a result of genetic instability within these tandemly repeats similar to, for example, the instability associated with the *Xenopus* rDNA tandemly repeated sequences[14].

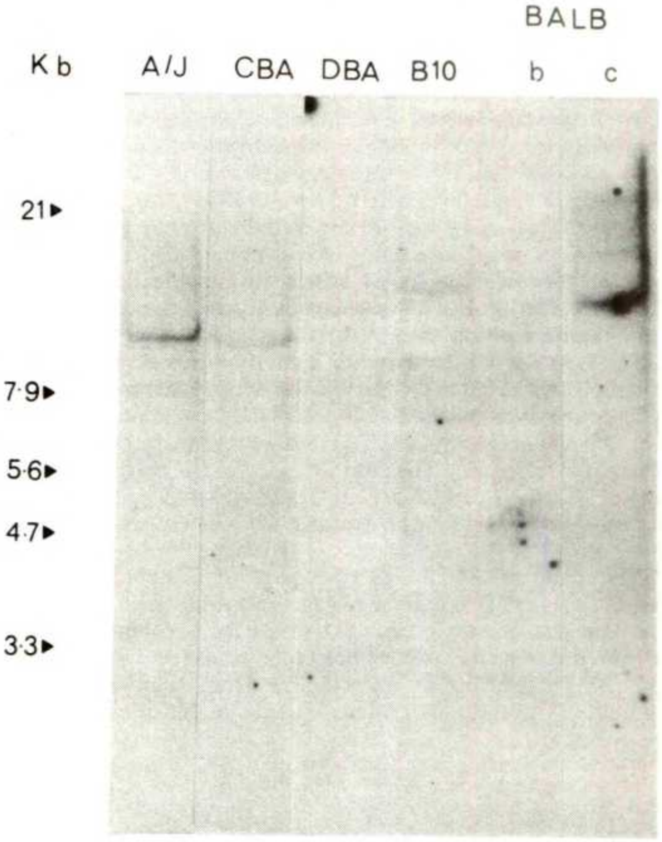

Fig. 1 Hybridization of $C\mu$ probe with liver DNA from various strains of mice. High molecular weight DNA was prepared from livers of A/J, CBA, DBA/2, B10A, BALB/c and BALB/b mice, digested to completion with *Kpn*I and 15-μg aliquots fractionated on 0.8% agarose (alongside λ phage DNA digested with *Eco*RI as size markers). The DNA was denatured and transferred to Schleicher and Schüll nitrate filters[10]. The $C\mu$ probe pμ/118 is a cDNA clone containing all of the $C\mu$ coding region plus a substantial amount of 3′ noncoding sequence[12], and was radioactively labelled by nick-translation (specific activity 4×10^7 c.p.m. per μg). The filters were hybridized as previously described[28,29] using $6\times$SSC salt conditions and 10^6 c.p.m. ml^{-1} of probe for 2 days at 65 °C. The filters were washed after hybridization in $1\times$SSC salt conditions and autoradiography was carried out for 2 weeks at −70 °C using prefogged film and an intensifying screen[30]. Fragments found in BALB/c, BALB/b and DBA are around 14 kilobases (kb), about 15 kilobases in B10A DNA, 12 kilobases in CBA and 12.5 kilobases in A/J DNA.

To detect rearrangement events around a J segment it is necessary to cleave the DNA to the 5′ side of the J segments. *Kpn*I cleaves about 1.5 kilobases to the 3′ side of the $C\mu$ gene[15]: therefore, the sizes of the *Kpn*I fragments (see Fig. 1 legend) of the different strains are all consistent with the possibility of a second cleavage site to the 5′ side of the JH region, given that JH and $C\mu$ are separated by about 8 kilobases[15]. Figure 2 compares the hybridization of pμ/118 ($C\mu$ probe) with *Kpn*I-digested T-cell DNA or liver DNA from the respective strain with a myeloma cell line (McPc 1748) which produces IgM. In each case, the liver DNAs display only a single hybridizing band which presumably reflects the presence of a single $C\mu$ gene in these mice. Compared with the liver DNA, DNA from the myeloma line (Fig. 2*a*) and the killer T-cell clones (Fig. 2*b*, *c*) display new restriction fragments hybridizing to the $C\mu$ probe. The IgM-producing myeloma shows two new hybridization bands (about 20 and 18.5 kilobases), indicating that rearrangement events have occurred on both immunoglobulin-bearing chromosomes in this cell line. Unlike the myeloma DNA, T-cell DNAs possess only single new rearranged fragments containing a $C\mu$ gene as well as a fragment approximately coincident with that found in the liver DNA. Thus, it seems likely that these cells have undergone DNA alteration at the JH cluster but that this event has occurred on only one chromosome, in contrast to the IgM-producing cell line. We have also found evidence of similar rearrangements in a Moloney virus-transformed cell line (Thy-1 positive, A. D. Lowe, personal communication), but we could find no rearrangement in a cell line such as P815 (a mouse mastocytoma).

0028–0836/80/350897—03$01.00

Furthermore, cleavage of the DNA with *Eco*RI, which cleaves between Cμ and JH[9,15], obliterates the evidence of rearrangement (unpublished data), lending support to the hypothesis that the events involve the JH region.

We have examined the possiblity of κ-chain rearrangement in the T-cell clones and in the IgM-producing clone using a similar strategy—digesting DNA with enzymes which cleave 3′ of Cκ and 5′ of Jκ (*Bst*I and *Eco*RI). McPc 1748 (Fig. 3*a*) possesses two *Eco*RI fragments hybridizing to the Cκ probe (23 and 15 kilobases) of which the latter is common to the unique Cκ-containing *Eco*RI fragment of BALB/c liver, indicating that this cell line has an integrated Vκ–Cκ gene in one chromosome. The comparative hybridization of the Cκ probe to AD9 DNA and CBA liver DNA digested with *Bst*I (Fig. 3*b*) shows only a common hybridization component (about 12.5 kilobases) which may be attributed to the unintegrated Cκ gene. Similar results were obtained with both HY72 DNA and the mastocytoma cell (P815) (unpublished). The absence of Cκ or Cμ rearrangement in P815 DNA is consistent with results recently published by Kemp *et al.*[16], who found no evidence of Cκ or Cμ transcripts in P815 RNA.

The data presented are, therefore, consistent with the conclusion that DNA changes have occurred which are associated with sequences to the 5′ end of the Cμ gene but that κ-gene rearrangements have not occurred in the T-cell clones studied. These changes around the Cμ gene, by analogy to the results in B cells, could be due to VH–JH joining or may be due to an as yet unknown DNA activity in this area. Although the T-cell and B-cell DNA may share these rearrangement features around the Cμ gene, they differ in that the T-cell DNAs show no evidence of Cκ-gene rearrangement. Although the results presented here do not necessarily imply T-cell expression of this region of the immunoglobulin locus, there is evidence that Cμ genes are expressed in thymocyte population or T-cell lymphomas[16,17]. The present study utilizes cloned T-cell lines as a source of DNA rather than tumour lines or thymus cells.

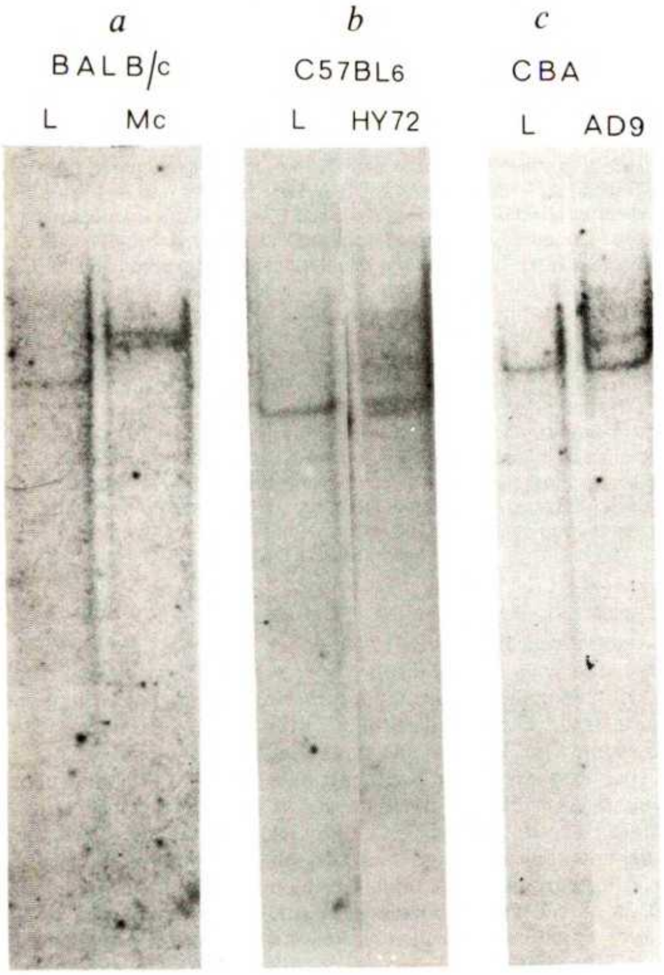

Fig. 2 Profiles of T-cell and B-cell DNA hybridization with Cμ probe. High molecular weight DNA of BALB/c liver (L) and McPc 1748 cells, C57B16 liver and HY72 cells, and CBA liver and AD9 cells were digested to completion with *Kpn*I, fractionated and hybridized as in Fig. 1 with pμ/118. *a–c* Represent separate fractionations of DNA.

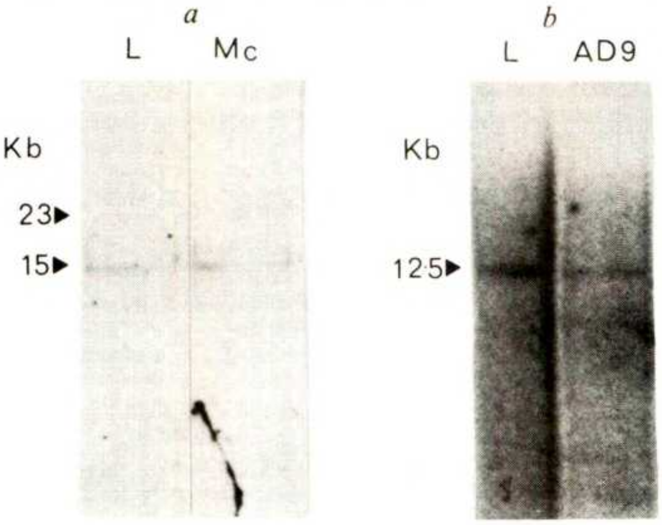

Fig. 3 Hybridization of mouse DNA to Cκ probe. The various high molecular weight DNAs were completely digested with *Eco*RI (panel *a*) and *Bst*I (panel *b*), fractionated and transferred to cellulose nitrate filters as in Fig. 1. The Cκ probe was isolated from the cloned cDNA pκ(11)[24] (ref. 31) by digestion with *Hpa*I: this enzyme cuts once in the pMB9 vector and once within the Cκ region of the insert near the V/C junction[32] to yield two fragments of which the 3.7-kilobase fragment contains the Cκ region. The fragment was isolated from a preparative agarose gel and labelled by nick-translation. The filters were hybridized and washed as in Fig. 1. *a*, L = BALB/c liver DNA; Mc = McPc 1748 DNA. *b*, L = CBA liver DNA; AD9 = AD9 killer T-cell DNA.

One can speculate on possibilities which could reconcile these results with what is known of T-cell receptors at the cellular level and H-chain genes at the molecular level. It seems that deletion of DNA between VH and CH genes occurs during the H-chain class switch[8,18–20]. Thus, as the T cells possess Cμ genes, it can be inferred that a putative constant region sequence of the T-cell receptor (C$_T$) would need to be located between the VH cluster and the Cμ gene or within the Cμ gene itself. In the mouse, JH segments and the Cμ genes are separated by about 8 kilobases of intervening sequence[15] which could easily accommodate a constant-region gene. A second possibility is that C$_T$ is generated from the Cμ gene, partly from the Cμ coding reading frame sequence and partly from new reading frames, or new combinations of coding sequences created by differential splicing, such as occurs in the formation of the SV40 and polyoma virus T antigens[21–23] or as is now known for the formation of the membrane form of μ-heavy chains[24,25]. A third possibility is that C$_T$ is located on a separate chromosome which can recombine with the immunoglobulin locus to translocate VH to C$_T$ or vice versa.

Projection patterns of single physiologically characterized optic tract fibres in cat

Douglas B. Bowling & Charles R. Michael

Department of Physiology, School of Medicine, Yale University,
New Haven, Connecticut 06510

Because the axons of retinal ganglion cells are the sole channels carrying information from the eye, the organization of their central projections is important in visual processing. However, their detailed destinations and patterns of synaptic distribution at the level of single, functionally identified cells are not known. Most anatomical studies involve populations of cells or fibres and do not examine their physiological properties; physiological studies involving intracellular recording and injection of marker substances into cell bodies[1–3] of single cells do not reveal distant axon terminals because the markers stain the fibres for only a few millimetres from the perikarya. To examine the central projections of retinal ganglion cells we have impaled single optic tract fibres near their sites of termination[4,5] and injected them iontophoretically with the marker enzyme horseradish peroxidase (HRP). We now report that this method has revealed the thalamic and midbrain ramifications of single physiologically characterized axons. The individual optic-tract fibres branch repeatedly, sending collaterals to the superior colliculus (SC), the medial interlaminar nucleus (MIN), and to one or more laminae within the dorsal lateral geniculate nucleus (LGNd). In different nuclei the single axons form arborizations of characteristically different shapes and distribute their synaptic terminals in columns (LGNd), sheets (MIN) or widely spread patches (SC).

We used standard procedures for studying visual physiology in mammals[6], for HRP histochemistry[7,8] and for morphological reconstruction. To maximize transport of the HRP out of the electrode tips we used high enzyme concentrations and large d.c. currents. The electrodes were filled by centrifugation with a pre-centrifuged solution of 200 mM potassium acetate (*p*H 6.8) and 10% HRP. The tips were broken to diameters of about 0.5 μm, giving d.c. resistances of 200–500 MΩ. To protect their tips and guide their descent to the optic tract, the electrodes were lowered from the surface of the cortex inside a stereotaxically positioned glass micropipette (Horsley–Clarke ant. 6, lat. 9; see Fig. 1*a*). The membrane potentials recorded from the axons were 10–40 mV negative with positive-going action potentials of 2–10 mV amplitude. On completing physiological testing of an impaled axon, we injected it with HRP using a current of 20–50 nA (electrode-positive) for 30–200 s. During the injection the current was periodically turned off and action potentials from the axon were observed to confirm that it remained impaled. The length of stained axon varied with the total injected charge and appeared complete in the geniculate and colliculus with 5–10 μC. At their injection sites the axons appeared swollen and were surrounded by extracellular debris (see Fig. 1*b*). Several hundred micrometres away the axons appeared normal and had diameters, including myelin, of 2–5 μm. Results reported here are based on 9 of 14 axons we recorded and injected in the optic tracts of four adult cats. All nine axons (three from ipsilateral and six from contralateral eyes) were functionally classified as Y-type based on standard criteria including high conduction velocities[9,10] (30–40 m s^{-1}) and nonlinear spatial summation in their receptive fields[11,12].

Figure 2 represents a frontal view of the left thalamus and midbrain showing the reconstruction of an on-centre optic tract axon from the contralateral eye. The axon was impaled (arrow) in the optic tract just ventral to the LGNd. The centre of the axon's receptive field was 1° in diameter and was located on the vertical midline 13° below the projection of the area centralis. The axon was spontaneously active, gave transient responses to steps of light, and responded well to rapidly moving stimuli. Based on a contrast reversal test[13], the effects of light were nonlinearly summed in its receptive field. The axon's retinal origin and its high conduction velocity (latency 0.36 ms) were demonstrated by electrical stimulation with a hook electrode placed near the head of the optic nerve.

Each of the nine axons sent collaterals to three nuclei: the LGNd, the MIN and the SC. In each nucleus the collaterals formed arborizations with characteristic patterns (see Fig. 2): converging to single loci in the LGNd, diffuse and radiating in the SC, and spread out in thin sheets in the MIN. Thus, individual ganglion cells have structurally different patterns of arborization at each of their nuclear destinations. Each axon gave rise to a total of 1,000–2,000 synaptic-like boutons which appeared in the sections as spherical or irregular swellings 0.5–3 μm in diameter. Such swellings have been identified in the LGNd as synaptic terminals[14]. The axon shown in Fig. 2 had about 1,400 of these terminals: 225 in the SC, 1,134 in the LGNd and 34 in the MIN.

In the LGNd the single axons from the contralateral eye always terminated in both laminae A and C. This is illustrated by

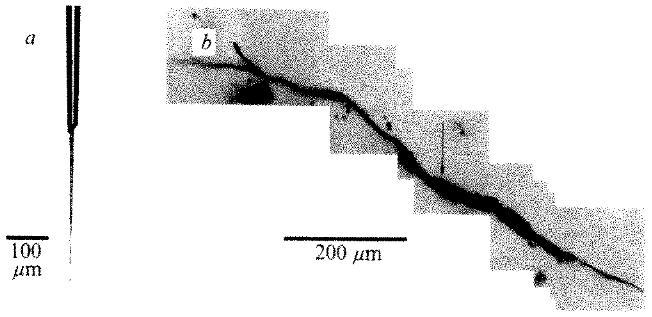

Fig. 1 *a*, Photograph of the glass micropipette used to protect and guide the tip of the electrode into the optic tract. The recording microelectrode extends out of the pipette. The micropipette was made from 1.6 mm o.d. glass pulled to a taper of 25 mm and broken to a tip diameter of about 30 μm. The electrodes were made with 30-mm tapers so that they could extend several millimetres out of the micropipette. *b*, Photographic montage showing detail of the axon of Fig. 2 at its injection site in the optic tract. The axon passes from the upper surface of the 100-μm section (lower right) to the lower surface (out of the picture at far left). It branches and sends a collateral back to the upper surface of the section (upper left). The arrow indicates the site of injection based on a line projected from the electrode track.

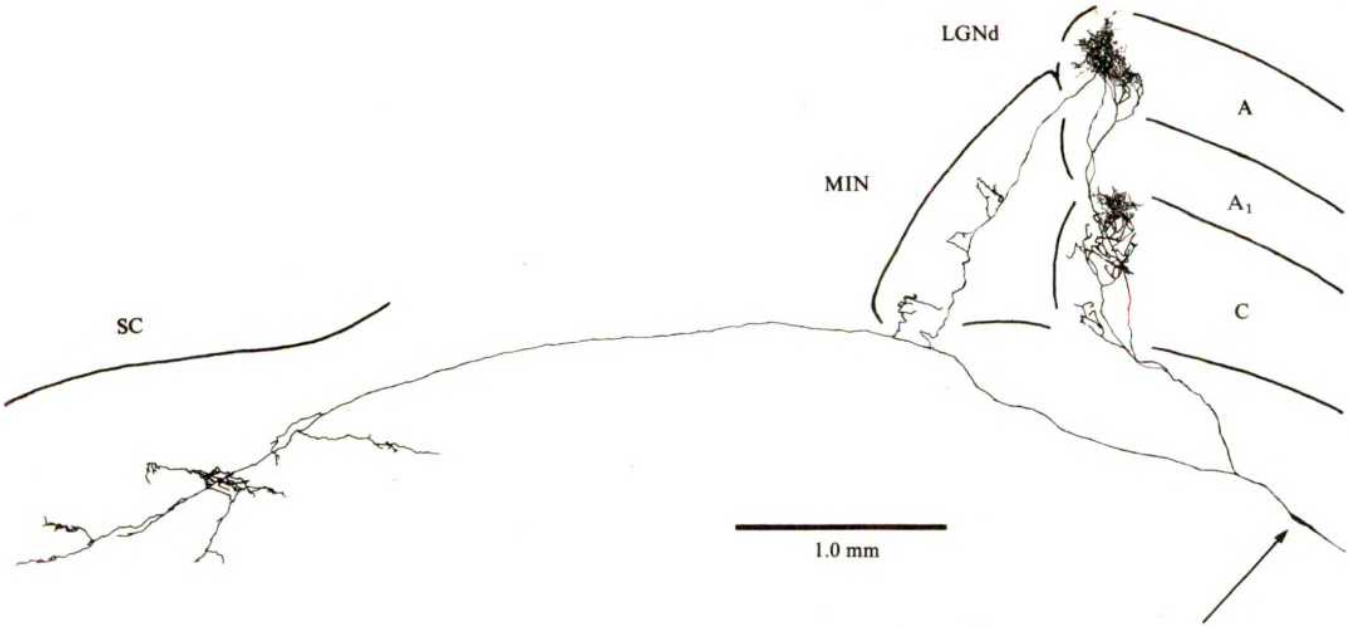

Fig. 2 Reconstruction from coronal sections of a single on-centre Y-type axon showing its terminations in the LGNd, MIN and SC. The arrow indicates the site of injection into the axon (see Fig. 1*b*). The figure represents over 3 mm of depth in the anterior–posterior axis (perpendicular to page) so that the perspective is flattened and the shapes of the nuclei and laminae are not representative of a single coronal plane. The arborization in the SC is in the anterolateral part of the nucleus.

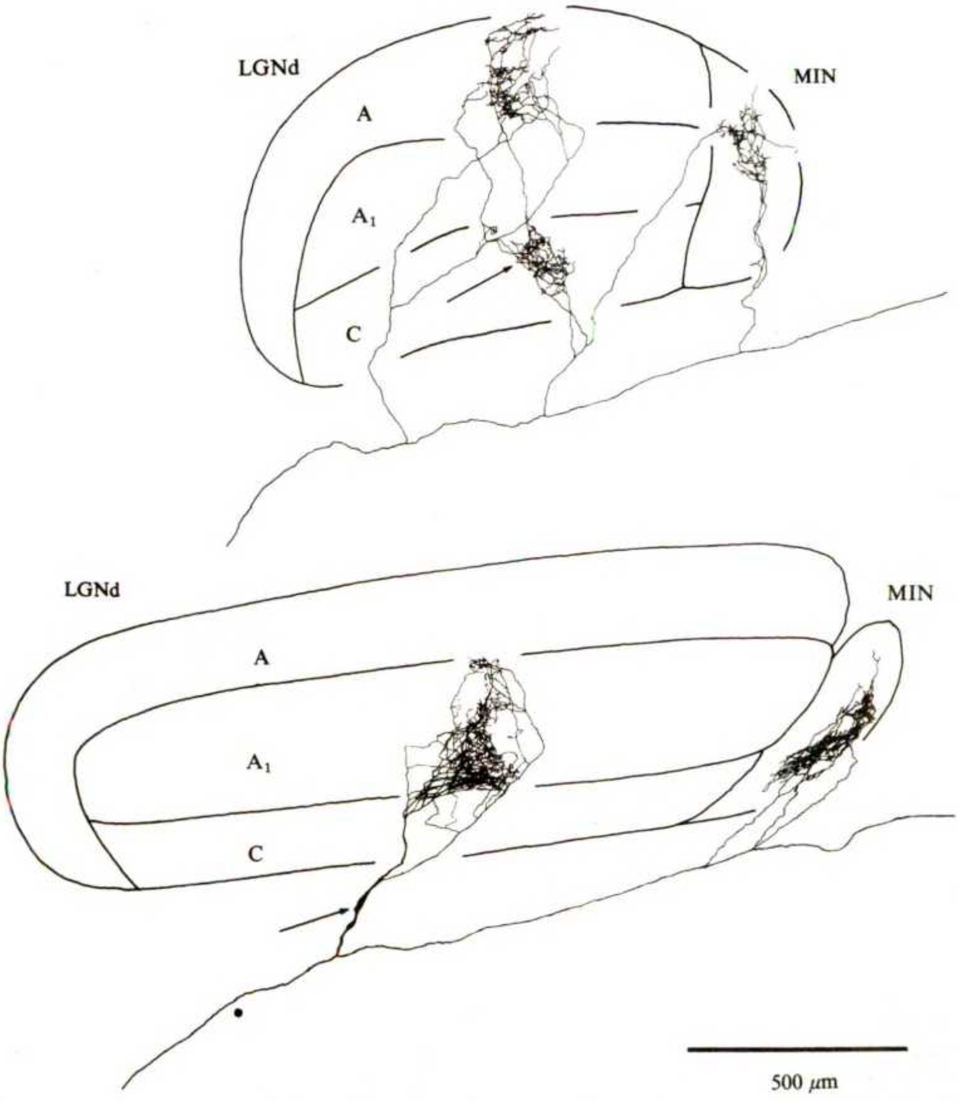

Fig. 3 Reconstructions of single axons showing their terminations in the right LGNd and MIN. The shapes of the terminal distributions in the MIN are bowl-like (concave toward the LGNd) and extend in the anterior–posterior axis about as far as they do in the plane of the figure. Arrows indicate injection sites. Upper: on-centre Y axon from the contralateral eye with a 4.5° receptive field centre located 28° below the horizontal meridian and 26° from the vertical midline. Lower: off-centre Y axon from the ipsilateral eye with a 4.5° receptive field centre located 1° above the horizontal meridian and 8.5° from the vertical midline.

the axons of Figs 2 and 3 (top). In at least two cases (for example see Fig. 2), these axons terminated in all three of the contralateral laminae (A, C, C_2). Whether this was always the case is not clear because the borders of C_2 were not always evident in our sections[15]. Axons from the ipsilateral eye terminated in only a single lamina. They arborized in A_1 but not in the other lamina (C_1) that receives ipsilateral input (see Fig. 3, bottom).

In three instances in which the sections were cut at right angles to the planes of the laminae, the synaptic terminals were seen to be distributed in broad-based columns that spanned the thickness of lamina A or A_1. Figure 4 shows one of these columns reconstructed from the axon of Fig. 3 (bottom). Each dot represents the position of a single terminal in A_1. The columns provide an anatomical basis for the physiologically observed 'projection columns'[16] which run through the nucleus. As with the projection columns at the same locations, the columns of terminals were tilted forward with respect to vertical[17]. Their broad bases, resulting in a greater density of Y terminals in the ventral portions of the laminae, may account for the apparent segregation of Y afferents that has been seen in field potential recordings[18]. The shape of the columns shows that there is an intra-laminar gradient in the spatial distribution of synaptic connections across the laminae. The functional significance of this gradient is unknown.

In the planes of the geniculate laminae, which correspond to the plane of the retinotopic map, the distributions of the terminals were basically circular. The maximum lateral spread was constant (300–400 μm) in spite of the fact that the receptive fields ranged from 1° to 4.5° in diameter and were located between 8° and 38° from the area centralis. This constancy of spread is consistent with the idea[17] that variations in geniculate receptive field sizes result from response properties of the input fibres rather than from anatomical differences within the nucleus. It also suggests uniformity and repetition in the geniculate, a plan of organization similar to that in the striate cortex, and one that may have developmental advantages[19].

In the MIN the retinotopic map is a mirror image of that in the LGNd[20]. Each axon distributed its terminals in the MIN as a sheet 300–400 μm across and about 50 μm thick. The sheets were slightly concave toward the LGNd, conforming to the general curvature of the MIN. They were orientated approximately perpendicular to the geniculate laminae. The form of the sheets can be appreciated from Fig. 3, taking into account that the perspective is distorted by projection onto a flat surface. The spread of the terminals in the plane of the MIN map (about 50 μm) was a factor of six to eight times less than the spread of the terminals in the plane of the geniculate map, a factor which is of the same order as the overall size difference between the MIN and LGNd. Thus, on the basis of the lateral spread of afferent terminals, the nuclei seem to be scaled similarly.

The synaptic terminals in the SC were in the superficial layers of the nucleus. A dorsal view of the SC arborization from Fig. 2, obtained by rotating the reconstruction graphically, revealed that the terminals were grouped into irregular patches which were distributed as an ellipse (1 × 2 mm) with its major axis orientated approximately medio-laterally. It would be interesting to know exactly how these patches are positioned relative to the columnar organization described in the SC for ipsilateral eye afferents and acetylcholinesterase activity[21]. It is clear that the major axis of distribution was approximately orthogonal to the columns and must have spanned several of them.

In the geniculate complex single axons often had two or more long branches which travelled along different paths to converge on the same retinotopic location (see especially Figs 2 and 3, top). It is not clear what functional significance, metabolic constraint, or mode of development these multiple and somewhat indirect pathways may reflect. What they do show is that in the adult there is considerable freedom in the paths that an axon may take to its target.

A second and perhaps related feature was that the forms of the arborizations in the LGNd and MIN were often only a crude guide to the spatial distribution of the axons' terminals. Some arborizations were diffuse and composed of processes that arose from branch points well outside the area of their actual terminations (compare Fig. 3, bottom, with the terminal distribution in Fig. 4). Other arborizations, such as the one in lamina A of Fig. 2, were dense and nearly congruent with the terminal distributions. The lack of close correspondence between the forms of the arborizations and the spatial distributions of the terminals was especially marked in the anterior–posterior axis of the LGNd. Here, sagittal sections showed that the arborizations were stretched out toward the posterior of the nucleus in 'cypress-like'[22] fashion. The form of the arborizations and the multiple pathways of the axons' long branches may arise during development as a result of morphological changes following synaptogenesis in the target nuclei. In the developing cat geniculate, the formation of the laminae, as well as growth and rotation of the nucleus, occurs after the arrival of the retinal afferents[23]. In the monkey geniculate similar events have been specifically shown to occur after synaptogenesis has begun[24]. If the migrating cells drag their presynaptic axons with them, then the terminals could be carried far away from the axons' branch points. In contrast to their geniculate patterns, axons in the colliculus go directly to their sites of termination by single, short paths (see Fig. 2). In this regard it would be interesting to know how the sequences of developmental events and patterns of morphogenesis differ between the cat colliculus and geniculate.

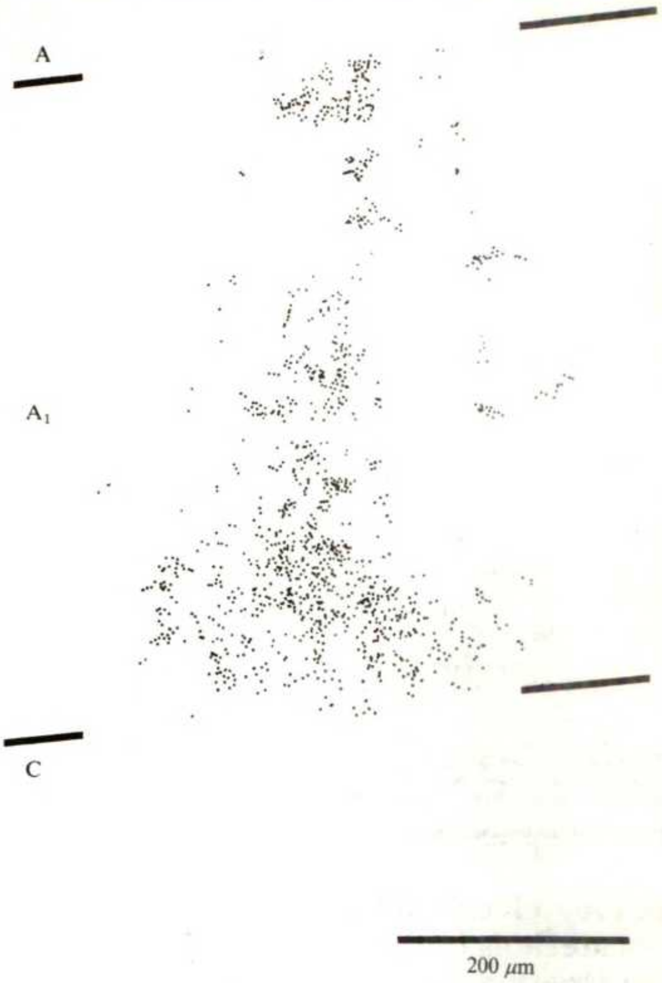

Fig. 4 Columnar distribution in lamina A_1 of terminals from the axon of Fig. 3, bottom. Reconstructed from four 100-μm serial sections. Number of terminals is about 1,200.

The results reported here are based on a sample of one physiological class of retinal axons. It will be of interest to examine single axons of other functional types, such as those from X cells[12] which have linear spatial summation and from colour cells which have opponent spectral properties. The experimental approach of staining single axons may also be useful in answering questions about axonal growth in developing preparations and in adult animals whose development has been altered by early experience, lesions or genetic factors.

We thank Drs Michael Cooper, Frederic Richards, Jonathan Stone and Mrs Winifred Craig and Faye Gomes for helpful advice and discussion and Drs Jeff Noebels, Martha Nowycky and Roger Thomas for reading the manuscript. This work was supported by NIH grant EY00568 and NIH training grant NS07102–03.

In vivo electrochemical detection of catechols in the neostriatum of anaesthetized rats: dopamine or DOPAC?

François Gonon, Michel Buda, Raymond Cespuglio*, Michel Jouvet* & Jean-François Pujol

INSERM U 171 and INSERM U 52*, Département de Médecine Expérimentale, Université Claude Bernard, 8, avenue Rockefeller, 69373 Lyon Cédex 2, France

Electroanalytical techniques for the *in vivo* measurement of neurotransmitters in brain tissue have been applied especially to the catecholamines, which are easily oxidizable[1–6]. Measurements are, however, complicated by the presence of ascorbic acid (AA) in brain tissue[1,3–6]. Lane *et al.*[7] have been able to circumvent this problem, at least in part, by the application of differential pulse voltametry (DPV) to a surface-modified platinum electrode, obtaining distinct oxidation current peaks in recordings from the rat neostriatum which are attributed to AA and to dopamine (DA), respectively, but which are also unstable. We have recently described a new type of electrode[2,8], consisting of a pyrolytic carbon fibre 8 μm thick and 0.5 mm long. We now report that the DPV method used in conjunction with an electrochemical treatment of this electrode yields stable and reproducible peaks in which catecholamines and AA are resolved from each other. Moreover, pharmacological investigations suggest that the catecholamine peak measured *in vivo* in the rat neostriatum should be attributed to 3, 4-dihydroxyphenylacetic acid (DOPAC), suggesting that our technique may be a useful means of following dopaminergic activity *in vivo*.

A classical three-electrode system was used with a conventional Ag/AgCl reference electrode. The carbon fibre electrodes were prepared as described elsewhere[8], and electrochemically treated by applying a triangular wave potential (0–3 V, frequency 70 Hz) for 20 s, with the electrode tips immersed in phosphate-buffered saline (PBS). Differential pulse (DP) voltammograms (Polarograph Tacussel PRG5; scan rate 20 mV s^{-1}, pulse modulation of 20 mV per 0.2 s) were recorded *in vitro* in PBS containing 20 μM DOPAC and 200 μM AA until the signal remained stable (~15 min). Before and after implantation each electrode was calibrated in standard solutions of DA, DOPAC, AA and dihydroxyphenylalanine (dopa). AA peaked at −50 mV and catechols, such as DOPAC, DA or dopa, peaked at +100 mV (Fig. 1). They yielded linear current responses with increasing concentrations of AA (0–1 mM), DOPAC (0–60 μM), DA or dopa (0–2 μM). These linear responses were not affected by the *in vivo* utilization of the electrode. The minimum measurable signal corresponded to about 2 μM for DOPAC and 0.2 μM for DA or dopa.

Carbon fibre electrodes were implanted in the neostriatum of anaesthetized rats (chloral hydrate 400 mg kg^{-1}). DP voltammograms recorded each 2.5 min showed two peaks: 'peak 1' appeared at the same potential as AA *in vitro* (−50 mV); and 'peak 2' appeared at the same potential as the catechols (+100 mV) (Fig. 1). We have shown that peak 1 disappeared in the striatum of guinea pigs that had been fed on a vitamin C-deficient diet and have suggested that peak 1, obtained from the striatum, is therefore due to AA[9]. Unfortunately, peak 1 was often found to be distorted, showed considerable variance from one animal to another, and appeared to be a function of the depth of anaesthesia. Thus, further work is needed to find better conditions (different parameters for the treatment of the microelectrode, use of chronic implanted rats) that will allow a more precise determination of AA *in vivo*.

In contrast, peak 2 appeared very stable and reproducible (Fig. 2). After an unilateral and selective destruction of the nigrostriatal dopaminergic pathway (performed and controlled as previously described[2]), peak 2 was suppressed in the striatum where the dopaminergic terminals degenerated, but was still present on the intact side (Fig. 1). Moreover, administration of α-methyl-*p*-tyrosine, a specific inhibitor of catecholamine synthesis[10], decreased the amplitude of peak 2 (Fig. 2). These results indicate that peak 2 represents the DP oxidation current of one or several catechol compounds, probably related to catecholaminergic nerve terminals in the striatum.

Several catechol compounds present in the striatum can be ruled out as being significant contributors to peak 2. Noradrenaline content in the striatum is about 1% that of DA[11]

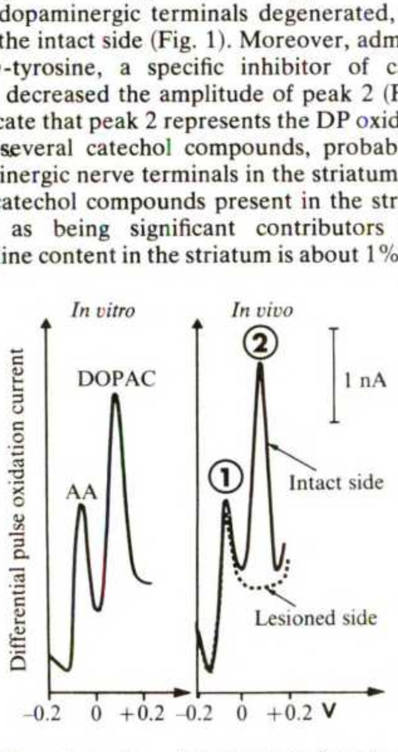

Fig. 1 Differential pulse voltammograms from *in vitro* experiments and from the neostriatum of anaesthetized rats (*in vivo*). Electrochemically treated carbon fibre electrodes were tested in PBS containing AA (200 μM) and DOPAC (20 μM). *a* Shows typical DP voltammogram. *b* Represents one typical example of DP voltammograms recorded in one rat with the same electrode implanted alternately in both striata. The lesioned side corresponds to a striatum in which the dopaminergic terminals were selectively destroyed following 6-hydroxydopamine injection in the substantia nigra[2]. Peak 2 suppression was observed with all the lesioned rats ($n = 6$).

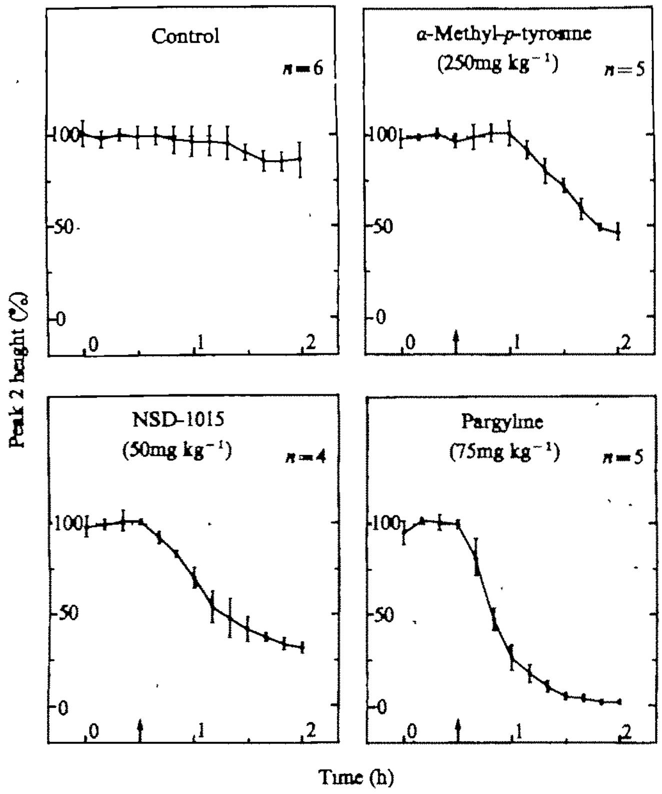

Fig. 2 Evolution of peak 2 height measured from DP voltammograms obtained from the neostriatum in control rats and rats treated with α-methyl-*p*-tyrosine (Sigma), NSD-1015 (Sandev) and pargyline (Sigma). All animals were anaesthetized with chloral hydrate (400 mg kg^{-1}, i.p.) and kept anaesthetized with additional injections as needed. Arrows indicate that i.p. drug injections were performed 30 min after the beginning of the recordings. For each animal the results were expressed as the percentage of the mean control value calculated by averaging the four initial absolute values of peak 2 height (100%). These four initial baseline responses were estimated by comparison with DOPAC calibration curves obtained after the *in vivo* experiment: the mean average value for all experiments was 22±4 μM (mean ±s.d., $n=33$). Results represent the mean ±s.d. of n rats

and the contribution of noradrenaline and its metabolites to peak 2 is thus negligible compared to that of DA and its metabolites. O-methylated metabolites of DA, such as homovanillic acid and 3-O-methyldopamine, are oxidized at more positive potentials[3,12]. dopa, DA and DOPAC are oxidized at +100 mV and consequently could contribute to peak 2 *in vivo*. They are present in the dopaminergic nerve terminals: DA is the neurotransmitter released from the nerve terminals, synthesized from dopa through dopa decarboxylase, and its major breakdown product due to monoamine oxidase activity is DOPAC. To elucidate which product was the major contributor of peak 2 the DA system was manipulated with drugs known to act at different levels of the dopaminergic metabolic pathway. Inhibition of dopa decarboxylase by NSD-1015 rapidly increases the striatal dopa concentration[13]. In our study, NSD-1015 induced a marked decrease of the peak 2 height (Fig. 2). Consequently, it is unlikely that dopa is responsible for the peak 2 recorded *in vivo*. Pargyline, which inhibits monoamine oxydase, is known to cause a rapid decrease in DOPAC[14,15] and an increase in DA concentration [16] in the striatum. Pargyline suppressed peak 2 with a half life of ~15 min, in agreement with previous observations[15,17] and this supports the notion that DOPAC is the major contributor to peak 2.

This suggestion was confirmed by the results obtained with other drugs. In fact, reserpine and haloperidol, which are known to raise striatal DOPAC levels[10,14,16,18], induced a pronounced increase in the peak 2 amplitude (Fig. 3). Amphetamine, which markedly increases DA release[10] and decreases the striatal DOPAC concentration[14,16], caused a diminution in peak 2 height. The effects of these three drugs were tested again in pargyline (75 mg kg^{-1}, intraperitoneally (i.p.)) pretreated rats (1.5 h before drugs). In these conditions, peak 2 disappeared completely and did not reappear after reserpine. After haloperidol and amphetamine (five animals each) a very small peak 2 reappeared, which reached a maximum after about 40 min. Its amplitude was in all cases found to correspond to an estimated concentration <0.2 μM DA.

These results show that peak 2 is mainly due to DOPAC oxidation. For all drugs tested alone, the variations in amplitude and time course of peak 2 were consistent with previous studies of DOPAC concentrations measured using fluorimetric or radioenzymatic methods[14–18]. In our study the concentration of DOPAC in the striatum was calculated by comparing peak 2 heights *in vivo* and *in vitro*, and was estimated to be 22±4 μM (mean ±s.d., $n=33$). This value is compatible with a global striatal tissue concentration of DOPAC under chloral hydrate anaesthesia of 7–15 μM refs 10, 14, 18).

A very slight contribution of DA to peak 2 was observed only after amphetamine or haloperidol. The very low DA levels thus measured are consistent with values found using the push–pull technique[19]. In the light of these observations and considering the size of the active part of the electrode, it can be assumed that events are recorded in the extracellular space occupying about 20% of the total tissue[20]. The presence in the striatum of a potent DA inactivating process acting through high affinity uptake by nerve terminals[21] prevents DA diffusing from the synaptic cleft to the extracellular space. thus contributing to maintaining in this space very low DA concentrations. This questions the interpretation of our previous results, suggesting that DA was responsible for the increase in the oxidation current measured in the striatum after amphetamine[2]. However, these experiments were performed using a non-selective technique (pulse amperometry and untreated carbon fibre electrodes). In the present study the decrease in peak 2 amplitude observed after amphetamine treat was always associated with a significant rise in peak 1 height, although important differences in the amplitude of this peak were observed.

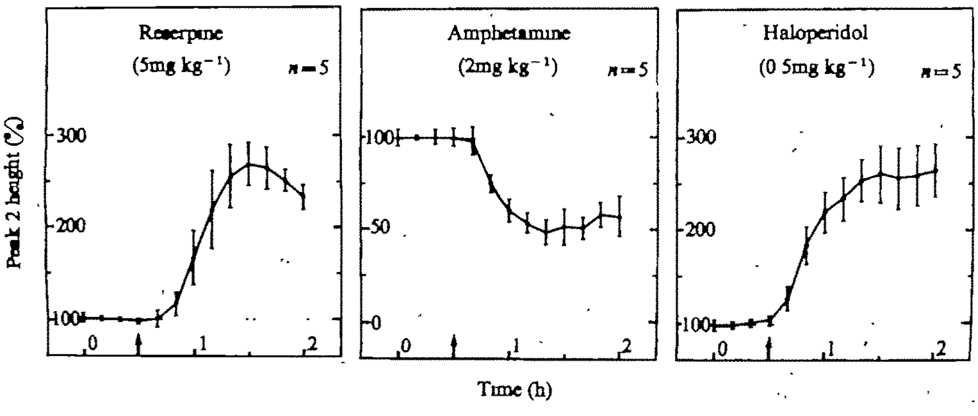

Fig. 3 Effect of reserpine (Serpasil, Ciba-Geigy), amphetamine (La Cooperation Pharmaceutique Française) and haloperidol (Haldol, Le Brun) on peak 2 height measured on DP voltammograms recorded from the neostriatum of anaesthetized rats.

The electrochemical treatment used in this study improves the selectivity, sensitivity and reproducibility of the carbon fibre electrode. In conclusion, the present investigation clearly demonstrates that the catechol oxidation current peak obtained *in vivo* from the striatum of anaesthetized rats is DOPAC and not DA.

We thank Dr T. A. Reader for reviewing this manuscript and Mr G. Verchère and Mr G. Guidon for technical assistance. This work was supported by CNRS (LA 162), INSERM (U 52 and U 171), and DGRST (grants nos 78.7.0156 and 78.7.2788).

Insulin triggers cyclic AMP-dependent activation and phosphorylation of a plasma membrane cyclic AMP phosphodiesterase

Robert J. Marchmont & Miles D. Houslay

Department of Biochemistry, University of Manchester Institute of Science and Technology, PO Box 88, Manchester M60 1QD, UK

Regulation of blood glucose levels by the liver is primarily achieved by the action of two peptide hormones, insulin and glucagon, which bind to specific receptors associated with the hepatocyte plasma membrane. Whilst the molecular action of glucagon at the level of the cell plasma membrane in activating adenylate cyclase is relatively well understood, we know little, if anything, of the molecular consequences of insulin occupying its receptor. We demonstrate here that insulin, at physiologically relevant concentrations, can trigger the cyclic AMP-dependent activation and phosphorylation of a low K_m cyclic AMP phosphodiesterase attached to the liver plasma membrane. Such an effect may in part explain the ability of insulin to inhibit the increase in cellular cyclic AMP content that glucagon alone produces by activation of adenylate cyclase. Our observation that basal, intracellular cyclic AMP levels are insufficient to allow insulin to activate the cyclic AMP phosphodiesterase, yet those cyclic AMP levels achieved after exposure of the cells to glucagon are sufficient, gives a molecular rationale to Butcher and Sutherland's proposal[1] that it is necessary to first elevate cellular cyclic AMP levels before they can be depressed by insulin.

The cyclic AMP phosphodiesterase activity of rat liver plasma membranes can be divided into a high K_m intrinsic enzyme exhibiting normal Michaelis kinetics and a low K_m peripheral enzyme exhibiting apparent negative cooperativity[2]. The low K_m enzyme is distinct from cytosol forms[2] and binds with high affinity to a protein site on the plasma membrane (R.J.M. and M.D.H., unpublished observations).

Treatment of purified rat liver plasma membranes with combinations of insulin, cyclic AMP and Mg^{2+}-ATP, in the conditions described in Fig. 1, resulted in a doubling of the cyclic AMP phosphodiesterase activity only when all three components were added and when native insulin was used. The activation attained maximal levels within 3 min (Fig. 1A) and was not reversed by washing the membranes with 1 mM $KHCO_3$, *p*H 7.4. The activation was entirely due to the peripheral, low K_m enzyme which could be released by high ionic strength treatment[2] in a 2.5-fold activated state when assayed at 4×10^{-7} M cyclic AMP (Fig. 1B). Relative to the native enzyme[2], the released, activated protein exhibited a slightly lower K_m, 0.59 μM, and similar V_{max}, 1,140 pmol min^{-1} mg^{-1}, but there was a significant reduction ($P<0.01$) in the Hill coefficient from 0.59 ± 0.05 (s.d., $n=4$) for the native enzyme[2] to 0.45 ± 0.03 (s.d., $n=4$) after activation.

Dose–response curves for the insulin-mediated activation of the cyclic AMP phosphodiesterase yielded a K_a of 1.4×10^{-10} M (Fig. 2), demonstrating the effectiveness of physiological concentrations. Interestingly, the cyclic AMP dependence of this phenomenon, exhibiting a K_a of 1.6×10^{-6} M, indicates that, at basal intracellular cyclic AMP levels of 0.3–0.5 μM (refs 3, 4), little if any activation would be triggered by insulin (Fig. 2). However, after exposure to glucagon, cyclic AMP levels rise to 2.0–4 μM (refs 1, 5) which would allow activation by insulin (Fig. 2).

The dependence of insulin's activation of the cyclic AMP phosphodiesterase on both Mg^{2+}-ATP and cyclic AMP indicated that a cyclic AMP-dependent phosphorylation might be involved. Because cyclic AMP-dependent protein kinases may be blocked by a specific inhibitor protein acting at the cyclic AMP regulatory subunit[6], we added such an inhibitor protein to the system and found that it prevented the activation of the cyclic AMP phosphodiesterase in a dose-dependent fashion (Fig. 1). Furthermore, polyacrylamide gel electrophoresis (PAGE) of the peripheral proteins of the liver plasma membrane after treatment with insulin, cyclic AMP and ^{32}P-ATP yielded three distinct peaks of radioactivity (Fig. 3). The major peak clearly migrated with the peripheral cyclic AMP phosphodiesterase activity. No ^{32}P from ^{32}P-ATP was incorporated into these peaks when (1) either or both cyclic AMP and insulin were absent, or (2) when a concentration of cyclic AMP protein kinase inhibitor protein just sufficient to prevent activation of the cyclic AMP phosphodiesterase was also present (Fig. 3). SDS-PAGE of the peripheral proteins obtained from liver plasma membranes pretreated with ^{32}P-ATP, insulin (10^{-9} M) and cyclic AMP (10^{-5} M) resolved three peaks of radioactivity. The major one, which is presumably the cyclic AMP phosphodiesterase, migrated with an apparent molecular weight of 52,000. From the estimates of molecular size of the enzyme in non-denaturing conditions[2], this would imply that it is a monomeric species. The two minor bands migrated with apparent molecular weights of 28,000 and 14,000. The dose–response curves for incorporation of ^{32}P into this major peak are given in Fig. 2*a*, *b*, where they demonstrate K_a's for insulin and cyclic AMP which are identical to those exhibited for the activation of the phosphodiesterase by these ligands. Indeed, a K_a of $\sim10^{-10}$ M for insulin's action is reflected in a similar affinity of insulin for specific binding to its receptor[7,21].

It is generally accepted and confirmed here (Fig. 1) that insulin alone does not activate the liver plasma membrane cyclic AMP phosphodiesterase of membrane fragments[8–11] although there is consistent evidence that such an activation can occur in intact adipocytes[8] and, in some instances, in intact hepatocytes[8,9]. Our novel observation is that for insulin to achieve such an activation then cyclic AMP and Mg^{2+}-ATP must both be present at appropriate concentrations. This may explain insulin's

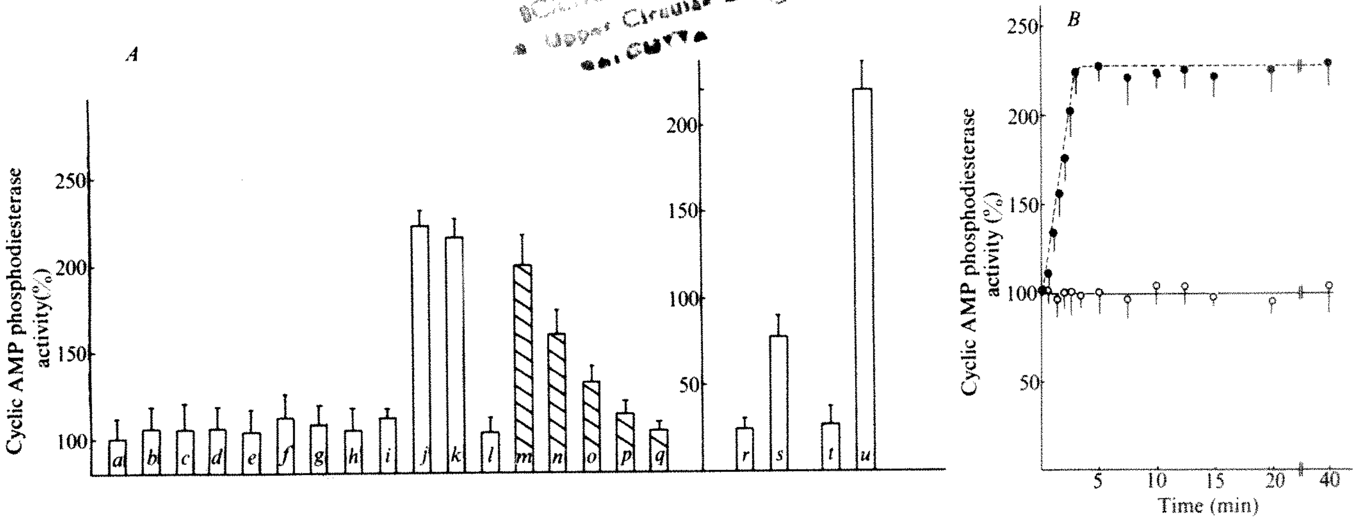

Fig. 1 *A*, Insulin requires ATP and cyclic AMP to stimulate the peripheral plasma membrane cyclic AMP phosphodiesterase activity. Purified rat liver plasma membranes[2,11] (500 μg protein ml^{-1}) were incubated for 5 min at 30 °C in a cocktail with final concentrations of 5 mM $MgCl_2$, 100 μM $CaCl_2$, 20 mM Tris HCl, *p*H 7.4, at a final volume of 250 μl. Various additions to the cocktail were made at the final concentrations stated and at a final *p*H 7.4. *a*, No additions; *b*, 3×10^{-3} M ATP; *c*, 10^{-9} M insulin; *d*, 10^{-6} M insulin; *e*, 10^{-7} M cyclic AMP; *f*, 10^{-4} M cyclic AMP; *g*, 3×10^{-3} M ATP + 10^{-6} M insulin; *h*, 3×10^{-3} M ATP + 10^{-4} M cyclic AMP; *i*, 10^{-6} M insulin + 10^{-4} M cyclic AMP; *j*, 10^{-6} M insulin + 10^{-4} M cyclic AMP + 3×10^{-3} M ATP; *k*, 10^{-9} M insulin + 4×10^{-6} M cyclic AMP + 3×10^{-3} M ATP; *l*, as in *j*, but using insulin denatured as described in ref. 13; *m–q*, as *j*, but a cyclic AMP-dependent protein kinase inhibitor, prepared as described in ref. 22, was added at final concentrations of *m*, 0.2 μg ml^{-1}; *n*, 0.4 μg ml^{-1}; *o*, 1.0 μg ml^{-1}; *p*, 1.0 μg ml^{-1}; *q*, 4.0 μg ml^{-1}. After this incubation the mixture was rapidly cooled on ice and then washed three times with 1 ml ice-cold 1 mM $KHCO_3$, *p*H 7.4, by repeated centrifugation at 14,000*g* for 10 min at 4 °C with subsequent resuspension. Aliquots (40 μg protein) of intact plasma membranes were then assayed for cyclic AMP phosphodiesterase activity as described previously[2] using 4×10^{-7} M cyclic AMP as substrate. Routinely, a modified two-step radioassay based on that described by Thompson and Appleman[23] was used as we could demonstrate negligible adenosine deaminase activity contaminating our preparations[2], although similar results were obtained using the method of Rutten *et al.*[24]. Corrections were made for adenosine bound to the resin[2]. The activity of the intrinsic enzyme was identical for both *r* (native) and *t* (treated), whereas that of the native peripheral enzyme (*s*) was increased 2.5-fold in the treated case (*u*). Separation of the peripheral and integral enzymes was carried out as in ref. 2. Similar results were obtained using plasma membrane derived from hepatocytes as isolated in ref. 2. Errors are ±s.d., $n = 6$ using six different plasma membrane preparations. *B*, Time course of the insulin-triggered, cyclic AMP-dependent activation of liver plasma membrane cyclic AMP phosphodiesterase. Liver plasma membranes were incubated in the cocktail described in legend to *A* either ●, with 10^{-9} M insulin + 4×10^{-6} M cyclic AMP + 3×10^{-3} M ATP, or ○, without such additions. Reactions were terminated as described in *A* and samples taken for assay of cyclic AMP phosphodiesterase at 4×10^{-7} M cyclic AMP. Errors are ±s.d. for three membrane preparations ($n = 3$). The initial activity of the cyclic AMP phosphodiesterase was 45 pmol min^{-1} mg^{-1} in the assay conditions used. The control enzyme was unaffected by incubation in this cocktail over a period of 40 min.

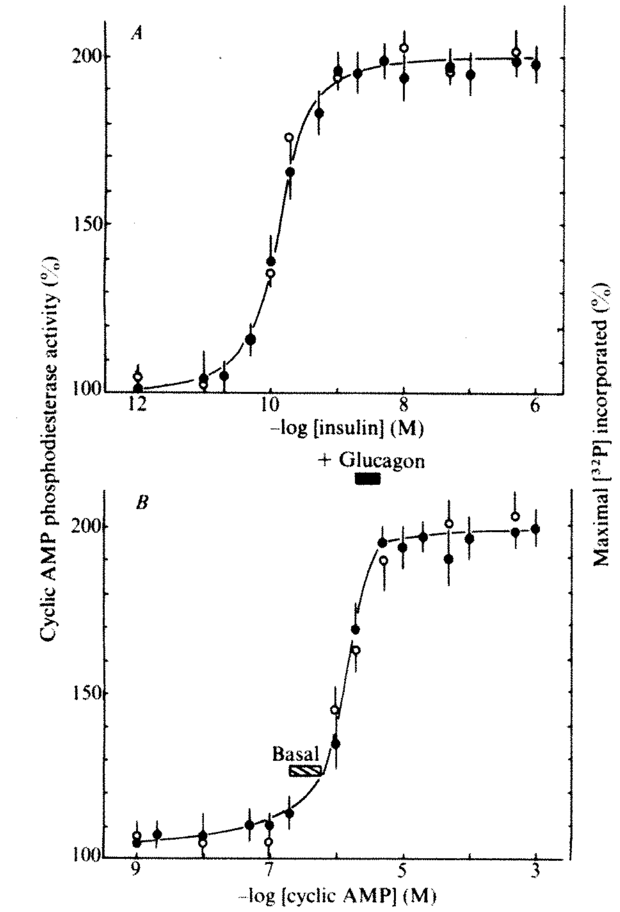

Fig. 2 Dose–response curves for the activation of the peripheral plasma membrane cyclic AMP phosphodiesterase. Incubations, assay of cyclic AMP phosphodiesterase and the release and separation of the peripheral enzyme after exposure to the stimulating ligand were carried out as described in Fig. 1*A* legend. For the assay of ^{32}P incorporation from [γ-^{32}P]ATP, the incubation mixture contained 1 mM ATP at a specific radioactivity of 200 mCi $mMol^{-1}$. The incorporation of radioactivity into the major peak found by SDS-PAGE of the peripheral proteins (see Fig. 3 legend) is plotted as a function of either insulin or cyclic AMP concentration. *A*, Dose–response curve for the activation of the peripheral cyclic AMP phosphodiesterase (●) in the presence of saturating, 10^{-6} M, bovine insulin. Similar results were obtained using 10^{-9} M insulin. The ATP concentration was 3×10^{-3} M. The dose–response curve for the incorporation of ^{32}P into the major peak obtained upon SDS-PAGE of the peripheral proteins (○) was carried out at an insulin concentration of 10^{-9} M. *B*, Dose–response curve for the activation of the peripheral cyclic AMP phosphodiesterase (●) in the presence of saturating, 10^{-4} M, cyclic AMP. Similar results were obtained using 4×10^{-6} M cyclic AMP. The ATP concentration was 3×10^{-3} M. The dose–response curve for the incorporation of ^{32}P into the major peak obtained upon SDS-PAGE of the peripheral proteins (○) was carried out at a cyclic AMP concentration of 4×10^{-6} M. Errors are ±s.d., $n = 6$ for six different plasma membrane preparations. Similar dose–response curves can be obtained when plotting ^{32}P incorporation into the two other major peaks obtained on SDS-PAGE.

apparently elusive effect on liver[9], for in the liver, cyclic AMP levels must be raised above their basal levels before insulin can trigger the cyclic AMP-dependent activation and phosphorylation of the cyclic AMP phosphodiesterase (Fig. 2).

Assayed at 1 μM cyclic AMP, the plasma membrane cyclic AMP phosphodiesterase activity of 55 pmol min^{-1} mg^{-1} represents only some 10% of the total cellular activity[2,9], which one can compare with a basal adenylate cyclase activity of 17 pmol min^{-1} mg^{-1} (refs 12, 13). Activation of the phosphodiesterase by insulin doubles its activity, to some 18% of the total, and in the presence of 1 nM glucagon, adenylate cyclase activity increases about fourfold[11,12]. It has been pointed out that small changes in phosphodiesterase activity could have a considerable effect on cyclic AMP concentration if the turnover rate was high[14] and the stimulation by insulin may take

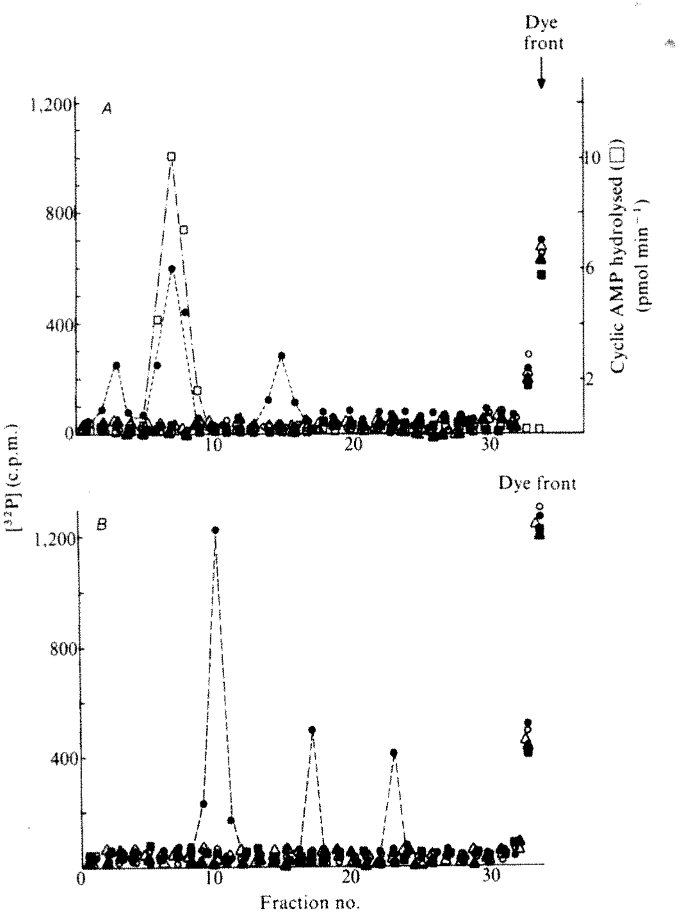

Fig. 3 Polyacrylamide gel electrophoresis of the peripheral proteins of rat liver plasma membranes. *A*, Peripheral proteins were released and subjected to PAGE in non-denaturing conditions with subsequent slicing of the gel as described in ref. 2. This figure demonstrates a typical experiment which we have now carried out over 10 times. Membranes were pretreated with various ligands in the conditions described in the Fig. 1 legend except that [γ-^{32}P]ATP was present at a final concentration of 1 mM with a specific radioactivity of 200 mCl mMol^{-1}. 100 μg of protein was loaded onto each gel. Gel slices were assayed for ^{32}P after incubation overnight in buffer[2]. △, [γ-^{32}P]ATP alone; ▲, [γ-^{32}P]ATP + 10^{-4} M cyclic AMP; ○, [γ-^{32}P]ATP + 10^{-6} M insulin; ●, [γ-^{32}P]ATP + 10^{-4} cyclic AMP + 10^{-6} M insulin; ■, [γ-^{32}P]ATP + 10^{-4} M cyclic AMP + 10^{-6} M insulin + cyclic AMP protein kinase inhibitor protein (4 μg ml^{-1}). Where [γ-^{32}P]ATP + 10^{-4} cyclic AMP + 10^{-6} M insulin were used, the eluted gel slices were also assayed for cyclic AMP phosphodiesterase activity[2]. Identical quantities of protein were loaded onto and extracted from each gel, making the results directly comparable. *B*, SDS-PAGE of the peripheral proteins. An identical experiment to that described above was set up, except that 100 μg of protein in 10 μl was mixed with 5 μl of a cocktail containing 6 mM EDTA, 0.75 M sucrose, 6% SDS, 0.03% bromothymol blue at a final *p*H 7.4. 160 mM dithiothreitol (5 μl) was added and the mixture incubated for 5 min at 100 °C. After cooling, 3 μl of 0.5 M iodoacetamide was added and this mixture incubated for 15 min at room temperature. SDS-PAGE was then carried out by the method of Laemmli[25] and gels were then sliced and incubated[2] except that 0.1% SDS was added to the buffer. This figure demonstrates a typical experiment. Similar results were obtained in both instances using 4×10^{-6} M cyclic AMP and 10^{-9} M insulin.

advantage of this. Furthermore, theoretical studies imply an importance of a low K_m phosphodiesterase bound to the plasma membrane in regulating both overall and local cyclic AMP concentrations[15]. However, we should not discount the possibility that a considerable fraction of the cyclic AMP phosphodiesterase activity is associated with intracellular membranes[2] and that the rapid internalization of insulin by endocytosis[16] may lead it to achieve a similar activation there. Furthermore, insulin may depress cyclic AMP levels in part by inhibiting adenylate cyclase in a Ca^{2+}- and adenosine-dependent fashion[17].

Occupancy of the insulin receptor in liver can lead to the cyclic AMP-dependent phosphorylation of three peripheral membrane proteins. One of these is a low K_m cyclic AMP phosphodiesterase which becomes activated. It is intriguing to speculate whether the other proteins are involved in Ca^{2+} mobilization[5,18] or in the generation of a 'mediator' of some of the other known intracellular actions of insulin[19,20] and to what extent intrinsic proteins may be affected. It would seem that, unlike the glucagon receptor where occupancy leads simply to the activation of adenylate cyclase, an occupied insulin receptor may affect several target proteins by initially triggering a membrane-bound cyclic AMP-dependent protein kinase.

We thank Dr H. G. Nimmo for advice and for a gift of the cyclic AMP-dependent protein kinase inhibitor and Professor A. A. Eddy for critical discussion of the manuscript. This work was supported by the MRC, SRC and the California Metabolic Research Foundation.

Stimulation of RNA synthesis in isolated nuclei by an insulin-induced factor in liver

Agnes Horvat*

Case Western Reserve University, Department of Medicine, Cleveland, Ohio 44106

Insulin stimulates the transport of small molecules as well as the synthesis of triglyceride, glycogen, DNA, RNA and protein. Although it is widely accepted that its differing actions are consequent to the binding to surface receptors, there is suggestive evidence that it may also act intracellularly. In 1975, we reported two well defined intracellular insulin binding sites in rat liver: the nucleus and the endoplasmic reticulum[1]. Specific binding sites for insulin on intact nuclei were shown by an immunofluorescent and autoradiographic technique, and the kinetics of insulin binding to isolated nuclear membranes were described[2,3]. Similar results have been obtained by other investigators[4–6], and the more recent reports on the internalization of insulin[7–9] give further support for an intracellular site of action of intact insulin or of its metabolic product. Investigation of the stimulatory effect of insulin on the synthesis of DNA and RNA in diabetic rats and isolated hepatocytes[10–13]

*Present address: University of Texas Health Science Center and Veterans Administration Medical Center, 4500 S. Lancaster Road, Dallas, Texas 75216.

suggests that the stimulation of RNA synthesis precedes that of DNA, and is likely to be an early event in the stimulation of macromolecular synthesis. I report here evidence of a low molecular weight substance in rat liver perfused with insulin which can stimulate the synthesis of RNA in isolated nuclei. These results suggest that insulin may function by binding to the cell surface, initiating or enhancing endocytosis[14] and entering the cell via a micropinocytotic route[9]. Once inside the cell, the active principle could be insulin itself, an intracellular degradation product of insulin, or a metabolic product of insulin action.

Fasted male rats were anaesthetized with Nembutal and their livers perfused with the perfusion apparatus described by Miller[15] (MRA Corporation, Clearwater, Florida). The perfusions were performed for between 5 and 30 min at 37°C. The medium was Hank's balanced salt solution 50 mM in HEPES and 3% in bovine serum albumin *p*H 7.5, with (10^{-7} and 5×10^{-8}M), and without insulin. The perfusate was equilibrated with 95% O_2 and 5% CO_2. Flow rates of 15–20 ml per min were maintained by a constant hydrostatic pressure. In these experimental conditions livers remain viable for 2–3 h without red blood cells in the perfusing medium[16]. In some instances the O_2 uptake of the liver was measured. The P_{O_2} between the inflow and outflow was lowered from 450 to 150 mm Hg. The concentration of immunoreactive insulin was determined in the perfusion medium before the onset, and after termination of the perfusion. Between 40 and 50% of the insulin was lost from the medium which is in good agreement with other reports[17,18].

After the perfusion was completed, the liver was immediately washed with ice-cold saline, homogenized in 0.25 M sucrose (20 mM in Tris-HCL *p*H 8.0) and fractionated into three subcellular fractions, nuclear, MLP (see below) and cytosol, by differential centrifugation[19]. The mixed particulate fraction, MLP (mitochondrial-lysosomal-microsomal), was obtained by centrifugation of the nuclear supernatant at 180,000 *g* for 1 h. The pellet was washed twice, suspended in 10 ml of 50 mM Tris-HCl buffer *p*H 7.8, sonicated with the MSE sonifier for 2 min and finally centrifuged again at 180,000 *g* for 90 min. Identical results were obtained when the vesicles were disrupted by multiple freezing and thawing. The soluble part, MLP soluble, was carefully separated from the pellet and the pellet suspended in 6–7 ml of 50 mM Tris-HCl *p*H 7.8 (MLP membrane). Both the MLP soluble and cytosol in subsequent steps were fractionated with the use of the Amicon ultrafiltration system. The first filtration was performed with the PM 30 membrane filter. In several experiments the fraction containing cellular components below 30,000 molecular weight was further fractionated with the UM-2 Amicon filter. The final fractions of the respective experiments (molecular weights below 30,000 or below 1,000) were lyophilized, suspended in 1 ml of water and used in the nuclear RNA synthesizing system. Nuclei from young rats (130 g) were isolated and characterized as described earlier[3] by the method of Blobel and Potter[20]. The assay conditions for RNA synthesis are described in the legend to Fig. 1.

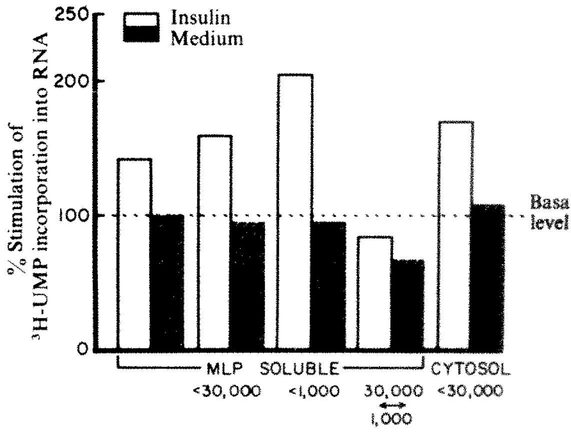

Fig. 1 Effect of insulin-induced factor on RNA synthesis in isolated rat liver nuclei. The livers were perfused with (5×10^{-8} M) or without insulin for 10 min; fractions and nuclei were isolated as described in the text. The assay for RNA synthesis was performed at 30 °C in a 250 l incubation mixture which was: ATP 400 μM, CTP, GTP 200 μM each, ^{3}H-UTP (NEN, 23.7 Ci mmol^{-1}) 330 nM, $MnCl_2$ and dithiotreitol 4 mM each, $(NH_4)_2SO_4$ 250 mM, Tris-HCl 40 mM, *p*H 7.9. The reaction was started with the addition of an aliquot of the nuclear suspension corresponding to 30–40 μg of DNA. After 5 min of incubation in a shaking water bath the reaction was stopped with 1 ml of ice-cold 10% trichloroacetic acid (TCA) and after 30 min at 0°C the precipitate was filtered on GF/C membrane filters, washed with 15 ml ice-cold 5% TCA, dried under IR lamp and counted in a scintillation counter with a 55% efficiency. The basal values (100% on the ordinate) correspond to an incorporation of 20 to 25 pmol UMP per mg DNA per 10 min. The amount of various fractions added was between 50 and 100 μg of protein as determined by the method of Miller[21] with bovine serum albumin (Armour) as standard.

Table 1 Effect of α-amanitin on the stimulation of RNA synthesis by a factor induced in liver perfused with insulin

Medium	^{3}H-UMP incorporated (d.p.m.)
Basal	21,000
+ α-amanitin	5,200
Basal + MLP soluble	29,000
+ α-amanitin	5,300

The assays were performed as described in the legend to Fig. 1. α-Amanitin concentration 0.8 μg ml^{-1}, MLP (100 μg protein) added where indicated.

Figure 1 depicts the results of a typical experiment indicating that perfusion of rat liver with 5×10^{-8} M insulin for 10 min produced a factor that directly stimulated the incorporation of ^{3}H-UMP into trichloroacetic acid insoluble material by isolated rat liver nuclei. The range of results obtained with different nuclear preparations and with fractions obtained from five insulin perfused and four non-insulin perfused liver preparations was as follows: insulin: MLP soluble, 138–200%; MLP soluble <30,000, 142–185%; MLP soluble <1,000 148–250%; cytosol <30,000, 124–200%. The corresponding values for the fractions from control livers (no insulin) were: 98–108%; 95–108%; 95–120%; 95–103%; and 96–110% of the basal levels. No stimulation was observed when intact insulin (10^{-8} – 10^{-6} M) was substituted for the perfused liver fractions in incubations with isolated nuclei (three experiments). With the MLP membrane fraction, an inhibition was noticed in two experiments. Both the basal level of RNA synthesis and the degree of stimulation depended greatly on the nuclear preparation, an observation also made by other workers[22]. Therefore, each nuclear preparation before use was checked for linearity in incorporation of ^{3}H-UMP with time and concentration of nuclei.

The results shown in Fig. 1 were all obtained in assay conditions optimal for RNA polymerase II, that is high [NH_4^+] and in the absence of α-amanitin. As shown in Table 1, when α-amanitin was added to the incubation mixture at a very low concentration (0.8 μg ml^{-1}), 75% of the basal activity was inhibited indicating that a large portion of the measured basal activity is due to RNA polymerase II[23]. All of the stimulation obtained by the MLP soluble fraction from the insulin perfused liver was completely abolished by the addition of this low concentration of α-amanitin. This could indicate that the stimulator specifically enhanced the synthesis of hnRNA in isolated nuclei[23]. The remaining activity is probably due to RNA polymerase I since the addition of 100 μg ml^{-1} α-amanitin did not affect the residual incorporation of ^{3}H-UMP into RNA[23].

In another set of experiments a dose-response effect could be demonstrated with fractions containing as much as 100 μg of protein, the latter amount not consistently exhibiting stimulation above that obtained with 50 μg. In a few experiments, the livers (insulin perfused and control) were fractionated into separate particulate subcellular fractions: nuclei, mitochondria, lysosomes, microsomes each of which was treated as described above for the MLP. Stimulation of RNA synthesis was observed with the lysosomal and to some extent with the microsomal fraction, but not with the mitochondrial or nulear fraction.

These results suggest that the vacuolar apparatus of the cell is associated with an active principle resulting from exposure of the cell to insulin. The substance is of low molecular weight, 1,000 or less, and conceivably could be a degradation product of insulin. Alternatively, it could be a compound chemically unrelated to insulin. In this regard, reports of a synthetic hexapeptide corresponding to the B_{21-26} fragment of insulin having a stimulatory effect on glucose uptake in the hind limb of rats could be pertinent to these results[24,25].

Turakulov *et al.*[26] reported the partial purification of a cytoplasmic regulator of Ca^{2+} transport by mitochondria isolated from rat liver 45 min after an intraperitoneal injection of insulin. These authors define the cytoplasm as the 30,000 *g* supernatant of the homogenate which actually contains both lysosomes and microsomes. From their results it seems that the factor is present in free and bound form supporting the suggestion presented in this paper, that is, that the primary site of formation of the active principle are membrane bound vesicles. The stimulation of RNA synthesis observed by the cytosol does not invalidate this suggestion since lysosomes are very fragile organelles and easily disrupted even with the most careful homogenization. Insulin has a delayed effect on the stimulation of RNA synthesis as compared to its very rapid effect on transport. If the formation of the active principle is indeed taking place in the vacuolar apparatus of the cell, and if it is a degradation product of insulin, the delay can be explained by the time needed for the content of the vesicles to be released into the cytoplasm. In general it is considered that the lysosomal membrane is freely permeable to small molecules, although it was also shown that 2 hours after the injection of ^{14}C-sucrose into the rat, subsequently isolated lysosomes contained both ^{14}C-glucose and ^{14}C-fructose[27]. As the factor appears to be of molecular weight below 1,000 it could reach the cytoplasm and finally the nucleus either by diffusion from the secondary lysosomes or alternatively by pyranhalysis, a process by which material entering the cell via endocytosis can be released into the cytoplasm of the cell without necessarily being completely degraded[28].

Recently, a low-molecular weight 'insulin mediator', probably a peptide, was reported to be present in insulin-treated rat muscle[29]. It mimics the action of insulin on cyclic AMP-dependent protein kinase, phosphoprotein phosphatase[29] and pyruvate dehydrogenase[30] in a cell-free system. There are several similarities between the 'mediator' and the factor detected in the present study. Both appear after a short exposure of the tssue to insulin, are of low molecular weight and have insulin-like action in a subcellular system, contrasting with previous experience where the action of insulin could be observed only in the whole animal, organ, or at least in the intact cell. There have been no previous reports of any effect of insulin or any compound derived from its action on the stimulation of RNA synthesis in a cell-free system. This report indicates the formation of a compound acting directly on the genetic material. As the insulin-induced factor enhances the synthesis of mRNA precursors it is possible that the factor affects the expression of genes known to be under the control of insulin[31-34].

I thank Drs B. R. Landau and J. Carter Jr, co-chairmen of the Division of Endocrinology, Department of Medicine, Case Western Reserve University, Cleveland, Ohio for their financial support of this investigation and many helpful discussions. I thank Susan Mann and Ed Burkett for assistance with liver perfusions and RIA assays of insulin respectively. This work was supported by the National Institutes of Health and the National Institute of Arthritis, Metabolic and Digestive Diseases.

Sequencing of 16S–23S spacer in a ribosomal RNA operon of *Euglena gracilis* chloroplast DNA reveals two tRNA genes

L. Graf, H. Kössel* & E. Stutz

Chloroplasts of the unicellular flagellate eukaryote *Euglena gracilis* contain several copies of a circular 135–140-kilobase pair DNA[1] which codes for chloroplast-specific stable RNAs (16S, 23S (refs 2, 3), 5S rRNAs[4] and tRNAs[5]) and for an unknown number of chloroplast-specific proteins. The rRNA genes are located within three tandemly repeated DNA regions of approximately 5.6 kilobase pairs each[6-8] and the arrangement of the structural genes within each repeat follows the prokaryotic pattern, being 5′-16S-23S-5S-3′ (ref. 9). Total chloroplast tRNA hybridizes to fragments of rDNA[9] and it was suggested that the 16S–23S spacer region contains tRNA coding sequences as is observed in *Escherichia coli*[10,11] and in spinach chloroplast[12] rDNA. We have therefore analysed *E. gracilis* strain Z 16S–23S spacer DNA at the nucleotide level, hoping this would allow identification of tRNA genes together with the processing sites of the respective primary transcripts. Maize chloroplast 16S rDNA shows strong sequence homology with *E. coli* 16S rRNA[13]. Sequence analysis of a total spacer in *E. gracilis* should demonstrate whether such similarities are also preserved in the chloroplast rDNA spacer region, or if this region has suffered a higher genetic drift rate. The latter is suggested from the 189 bases which have been sequenced from the 2.4-kilobase pair rDNA spacer from maize chloroplasts[14]. Flanking sequences, coding for the 3′-terminal region of 16S rRNA and for the 5′-terminal region of 23S rRNA have also been sequenced, to compare the drift rates between the spacer and its adjacent structural genes.

0028–0836/80/350908—03$01.00

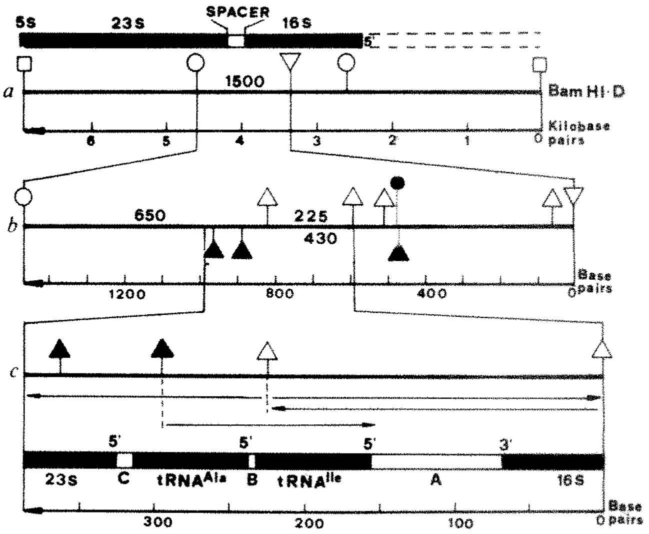

Fig. 1 *a*, Position of the *E. gracilis* rDNA region and of the spacer-containing fragment *Bgl*II–*Hpa*I$_{1,500}$ within the cloned fragment *Bam*HI·D (pEgc11)[8]. *b*, Fine mapping of fragment *Bgl*II–*Hpa*I$_{1,500}$ using the enzymes *Hae*III, *Hpa*II and *Hin*fI. *c*, Fragments used for sequence analysis of the spacer region. The arrows represent portions of 5′-terminally labelled single fragments from which unambiguous sequences could be obtained by a series of overlapping gels. Nearly all positions of fragment *Hae*III$_{225}$ have been analysed from both strands. Sequences of the right-hand portion of fragment *Bgl*II–*Hae*III$_{650}$ could be confirmed by analysing part of the complementary strand of fragment *Hin*fI$_{430}$, which also gives the necessary overlap between fragments *Bgl*II–*Hpa*I$_{650}$ and *Hae*III$_{225}$. Positions of rRNA and tRNA coding sequences and of the intergenic regions A, B and C are indicated. □, *Bam*HI; ▽, *Hpa*I; △, *Hae*III; ○, *Bgl*I; ●, *Hpa*II; ▲, *Hin*fI.

Figure 1 shows the protocol which was followed for mapping and identification of the spacer region within the restriction fragment *Bam*HI·D. This fragment, which contains one of the three rDNA repeats, has previously been cloned using the plasmid pBR322 as vector[15] and the respective clone pEgc11 (formerly pEgcKS11) was used for isolation of fragment *Bam*HI·D and its subfragments. Partial sequencing of several of the subfragments[16] revealed strong homology with regions from *E. coli*[17,18] and maize chloroplast[13] 16S rRNA (rDNA) and thereby allowed location of the 3′-terminal region of the 16S rRNA gene on the right-hand third of fragment *Hae*III$_{225}$. Since hybridization and fine-mapping data had indicated[6,7,19] that the spacer should not exceed 300 base pairs, the left-hand two-thirds of fragment *Hae*III$_{225}$ together with the neighbouring portion of fragment *Bgl*II-*Hae*III$_{650}$ should comprise the entire spacer sequence. These fragments were therefore chosen for sequence analysis according to the dimethylsulphate/hydrazine procedure[20] and the necessary overlap between the two *Hae*III fragments was obtained by sequencing the left-hand portion of fragment *Hin*fI$_{430}$.

In Fig. 2 the RNA-like strand of the *E. gracilis* spacer DNA sequence is depicted alongside the respective sequences from the *E. coli* rrnD operon. The first 63 positions comprise the 3′-terminal region of the 16S rRNA gene, the 'prokaryotic character' of which is documented by its high degree of homology with the corresponding rDNA region from *E. coli*. The reported 3′-terminal oligonucleotide AACAACUCN of *E. gracilis* 16S rRNA[21] allows exact positioning of the 3′-terminal end of the structural part of this gene. The reported T$_1$ oligonucleotide UAACAAG[21] which is highly conserved in prokaryotic 16 S rRNA[22] is found at position 22–28. The non-conserved position 59 is of particular interest, as it partly changes the recognition sequence for translational initiator regions[23,24]. This suggests that *E. gracilis* chloroplast ribosomes have a slightly altered pattern of recognition for mRNA in comparison with *E. coli* whereas in maize chloroplast ribosomes the corresponding sequence is identical to the *E. coli* 16S rRNA 3′ end[14].

A stretch of 66 nucleotides shown in the lower part of Fig. 2 represents the 5′-terminal portion of the 23S rRNA gene as evidenced by its extensive homology with the 5′-terminal region of *E. coli* 23S rDNA[10,11]. However, since the 5′-terminal oligonucleotides of *E. gracilis* 23S rRNA are not known, exact positioning of the 5′ terminus of the 23S rRNA gene is not

Fig. 2 Nucleotide sequence of the 16S–23S intergenic spacer region and of the flanking region of the 16S and 23S rRNA genes from *E. gracilis* chloroplast DNA (top row) and from the rrnD operon of *E. coli*[10,11]. Only the sequences of the RNA-like strands are depicted. Homologous sequences are marked by boxing. Within the *E. coli* sequence the symbols ▲, △ and *I* indicate single point deletions, multiple deletions and insertions in respect to the *E. gracilis* sequence. The number *a* of inserted bases is indicated by I_a. Note that the *E. gracilis* sequence is depicted in the opposite orientation from that of Fig. 1. Cleavage sites for the restriction enzymes used in Fig. 1 are indicated.

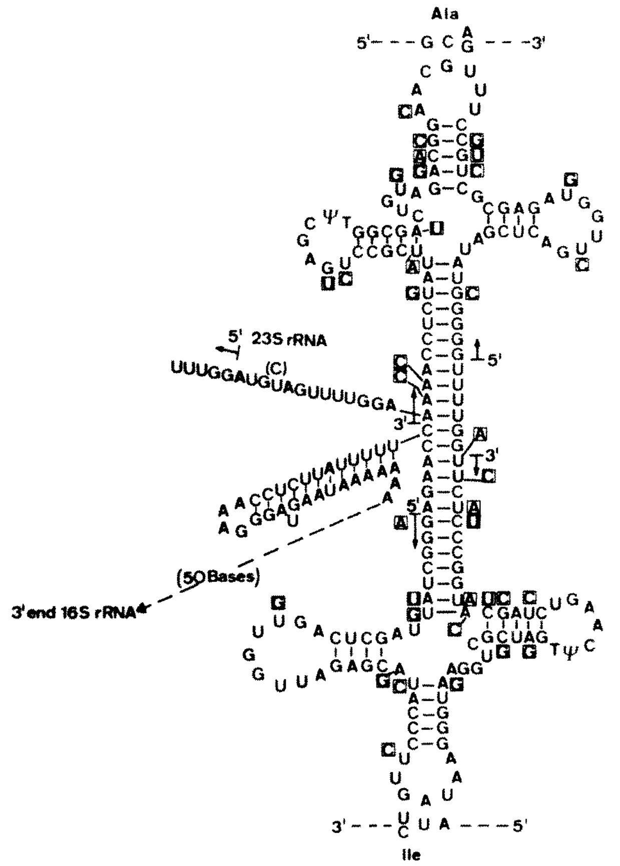

Fig. 3 Possible secondary structure of the dimeric tRNA precursor region as predicted from the corresponding DNA sequence of Fig. 2. The two tRNA cloverleaf structures are depicted without modifications of the bases except for the TΨ sequences in the T-arms. Bases different in the respective *E. coli* tRNA species[10,11] are indicated within boxes.

possible. The 16S–23S spacer DNA is thus represented by the 259 base pairs confined within positions 63 and (probably) 322. The analogous region in the *E. coli* rrnD operon is considerably larger with 437 nucleotide positions. In *E. coli* the spacer region is known to be transcribed as a part of the single transcriptional unit of the rrnD operon[10]. A large rRNA precursor containing both the 16S and 23S rRNA sequences was also observed in spinach[25,26] and *Chlamydomonas*[27] chloroplasts. A rRNA of similar large size has been observed also in *E. gracilis* chloroplasts[28] and therefore it is reasonable to assume that a similar situation exists in this case although direct experimental evidence for transcription of the intergenic spacer is lacking.

Screening for GTTC sequences, which are indicative for the GTΨC sequence present in the Ψ loop of all tRNA species[29], and for homology with the *E. coli* rDNA spacer region reveals two tRNA genes coding for an isoleucine (AU^{U}_{C})- and an alanine (GC^{A}_{G})-accepting species, respectively. The tRNA primary structures deduced from the two tRNA genes allow folding to a cloverleaf model completely consistent with all other structural criteria of tRNAs[29] (see Fig. 3). The deduced cloverleaf models contain several compensating base changes in the stem regions in addition to changes in the unpaired regions, which excludes the possibility that the two genes are derivatives of the *E. coli* genome due to a cloning or recombinational artefact. Also, the two chloroplast tRNA genes lack the CCA termini found in the respective *E. coli* tRNA genes[10,11]. The two tRNA genes are separated from each other by only six base pairs, which is reminiscent of the clustering of tRNA genes on the phage T_4 genome[30]. Within the precursor transcript, the two acceptor stems together with their neighbouring sequences can form a continuous stack of 24 base pairs (plus 2 × 5 base pairs of the two T-stems according to the tRNA tertiary model[31,32]) as drawn in Fig. 3. A possible hairpin structure directly preceding the 5′ end of the $tRNA^{Ile}$ is also depicted in Fig. 3, since its stem region could possibly also form an uninterrupted stack with the acceptor stem (and the T-stem[31,32]) of this tRNA within the precursor molecule. It is tempting to speculate that some of these possible secondary structures constitute at least part of the signal structures necessary for proper processing of the common precursor chain. Alternatively, or in addition to this, recognition of the sequence GGUUUUG, which is common to both the tRNA precursors immediately beyond the 3′ ends, may act as a signalling step during the processing events.

A comparison of the rRNA and tRNA coding sequences with the intergenic regions (Fig. 2) shows that the former are highly conserved contrary to the latter which are subject to many alterations, mainly by deletions but including some base substitutions. The short homologous stretches in the intergenic regions may have some functional significance for processing steps. Furthermore it is interesting that, similar to *E. coli* rDNA[10,11], the G + C content is high in the structural and low in the intergenic parts.

We thank Drs K. Edwards and R. Hertel for helpful criticism of the manuscript. This work was supported by grants from Fonds National Suisse de la Recherche Scientifique No. 3.452.79 to E.S. and from Deutsche Forschungsgemeinschaft (SFB 46) to H.K.

Erratum

In the letter 'Juvenile hormone mimics the photoperiodic apterization of the alate gynopara of aphid, *Aphis fabae*' by Jim Hardie, *Nature* **286**, 602–604, line 2 of paragraph 7 should read 'juvenile characters in the fifth instar. After scoring these alates' and line 5 of the same paragraph should read 'juvenilization are the second and third instars, an observation'.

MATTERS ARISING

The rhenium–osmium age of the Galaxy

LUCK, BIRCK AND ALLEGRE[1] have reported new meteoritic data on Re and Os which led to limits to the age of the Galaxy of between 13,000 and 22,400 Myr. Here I point out how these results change if one uses estimates of the s-process contribution to ^{187} Os given by Woosley and Fowler[2].

The isotope ratio used as a galactic chronometer can be written

$$R \equiv \frac{^{187}\mathrm{Os}^*}{^{187}\mathrm{Re}} = \frac{^{187}\mathrm{Os}^*}{^{186}\mathrm{Os}} \Big/ \frac{^{187}\mathrm{Re}}{^{186}\mathrm{Os}}$$

where all values are for the meteorites at formation and $^{187}\mathrm{Os}^*$ is the radiogenic component of $^{187}\mathrm{Os}$. The s-process component is written in terms of the ratio of neutron capture cross-sections and a correction factor, f, so that

$$^{187}\mathrm{Os}^*/^{186}\mathrm{Os} = (^{187}\mathrm{Os}/^{186}\mathrm{Os})_{\mathrm{total}} - (\sigma_{186}/\sigma_{187})f$$

Let us use from reference 1 the values $^{187}\mathrm{Re}/^{186}\mathrm{Os} = 3.20$ and $(^{187}\mathrm{Os}/^{186}\mathrm{Os})_{\mathrm{total}} = 0.805 \pm 0.011$ (2σ), and from ref. 2 the values $\sigma_{186}/\sigma_{187} = 0.504 \pm 0.034$ (2σ) (ref. 4) and $0.8 \leqslant f \leqslant 1.15$. These quantities give $R = 0.096 \pm 0.041$. Luck *et al*[1]. use a smaller s-process contribution, which gives $R = 0.152$.

A firm lower limit to the age of the Galaxy comes from assuming that all nucleosynthesis of Re occurred in a single burst at time $t = 0$. Then the time T of meteorite formation (4,550 Myr ago[1]) is given by $R = \exp(\lambda T) - 1$, where the decay constant $\lambda = 1.62 \times 10^{-11}$ yr^{-1} (ref.1); the age of the Galaxy is given by $t_0 > T + 4{,}550$ Myr. The value of R used by Luck *et al.* gives $t_0 > 13{,}300$ Myr, but the above revised value gives a lower limit of $10{,}200 \pm 2{,}300$ Myr.

An upper limit to t_0 cannot be obtained without a detailed model of chemical evolution, including gas flows[3]. As a simple example of an older model, the case stated by Luck *et al.* of 'steady-state nucleosynthesis' gave $t_0 = 22{,}400$ Myr with their value of R, but with the above value it gives $t_0 = 16{,}100 \pm 5{,}100$ Myr.

The main points are, as forseen by Woosley and Fowler[2], that uncertainties in the s-process seriously affect the Re–Os chronometer, and that use of the latest estimate of the s-process contribution to ^{187}Os reduces the lower limit to the age of the Galaxy by about 3,000 Myr.

Accuracy of thermoluminescence dates

WE congratulate Liritzis and Thomas[1] on the first combined application of thermoluminescence dating and magnetic palaeointensity determination, particularly in view of the disadvantageous magnetic characteristics of the kiln wall material used. It is a pity, however, that the thermoluminescence age errors in their Table 1 have been quoted without qualification, as they are liable to mislead archaeologists and others into expecting a higher accuracy from the technique than it can truly give. As has been learnt with radiocarbon dating, it is important to distinguish between precision of measurement and absolute accuracy. Evidently the errors quoted in Table 1 refer to the former (because the errors quoted for the averages are substantially less than the errors quoted for the individual measurements).

The systematic errors inherent in thermoluminescence dating are of a different type from those in radiocarbon but they are, nonetheless, important if comparison is being made with archaeologists' calendar year dates. Whereas the major systematic errors in radiocarbon dates have been worldwide effects—initially, uncertainty about the value of the half life and, more recently, uncertainty about the calibration curve by which radiocarbon years are converted into calendar years—the systematic errors in thermoluminescence dating arise from more intimate effects such as differences between types of fabric measured, burial environments and laboratory techniques.

It is not appropriate here to go into detail, but on the basis of a previous assessment[2,3] and taking into account two additional interfering effects also noted[4,5] specifically in respect of quartz, it seems unlikely that tighter limits than ±5% can at present be placed on the possible systematic error for a thermoluminescence date. This is at the 67% level of confidence. Neglecting any contribution from measurement error, this 5% systematic error limit corresponds to ±200 yr for a date at around 2000 BC, falling to ± 150 yr for 1000 BC. More realistically, we would put the best overall error limit that can be achieved for the average date on a group of contemporaneous samples, except in abnormally favourable circumstances, at ±7%, that is, ±300 yr and ±200 yr, respectively.

Obviously it is to be hoped that research will lead to improvement in the accuracy of thermoluminescence dating. One notable obstacle is the uncertainty introduced by possible variation in water content during burial; although techniques have been proposed[6,7] that eliminate this interference, they have not yet reached a better accuracy than that quoted above.

LIRITZIS REPLIES—I would like to clarify some points. First, the systematic errors in thermoluminescence (TL) dating of well-fired kilns clays are not pronounced (as they are in most other cases), due to the kiln structure; we used the internal part of the well-fired kiln wall or internal part of a fused kiln-surface clay. Second, the dated quartz samples (15 kiln clays and 3 tiles) come from the same fabric type of the respective kiln, and all have been subjected to the same climatological factors, an 'advantage' for precise water uptake and environmental γ-radiation measurements. This mineral similarity was also found from X-ray fluorescence analysis of many samples from the same kiln, and from the TL glow curves.

Third, in general, I agree that the systematic errors of ±5% exist for TL dating, but in the favourable circumstances of studying kiln materials they are much reduced. Fourth, the quoted 67% level of confidence will ensure improved accuracy for archaeologists' estimations. Fifth, some estimated errors (many due to the operator and technique used) cancel themselves out. Therefore, an average date for many contemporaneous samples, in the same burial conditions and weathering as in kiln materials, does make sense and justifiably reduces the overall error. Finally, by taking the 'permitted' average error of many TL dates as an overall error limit of the age of a kiln, the final quoted TL accuracy, as estimated % error, of our report is valid, and the precision obviously better.

Ignimbrite veneer deposits or pyroclastic surge deposits?

RECENTLY, Walker and others[1] applied the concept of aspect ratio[2,3] to ignimbrites and we accept this as valid reasoning. An outstanding feature of the low-aspect ratio Taupo and Rabual ignimbrites (deposits of pumiceous pyroclastic flows) they describe is a landscape-mantling deposit (ignimbrite veneer deposit) which can be traced into a more conventional topography-infilling ignimbrite (valley-ponded ignimbrite). According to Walker and others[1], recognition of these new features requires that a reappraisal be made of the emplacement mechanisms and new diagnostic criteria be drawn up for recognizing pyroclastic types. We, however, question this statement.

In the lesser Antilles, several pyroclastic flow deposits that fill valleys have been traced into finer-grained, stratified and cross-stratified deposits which mantle the interfluves between valleys. These deposits are interpreted by us as the deposits of ash-cloud pyroclastic surges. Ash-cloud surges are outwardly expanding dilute pyroclastic flows derived from an underflow or pyroclastic flow *sensu stricto*[4–6]. The flow and surge have fundamentally different transport mechanisms. Pyroclastic flows are high-concentration flows that move by laminar and/or plug flow[7,8]. Deposits are typically massive, poorly sorted and topographically controlled. Surges are flows that are turbulent and deposit beds with internal stratification and cross-stratification[4–6]. Surges are not topographically controlled and deposits can mantle landscape adhering to relatively steep slopes.

Walker and others[1] imply that the ignimbrite veneer deposit is the deposit of a high-concentration flow. The veneer is regarded by them as a 'tail deposit' left in the wake of the pyroclastic flow. From their description we contend that this tail deposit is the deposit of an ash-cloud surge derived from the main flow and is its lateral equivalent.

WALKER ET AL. REPLY—We accept without reservation the relationships described by Fisher and others from the Lesser Antilles. We have long believed in the concept that pyroclastic flows *sensu stricto* and pyroclastic surges have fundamentally different transport mechanisms. What is in question, however, is not the basic concept but the origin of certain rocks occurring specifically at Taupo and Rabaul Volcanoes: the rocks which we have called ignimbrite veneer deposits (IVDs).

We considered very carefully the possibility that our IVDs might have been emplaced in the way that Fisher and others propose, but rejected it for the five reasons outlined below.

First, apart from having a generally smaller content of coarse pumice, the IVD is identical in its grain-size characteristics with the valley pond ignimbrite, and has identical pumice density and crystal and lithic sizes and contents. There is no laboratory test that we can apply to distinguish between the two. Moreover, the IVD is visibly in lateral continuity with, and passes gradually into, the valley pond ignimbrite.

Second, the sheer scale of the IVD at Taupo seems to us to negate the idea that it could be the deposit of a surge generated at the vent; we think it highly unlikely that any pyroclastic surge is capable of moving radially outwards against air resistance, and of remaining highly turbulent long enough, to encompass a nearly-circular area measuring more than 160 km across, or of carrying $>10^{13}$ kg of poorly sorted pyroclastic material held entrained in its gas. We note that all known far-reaching pyroclastic surges have originated on steep and high cones, and the most far-reaching one (Bezymianny 1956[1]) was strongly directional, yet it travelled no further than 29 km. The Taupo IVD is not directional, and there is no evidence that it originated on a steep or high volcanic cone.

Third, the scale again seems to us to preclude the possibility that the IVD was generated by a whole succession of pyroclastic surges jetting forwards from the advancing ash-flow, which is presumably the mechanism that Fisher and others envisage. We do not deny that such jetting may and probably does occur, but we would expect the surges to carry much less particulate material than the parent body. This relationship certainly holds at Mt Pelée (Martinique) where one of us (G.P.L.W.) has worked. At Taupo, however, the IVD constitutes about 50% of the total ignimbrite volume, and at Rabaul as much as 75%. We note that the higher the proportion of 'surge-deposited' material, the more closely in effect does the 'jetting surge' concept converge on the single 'vent-generated-surge' one.

In the 'jetting surge' model we would, moreover, expect some kind of close relationship to exist between the thickness and lateral spread of a surge deposit and the position of adjacent valley ponds, but we find no such relationship. There are many places where a normal thickness of IVD is found several kilometres laterally from, and often several hundred metres higher than, the nearest substantial valley pond.

Fourth, at Taupo we have found ponded ignimbrite in many valleys where, to reach them, the parent flow must have crossed ridges or passes standing hundreds of metres higher than the present vent position. The most extreme ignimbrite pond we know is 2–3 m deep, contains pumice fragments up to 30 cm in diameter and occurs high on Tongariro Mountain, 45 km laterally from and 1,500 m higher than its source vent. We know of no way that this valley pond could have formed other than by the passage of a high-concentration pyroclastic flow right across the mountain.

Fifth, undoubted pyroclastic surge deposits differ notably in grain size and constitution from ignimbrite. The deposits of a more or less cold (and often wet) base surge are generally well stratified, and the beds (which have a thickness commonly measured in millimetres or centimetres) associated in the same bedding set commonly vary in median diameter over a range of 5 phi units or more. In contrast, in the IVD the layers (apart from certain pumice lenses) vary typically over a range of less than 1 phi, and the presence of carbonized vegetation indicates that they were hot. The deposits of a hot pyroclastic surge (such as the dilute component of a peléean *nuée ardente*) are totally different in character from ignimbrite, typically being very strongly enriched in the denser constituents (lithic fragments, crystals) and strongly depleted in fine dust.

We are convinced from these relationships that our IVD is indeed the deposit from a high-concentration flow, a pyroclastic flow *sensu stricto*, and cannot have been produced by any surge mechanism involving a dilute 'ash cloud'. Clearly, emplacements of both the Taupo and Rabaul ignimbrites were quite exceptionally violent events, far beyond the experience of civilized man, and we believe that there is a limit to how far their products can be interpreted from the study of such relatively minor eruptions as the 1902 *nuée ardente* of Mt Pelée.

BOOK REVIEWS

Mother science and prodigal sons: a history of haematology

William S. Beck

Blood, Pure and Eloquent: A Story of Discovery, of People, and of Ideas. Edited by M. M. Wintrobe. Pp.771. (McGraw-Hill: 1980.) $30, £18.50.

IN THE discharge of editorial duties one day, I received a critique that included the phrase "This monograph fills a much needed gap". That addled expression came to mind when I contemplated this handsome new book by Maxwell M. Wintrobe and a well chosen gallery of distinguished haematologists. There was indeed a gap — much needed if it inspired this book — in the literature of scientific history. That gap, more like a chasm, concerned haematology, a discipline that richly deserves to have its story told.

The field of haematology has several notable properties. Because blood has always fired the human imagination, it long interested philosophers and poets who contributed some of our earliest notions of it. By drawing the book's title from the emotional imagery of John Donne, Wintrobe reminds us of that fact. Because blood is readily available, it was also an early object of scientific investigation, yielding many important basic discoveries in which haematologists have taken a proper pride. Some were of such magnitude they significantly advanced whole branches of science. There can be no doubt, for example, that the discoveries of liver therapy for pernicious anaemia by Minot and Murphy in 1925 and of intrinsic factor by Castle in 1929 turned haematology from a musty descriptive discipline, dominated by blood cell morphology, into a dynamic science rooted in physiology and biochemistry. These advances launched the whole field of modern clinical investigation. For another example, the discovery that sickle cell anaemia is a 'molecular disease' opened an important new chapter in molecular biology.

These successes had interesting consequences for the mother science, which soon spawned a cluster of subdisciplines. Like prodigal sons, they achieved their own bountiful successes and left home. Those who would define haematology as the science of blood saw the perimeter breached again and again, as such subdivisions as oncohaematology, immunohaematology and haemostasis acquired their own journals, national societies, sections at the National Institutes of Health and other perquisites. This disconcerting situation is burdensome for all who teach haematology to medical students, who must take certifying examinations in medicine or pathology, who plan and fund research programmes, and who apply these disciplines in the care of patients. Still, though it has been something of a nightmare for intellectual taxonomists, haematology has been a raging success scientifically. Its opulent history is dealt with adequately for the first time in this volume. It is a grand homecoming.

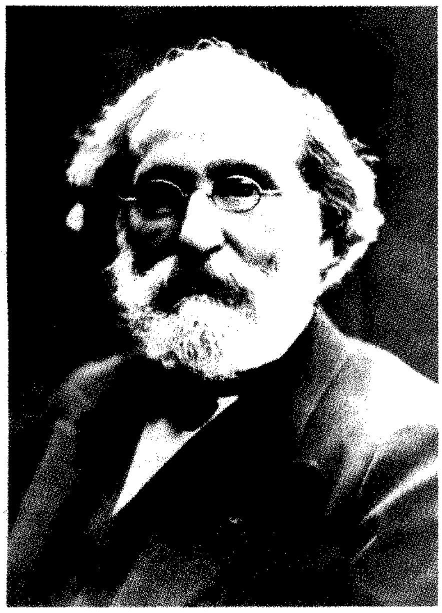
Wintrobe, a widely respected academic haematologist, has collected a series of articles on the several haematological subdivisions by recognized authorities, most of whom have themselves contributed significantly to the historical record. The book begins with an essay by Wintrobe that spans the early beginnings, from the ancient roots of haematology, through the great age of microscopy, up to the modern era. Next, an interesting chapter by Hart on palaeohaematology summarizes what can be gleaned about blood in ancient times from contemporary studies of bones, bodies and ancient art — an unusual topic for a treatise on history. There follow chapters on the bone marrow by Tavassoli, stem cells by Lajtha, the spleen by Crosby, red cell metabolism by Beutler, iron and haem by London, haemolysis by Dacie, effects of altitude on blood by Erslev, the conquest of pernicious anaemia by Castle, sickle cell anaemia by Conley, the molecular basis of thalassaemia by Weatherall, phagocytosis and granulocytes by Craddock, lymphocytes by Ford, leukaemia and lymphoma by Gunz, platelets by Spaet, plasma proteins by Janeway, haemostasis by Ratnoff, and blood transfusion and blood groups by Diamond. In a rather brief final chapter, Wintrobe draws the lessons of history.

Certain of the book's features merit commendation. It has a lively literary style and a gratifying uniformity of content, level and accent. Even so, some of the authors' personalities manage to shine through discreetly. Wintrobe wisely chose to steer between the extremes of readership. It should readily appeal to intelligent readers who may lack a rigorous scientific background but who are willing to make use of the book's convenient glossary. One hopes these will include legislators and other public officials. Yet it is detailed enough to be read profitably by haematologists and serious students. Indeed I can attest that in a recent course medical students found some of the essays a better guide to complex topics than conventional textbooks. This level adjustment is more successful in some parts than in others, but on the whole it has been well done.

Why write a history of haematology — or of any branch of science? Philosophers have long debated the purposes of historical scholarship. Is it the historian's purpose to be 'descriptive', to recount past events for their own sake or for the sake of making a credit-allocating record, or is it his purpose to be 'theoretical', to interpret, to generalize and to seek wisdom that might solve contemporary problems? Or is it simply to interest and amuse?

My only criticism of this attractive book — so lovingly compiled with its fine portraits and useful bibliographies — stems from private notions on historical writing. Most of the historian's purposes are meritorious, but it is possible to pursue them in different ways. One can recount what happened — the dates, names and facts — or one can tell what *really* happened in a sort of *cinéma vérité* style of reportage that conveys the important and fascinating details, never given in ordinary literature, behind the development of scientific ideas — the accidents, personalities, conflicts and inspirations that underlie every major discovery. In my opinion, writing in the latter mode is far more likely to achieve any of the possible purposes of a historian. I am especially impressed by several recent books that reached new levels of candour in the reporting of incidents, personal characteristics and idiosyncracies — books that seemed to tell it as it was. It is a much to be admired trend in the writing of scientific history. Alas, that trend is not greatly extended by this volume, which has a somewhat conservative tone.

The book's essayists are leaders who have contributed importantly to their own specialties. The editor tells us he chose them for that reason. But the essays are filled with the works of others and barren of the kind of information that one might relish from an important actor on the stage of history, the kind of information that only he possesses. In a felicitous chapter on "blood and mountains" Erslev refers to his discovery of erythropoietin in one sentence in the third person. Why did he do this experiment? How did he do it? There is no one better qualified to tell us than Erslev himself. Beutler deserves praise for having interviewed several major figures in preparing his chapter but he omits to explain how his own work on glucose-6-phosphate dehydrogenase deficiency anticipated what is now called the Lyon hypothesis. London tells us a bit about the Schoenheimer school at Columbia but not enough about his own perceptions of it. Castle speaks interestingly of Minot's personality and antecedents but is a shadowy figure in his third person references to himself. Spaet does not mention his own work. Such modesty!



Georges Hayem (1841–1935), one of the 'fathers of haematology'.

Of course, this is probably not fair comment because it suggests that the editor and authors should have written a different book. In fact, this book is splendid and highly recommended. My only quibble is that ample room exists for more effort in this area. We all should hope that Professor Wintrobe continues to explore the many trails he has blazed with this welcome work. □

Russian holography

P.W. Hawkes

Holography and Coherent Optics. By L.M. Soroko. Pp.818. (Plenum: 1980.) $59.50, £37.49.

THE decision to publish this translation, of a Russian text which first appeared in 1971, is most astonishing. At that date it was remarkably up to date, but holography is surely one branch of applied physics that has progressed out of all recognition during the 1970s. Further, the book lacks the merit of bringing early Russian work in this field to the attention of Western eyes, for there are no references at all. To cap this, it has the defect common to many Russian scientific texts: there is no index.

The book opens with some general ideas about holography, after which three chapters deal with various transforms of particular importance in optics, random signals and optical coherence. A chapter is then devoted to information theory in optics, followed by one on holography. The Russian text then concluded with a discussion of optical information processing, but for the English edition, the 'translation editor', G.W. Stroke, has included three of his own publications. Each topic is dealt with at some length, but for almost every subject much progress has been made since the book was written. In short, there really was not much point in translating this text, for in so fast-moving a subject students and research workers of the 1980s will need more recent information than that collected here. Access to a set of Professor Wolf's annual *Progress in Optics* (North-Holland) would be a great deal more useful. □

More of the Amboseli baboons

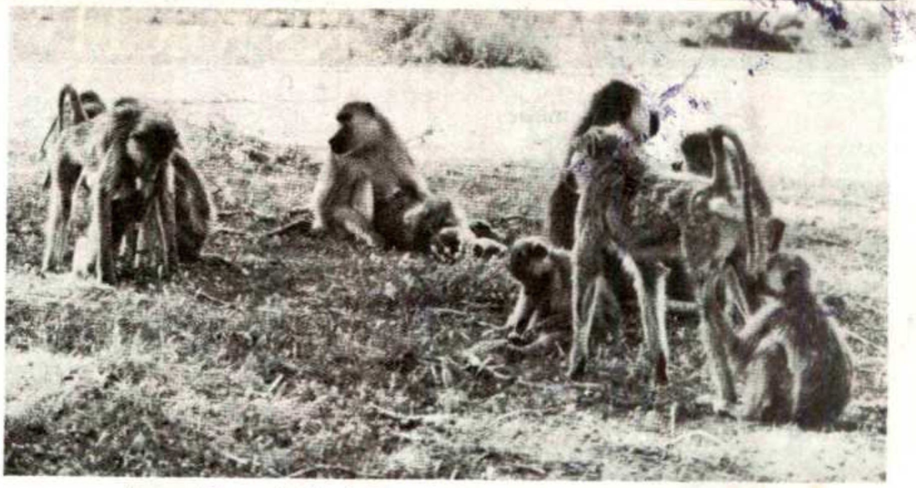
John M. Deag

Baboon Mothers and Infants. By Jeanne Altmann. Pp. 242. (Harvard University Press: 1980.) $17.20, £10.50.

EVER since the publication of *Baboon Ecology* by S.A. Altmann and J. Altmann (University of Chicago Press: 1970), primatologists have been waiting for further information on the social behaviour of the Amboseli baboons. *Baboon Ecology* set a new standard for primate ecological studies and Jeanne Altmann's *Baboon Mothers and Infants* will have equal influence on research into social relationships. This is no ordinary report of mother–infant behaviour and those most familiar with laboratory studies will find its scope unusual. Altmann summarizes her aims as follows: " . . . to assess the nature and extent of external influences on baboon mothers and their young infants. My general goal was to identify and measure factors affecting survival and behavior during motherhood and infancy, and to identify likely ontogenetic origins of differences in adult behaviour and life history patterns". The book therefore represents one of the first serious attempts to portray the total behavioural and ecological relationships among mothers, infants and the social group of which they form such a fundamental part.

It starts with an introduction to baboons and their habitat, and a short but important section on demography. During the first two years of life there was a per annum mortality of 0.3. Several infants were ill, wounded or suffering from possible nutritional deficiencies or poor mothering, and the author uses such cases when considering the costs and benefits of different sorts of behaviour. Mothers with young are themselves vulnerable, and older females with dependent young were found to be particularly at risk of dying when compared with younger females or those in other stages of the reproductive cycle. The effects of infants on their mothers' feeding patterns and time budgets are described and formalized in a theoretical model. It seems that if a mother had to provide all her infant's nutrition, severe time-budget problems would occur with infants more than 6–8 months old, even at slow rates of infant growth. A mother simply cannot gather enough food to maintain her body weight and to feed her infant; weaning is consequently forced upon the pair. Later sections of the book deal more directly with behavioural topics such as maternal care, infant development, spatial relationships, weaning and independence, and with how a mother's social relationships are affected by her infant's age.

The study group has been under observation since 1971 and a great deal of background information is available. The quantitative results on mothers and infants in the present study are drawn from 15 months of field work and 18 infants. Sound quantitative methods are used to provide an extremely detailed picture of the infants and their mothers. The major strength of this book lies in the detailed analyses attempted; but this is paradoxically also its main weakness, since it may make much of the book of little interest, except to the specialist prepared to wade through all the intimate details. The necessity of referring to individuals is a problem faced by all who deal in complex social relationships and yet who, except the author and her co-workers, can find it easy to follow a text studded with names which need constant back-reference to determine age, social rank and sometimes even sex? Such diversions are distracting but it is merely the presentation which is at fault — the philosophy of looking at individuals in detail is sound. No proper understanding of primate social behaviour and its evolution will be developed unless we have robust information on individual differences: on this count the book makes an important contribution. Although the sample of 18 infants may sound small it is in fact large by field (and even some laboratory) standards.



Jeanne Altmann's 'Alto's Group' of baboons, resting and grooming in Amboseli National Park, Kenya.

One of the major challenges of primatology is to see through the tangle of individual differences to reveal valid generalizations and thereby derive an understanding of the basic principles governing individual behaviour. As students of human personality will no doubt point out, this is not a straightforward task. Altmann searches for such generalizations wherever her sample size permits, and finds, for example, some interesting relationships between a mother's rank and her interaction with her infant and other group members. As would have been expected, low-ranking mothers gave more distress responses (submissive behaviour patterns) during social interactions and their infants were particularly prone to being interfered with by other members of the group. Mothers of different social rank also tended to show different styles of mothering: high rankers tended to be *'laissez-faire'* mothers (mothers tolerating separation from their infants); low rankers tended to be 'restrictive' mothers (mothers maintaining close contact with their infants). These differences in mothering appear to have consequences for infant maturation — infants of *laissez-faire* mothers became independent more rapidly. However it is much easier to describe such behavioural differences than to assess the costs and benefits (in terms of genetic fitness) with which the individual differences in behaviour are associated. The author recognizes this when considering the costs and benefits of mothering styles. Both forms have advantages and disadvantages but it is concluded that the styles adopted by mothers of different rank are adaptive because of the contrasting social pressures to which they are subjected by other group members. Arguments like this can only be speculative; they will become more convincing when larger samples of data are available.

The whole book is firmly based in modern evolutionary theory and those familiar with the parent–offspring conflict models of R. Trivers will find considerable interest in Altmann's analysis of weaning and independence. It has been proposed that the behavioural conflict during weaning between a mother and her infant is a reflection of an underlying conflict of interest — the infant attempting to secure more maternal care than the mother has been selected to provide. With her extensive field data behind her, Altmann helps to shift this argument from a theoretical to a practical plane and concludes that "parent–offspring genetic conflict of interest may arise infrequently as a relevant variable in many real-life situations".

In conclusion this book offers much to all those interested in social behaviour. Its holistic approach is attractive since it clearly acknowledges the undeniable complexity of primate social relationships but it does, however, leave one anxious for the day when sample sizes will be larger and selection pressures better understood. ☐

John M. Deag is a Lecturer in Zoology at The University of Edinburgh.

Magnetic resonance for biochemists and biophysicists

Karl-Erik Falk

ESR and NMR of Paramagnetic Species in Biological and Related Systems. Edited by I. Bertini and R.S. Drago. Pp.434. (Reidel: 1980.) Dfl.95, $50.

THIS volume comprises the papers given at a NATO Advanced Study Institute meeting held in June 1979, the subject of which was the magnetic resonance of paramagnetic species of biological importance. Twenty-four expert authors have contributed chapters covering various aspects of this large and important area of research.

The first part of the book is devoted to NMR and to the effects of paramagnetism on the NMR parameters, with chapters on the basic theory of relaxation and pulse techniques, paramagnetic effects in NMR, and a number of short reviews of current research. The applications for obtaining structural and dynamic information on various paramagnetic biological systems, ranging from purified small proteins to cell suspensions, are also discussed. The section on ESR contains a thorough consideration of theoretical aspects, focused on the 3d metal ions, followed by a discussion of the various classes of metalloproteins and, especially, the role of the metal ions. Throughout the book emphasis is put on the coupling between the unpaired electron and the nucleus, and about half of the volume deals with the complex effects of this interaction.

As a whole, the book is well balanced. NMR and ESR are given equal prominence, with theoretical descriptions, educational examples and reviews of current research results. Several of the chapters contain useful tables concerning, for example, the interpretation and description of the abbreviations used in multipulse NMR, and the network of equations and assumptions that form the basis for understanding paramagnetic relaxation. The discussion of the various metalloproteins clearly reveals the importance and applicability of magnetic resonance techniques in unravelling the biological role of the metal ions.

The collected writings are generally interesting and well prepared, although there is some duplication of material, perhaps inevitable in a multiauthor publication. Overall, then, a good book which will be of value to biochemists and biophysicists with an interest in the biological application of magnetic resonance. ☐

Karl-Erik Falk is Docent in Biophysics at the Department of Biochemistry and Biophysics, Chalmers Institute of Technology and University of Gothenburg, Gothenburg.
